ASSOCIATE EDITORS

E. DON STEVENS, JOSEPH J. CECH, JR. & JEFFREY G. RICHARDS

ENCYCLOPEDIA OF
FISH PHYSIOLOGY: FROM GENOME TO ENVIRONMENT

How to go to your page

This eBook set contains 3 volumes.

Each volume has its own page numbering scheme for the front matter.

For example, to go to Volume 1, page ii, type 'Vol1:ii' in the "page #" box at the top of the screen and click "Go".

To go to Volume 2, page v, type 'Vol2:v' in the "page #" box at the top of the screen and click "Go".

The chapter numbers are continuous between the all three volumes.

Please refer to the eTOC for any further clarification.

ENCYCLOPEDIA OF FISH PHYSIOLOGY: FROM GENOME TO ENVIRONMENT

Volume 1

THE SENSES, SUPPORTING TISSUES, REPRODUCTION, AND BEHAVIOR

Editor-in-Chief
ANTHONY P. FARRELL
Department of Zoology,
University of British Columbia,
Vancouver, BC, Canada

EDITORS' BIOGRAPHIES

Editor-in-Chief

Anthony P. Farrell, Department of Zoology, University of British Columbia, Vancouver, BC, Canada

Tony Farrell is a graduate of Bath University, where he was fortunate to study with Peter Lutz. His fortunes grew further when he moved in 1974 to Canada and the Zoology Department at the University of British Columbia (UBC) to complete his PhD degree under the excellent tutelage of Dave Randall. In 2004, Tony returned to UBC when he accepted an endowed research chair in sustainable aquaculture. In between these positions at UBC, Tony was employed at the University of Southern California (PDF), the University of New Brunswick (sessional lecturer), Mount Allison University (first real job), and Simon Fraser University (moving through the ranks to a full professor). In addition to highly controlled laboratory experiments on fish cardiorespiratory physiology, Tony is committed to working on animals in their own environment. Therefore, his research on fish physiology has taken him on an *Alpha Helix* expedition to the Amazon, the University of Gothenburg and the Kristineberg Marine Research Station in Sweden, the Portobello Marine Biological Station in New Zealand, the University of Christchurch and Massey University in New Zealand, the Bamfield Marine Science Station and the Huntsman Marine Station in Canada, the University of Aarhus in Denmark, the University of Adelaide Charles and Darwin University in Australia, and to the Danish Arctic Marine Station on Disco Island in Greenland. These travels have allowed him to work with many superb collaborators wordwide, as well as study the physiology of over 70 different species of fish. Tony has received a number of awards for his scientific contributions: an honorary degree from the University of Gothenburg in Sweden; Awards of Excellence from the American Fisheries Society for Fish Physiology, Conservation and Management; the Fry Medal from the Canadian Society of Zoologists; and the Beverton Medal from the Fisheries Society of the British Isles.

Associate Editor

Joseph J. Cech, Jr., Department of Wildlife, Fish, and Conservation Biology, University of California, Davis, CA, USA

Joe Cech grew up in northern Illinois <1 km from the Salt Creek Preserve, where he spent many hours as a boy. Summer trips to northern Wisconsin, northern Minnesota, and southern Ontario increased his interest in aquatic habitats and their fishes. He graduated from the University of Wisconsin (UW, Madison), where he was fortunate to study oceanography under Robert Ragotzkie and fish biology under Art Hasler and Fran Henderson in the UW Laboratory of Limnology. Before completing his BS degree in zoology, he was fortunate to serve as the resident zoologist aboard the R/V *Dante Deo*, for a year, as it crossed the Caribbean Sea and the South Pacific Ocean. Completing his degree upon his return, he was hired as a research assistant at the University of Texas' Marine Science Institute (UTMSI), where he earned his MA and PhD degrees in zoology, under the supervision of Curly Wohschlag. During his graduate education in Austin (Texas), he studied fish biology under Clark Hubbs and physiology under Jack Myers and Jim Larimer. After a 2-year postdoctoral position in Maine, he was hired as a fish physiological ecologist faculty member at the University of California (UC), Davis, in the Department of Wildlife, Fish, and Conservation Biology.

During his 32 years as an active faculty member at UC Davis, his research on the physiological ecology of fishes took him to Canada (University of British Columbia, Bamfield Marine Station), Finland (University of Helsinki), and to other laboratories in the USA (University of Tennessee, Scripps Institution of Oceanography, R/V *David Starr Jordan* in the North Pacific Ocean, UTMSI, Oregon Institute of Marine Biology, and the UC Bodega Marine Laboratory) where he collaborated with many excellent scientists. During this period, he taught courses in physiology of fishes, physiological ecology, and field studies in fish biology; he supervised 25 graduate students (10 MS and

15 PhD) in the disciplinary areas of ecology, physiology, zoology, and pharmacology/toxicology at UC Davis. He is a fellow of the AIFRB and AAAS, and he received Awards of Excellence from the American Fisheries Society (Physiology Section, and California-Nevada Chapter) and the UC Davis Prize for Undergraduate Teaching and Scholarly Achievement. Finally, he co-authored a popular ichthyology textbook, with Peter Moyle, and he published more than 160 peer-reviewed publications on the physiological ecology of fishes. He is currently Professor Emeritus of Fish Biology at the University of California Davis.

Associate Editor

Jeffrey G. Richards, Department of Zoology, University of British Columbia, Vancouver, BC, Canada

Jeffrey Richards is an associate professor in the Department of Zoology at the University of British Columbia, Canada. He started his academic career in the Department of Biology at Wilfrid Laurier University obtaining a BSc in 1995. He then went on to do an MSc at the University of Waterloo under the guidance of the late Prof. Richard Playle. With Prof. Playle, he studied environmental physiology and toxicology in fish. Following his MSc, he entered the laboratory of Prof. Chris Wood at McMaster University and focused his research on energy metabolism in swimming fish. He completed his PhD in 2002 and took up a postdoctoral fellowship at the University of British Columbia with Prof. Patricia Schulte. After a 2-year postdoctoral work, he started at the University of British Columbia as an assistant professor in 2004. His lab studies the relationship between plasticity and adaptive variation in the mechanisms that initiate, maintain, and coordinate metabolic energy balance in animals during exposure to environmental stress. He is particularly interested in the adaptations to low oxygen (hypoxia) in fish and other lower vertebrates. He prefers, whenever possible, to study animals in their natural habitat; thus, he travels extensively to unique and challenging environments, including the Amazon and the Tibetan plateau.

Associate Editor

E. Don Stevens, Department of Biomedical Sciences, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, PE, Canada

Don Stevens did an MSc with the late Edgar Black on the effects of severe exercise on metabolites in trout in the Physiology Department at UBC after an undergraduate degree in mathematics and zoology at the University of Victoria. He then moved across the street to do a PhD on effects of moderate exercise on respiration and circulation in trout with Dave Randall, who just had been hired in the Zoology Department at UBC (summarized in a JEB classics article, *Journal of Experimental Biology* 211: 1521). His first position was at the Zoology Department at the University of Hawaii where he discovered that there was more to the fish world than trout, and that there was no such thing as the physiology of fish, rather there was a physiology of fishes. In Hawaii, he worked mostly on the biology of tropical tunas with a focus on their warm-bodiedness, in particular how they achieved higher than ambient body temperatures and the adaptive advantage of them. He then joined the Zoology Department at the University of Guelph working in the general area of comparative physiology with a focus on exercise effects until he retired in 2004. He now has an adjunct position at the Atlantic Veterinary College and continues to do research in fish physiology.

HOW TO USE THE ENCYCLOPEDIA

STRUCTURE OF THE ENCYCLOPEDIA

The material in the Encyclopedia is arranged as a series of articles within a certain topic.

There are three features to help you easily find the topic you're interested in: a contents list, cross-references to other relevant articles in the Encyclopedia, and a full subject index.

1. CONTENTS LIST

The contents list, which appears at the front of all volume, lists the entries in the order that they appear in the Encyclopedia. It includes both the volume number and the page number of each entry.

2. CROSS-REFERENCES

All of the entries in the Encyclopedia have been extensively cross-referenced. The cross-references which appear at the end of an entry, serve three different functions:

i. To indicate if a topic is discussed in greater detail elsewhere
ii. To draw the readers attention to parallel discussions in other entries
iii. To indicate material that broadens the discussion

Example

The following list of cross-references may appear in text and at the end of the entry
The Muscles|Cartilaginous Fishes Cranial Muscles

See also: **Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics. **Chondrichthyes**: Physiology of Sharks, Skates, and Rays. **Food Acquisition and Digestion**: Energetics of Prey Capture: From Foraging Theory to Functional Morphology. **The Muscles**: Bony Fish Cranial Muscles. **The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis. **Ventilation and Animal Respiration**: Gill Respiratory Morphometrics.

3. INDEX

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4. CONTRIBUTORS

At the start of each volume there is list of the authors who contributed to the Encyclopedia.

This page intentionally left blank

CONTENTS

VOLUME 1 – THE SENSES, SUPPORTING TISSUES, REPRODUCTION, AND BEHAVIOR

SENSING THE ENVIRONMENT

BRAIN AND NERVOUS SYSTEM

Functional Morphology of the Nervous System: An Introduction *AB Butler* 1

Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern *B Fritzsch and DC de Caprona* 6

Functional Morphology of the Brains of Agnathans *MA Pombal and M Megías* 16

Functional Morphology of the Brains of Cartilaginous Fishes *I Rodríguez-Moldes* 26

Functional Morphology of the Brains of Ray-Finned Fishes *AB Butler* 37

Functional Morphology of the Brains of Sarcopterygian Fishes: Lungfishes and *Latimeria* *A González and RG Northcutt* 46

Motor Control Systems of Fish *S Grillner* 56

Physiology of the Mauthner Cell: Discovery and Properties *AE Pereda and DS Faber* 66

Physiology of the Mauthner Cell: Function *DS Faber and AE Pereda* 73

Autonomic Nervous System of Fishes *S Nilsson* 80

Opioids and Opioid Receptors in Fishes *MJ Herrero-Turrión, FM Sánchez-Simón, and RE Rodríguez* 89

VISION

Vision in Fishes: An Introduction *H-J Wagner* 98

Physiological Optics in Fishes *RHH Kröger* 102

Photoreceptors and Visual Pigments *JK Bowmaker* 110

Adaptations of Photoreceptors and Visual Pigments *JK Bowmaker* 116

Inner Retina and Ganglion Cells *MW Levine* 123

Optic Tectum *D Northmore* 131

Behavioral Assessment of the Visual Capabilities of Fish *S Schuster, P Machnik, and W Schulze* 143

Color Vision and Color Communication in Reef Fish *J Marshall and K Cheney* 150

Extraretinal Photoreception *H-J Wagner* 159

Visual Adaptations to the Deep Sea *RH Douglas and JC Partridge* 166

INDEX 2091

PREFACE

The *Encyclopedia of Fish Physiology: From Genome to Environment* is the first of its kind. It follows in the strong tradition built by the book series *Fish Physiology* that was pioneered in the late 1960s by Bill Hoar and Dave Randall and is still ongoing; however, the Encyclopedia differs markedly from this book series in three important respects.

Foremost, the Encyclopedia targets a much broader audience, not just the research community. My hope is that the Encyclopedia will serve as a general educational tool for biologists, as well as being of general use as an information resource for those interested in fishes. After all, the Encyclopedia is replete with magnificent examples of how fishes are marvelously adapted to almost every water body on the Earth, no matter how deep, how hot, how cold, how salty, or, in some cases, how dry!

Second, the articles span well beyond just the physiology of fishes. The intent here is to connect physiological functions, environmental factors, behavior, and the genome. This is the case even though the main focus here is on physiology.

Third, and as a result, the breadth of topics covered by the Encyclopedia far exceeds that of any focused volume of the *Fish Physiology* book series. Thus, the Encyclopedia is ambitious in both its content and its target audience.

The Encyclopedia contains a very impressive array of entries, each in the form of a discrete, self-standing article that is typically 3000–4000 words in length, not counting the ancillary material contained in figures, glossary, further reading, etc. In total, there are 252 articles written by over 200 international experts from over 20 countries.

The articles are arranged thematically. The larger thematic sections have an introductory article, written by a section editor, who explains contributions in that theme and places them in a broader and often historical context. Tributes are deservedly given to those who made key scientific advances.

The electronic format of the Encyclopedia was deliberate and a crucial requirement before this project even started. I have to thank Andy Richford for garnering Elsevier's support of this idea, as well as initiating this project when he was an acquisition editor. The electronic format, through 'hot keys', provides an easy and almost instant access to the glossary and related articles. Each article is generously linked to many others in this manner, offering the reader easy digressions or more detailed information and explanations. The 'Further Reading' section associated with each article provides additional resources.

This ambitious opus could not have been possible without the dedication and commitment of a great number of individuals. I had an idea that I have steered to completion, but others did most of the hard work. I am especially indebted to my associate editors, Don Stevens, Joe Cech, and Jeffrey Richards. They embraced my dream early on and stayed with me until completion. Without their wisdom, breadth of knowledge, and hard work, the Encyclopedia could not have come to fruition. I think we worked well together, and, on my part, it was a distinct pleasure to have such enthusiastic support.

I am equally indebted to the section editors: Colin Brauner, Ann Butler, Bruce Carlson, Brandon M Casper, Greg Goss, Jeff Graham, Toshiaki Hara, Sue Holmgren, Norman Maclean, Jay Nelson, Ken Olson, Catharina Olsson, Arthur Popper, Trish Schulte, Bob Shadwick, Kath Sloman, Adam Summers, Matt Vijayan, and Hans-Joachim Wagner. They shaped their section and carried the core of the editorial responsibilities for the contributed articles during the many rounds of review and revisions.

Finally, and importantly, there are over 200 authors and their collaborators, who contributed the articles. My hope is that your rewards go well beyond the recompense, which is a pittance for the time that I know you devoted to generating such marvelous articles. You are thanked for your dedication and trust in the project, and are congratulated for your respective skills and knowledge.

There is another side to the production of this Encyclopedia, and that is the Elsevier team, with whom the editors and authors interacted. This team was headed by Kristi Gomez, the acquisitions editor in San Diego. Milo Perkins, the

development editor in the Oxford office, was our go-to-man after Esmond Collins had set the ball rolling. Milo endured the rough and the smooth, and his rapid responses, as well as his flexible deadlines, were greatly appreciated. Kate Mittell worked quietly and efficiently in the background supporting Milo and was responsible for keeping me on track with the enormous glossary of terms. Nicky Carter, our project manager, superbly rounded out the team. We relied on her for the professional appearance and content of the final copy.

As Editor-in-Chief, I am ultimately responsible for any errors contained herein. If you find any, please let me know so that they can be corrected; likewise, if you feel there are important omissions, please let me know of these. They might be incorporated in future updates.

Bringing this Encyclopedia to its conclusion means one thing for me personally: Miriam, Dustin, Naomi, Nicole and Natalie will all be seeing a lot more of me over the next while! Miriam, your patience throughout was astounding, although it was pushed to the limit at times.

Tony Farrell
Vancouver

SENSING THE ENVIRONMENT

Brain and Nervous System

Contents

Functional Morphology of the Nervous System: An Introduction
Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern
Functional Morphology of the Brains of Agnathans
Functional Morphology of the Brains of Cartilaginous Fishes
Functional Morphology of the Brains of Ray-Finned Fishes
Functional Morphology of the Brains of Sarcopterygian Fishes: Lungfishes and Latimeria
Motor Control Systems of Fish
Physiology of the Mauthner Cell: Discovery and Properties
Physiology of the Mauthner Cell: Function
Autonomic Nervous System of Fishes
Opioids and Opioid Receptors in Fishes

Functional Morphology of the Nervous System: An Introduction

Glossary

Afferent Activity conducted toward the brain, normally sensory. Incoming, e.g., in the case of nucleus A projecting to nucleus B, the neurons in nucleus B would receive an afferent input from nucleus A.

Alar plate The dorsal, or upper, part of the developing neural tube. The alar plate gives rise to sensory structures, motor feedback structures (such as the cerebellum), and, except for the hypothalamus, the entire forebrain (telencephalon and diencephalon).

Basal plate The ventral, or lower, part of the developing neural tube. The basal plate gives rise to the hypothalamus and to the motor structures of the brainstem, such as the cranial and spinal nerve motor nuclei.

Caudal Toward the tail.

Cortex (pl., cortices) A neural structure in which several different populations of neurons are arranged in layers, or laminae. The dendrites of some of the neuron cell bodies extend across several laminae and thus can receive somewhat different inputs (afferent projections) that are segregated along the length of the dendrite. Likewise, outputs (efferent projections) to different targets can arise from different layers.

Diencephalon The more caudal of the two divisions of the forebrain. Caudal part of the prosencephalon (forebrain) associated with the third ventricle. The general subdivisions are (from dorsal to ventral): epithalamus, dorsal thalamus, subthalamus, and hypothalamus.

Efferent Outgoing, e.g., in the case of nucleus A projecting to nucleus B, the axons that arise from neuron cell bodies in nucleus A would be efferent projections of that nucleus. Note that the adjectives efferent and afferent can apply to the same set of axons; the terms are used in reference to the nucleus from which they arise vs. the nucleus to which they project, respectively.

Ganglion A collection of nerve cell bodies of similar function. A ganglion is a type of nucleus but often refers to structures in the peripheral nervous system. An exception is the basal ganglia that are nuclei of the telencephalic subpallium.

Mesencephalon Midbrain. It consists of a dorsal tectal region and a more ventral tegmentum.

Neural crest A transient developmental tissue at the interface between ectoderm and neuroectoderm found in craniates which gives rise to numerous adult tissue, for example, peripheral sensory neurons, melanocytes, and skeletal cells.

Neural tube The developing central nervous system, consisting of a tube formed by invagination (in-pocketing) of the dorsal part (in vertebrates) of the ectoderm (the outer body layer). It gives rise to the brain and the spinal cord.

Neuraxis The rostrocaudal length of the neural tube in both its developing and adult form, including the brain and the spinal cord.

Nissl stained The histological procedure that utilizes a Nissl stain results in the darkening of neuron cell bodies, making them visible against a pale background when viewed through a microscope. This stain does not darken most neuron cell processes, so most of the dendritic tree and the fiber pathways composed of groups of axons are not stained.

Nucleus (pl., clei) In neuroanatomy, this term refers to a discrete group of similarly connected neuron cell bodies that are not cortically laminated (see cortex). In a nucleus, the dendritic arborizations of all of the neurons, their receptive portion, are confined within the boundary of the nucleus.

Pallium Dorsal part of the telencephalon. The projection neurons of the pallium are glutamatergic.

Rhombencephalon The hindbrain; in jawed fish, it includes the cerebellum and the medulla.

Rostral The front end of a structure, opposite of caudal. Rostral refers to the beak or snout.

Subpallium Ventral part of the telencephalon. The projection neurons of the subpallium are GABAergic.

Telencephalon The more rostral of the two divisions of the forebrain.

Ventricles Fluid-filled cavities within the brain that are formed when the neural tube tissue invaginates, resulting in a cavity at the center of the newly formed tube. As the brain develops, each part of the ventricular system acquires its own dimensions in relation to the surrounding neural tissue. Each telencephalic hemisphere has a ventricular space (referred to as lateral ventricles in nonactinopterygian vertebrates), and these ventricles are continuous with the third ventricle, which runs vertically along the medial surfaces of each side of the diencephalon. The third ventricle is continuous with the ventricle of the midbrain, which, in turn, is continuous with the ventricle of the hindbrain, the fourth ventricle. (In fish, the midbrain ventricular space is enlarged laterally to include tectal ventricles, whereas in mammals, it is elongated and very small in diameter and is called the cerebral aqueduct.) The fourth ventricle is continuous with the central canal of the spinal cord. The ventricles are filled with cerebrospinal fluid, which is secreted by the choroid plexus, a structure composed of layers of ependymal cells and vasculature.

Overview of Brain Organization

In all vertebrates, the brain develops by the generation of neurons in the ventricular zone, which lies along the ventricular surface of the developing neural tube (**Figure 1**(**a**)), and, in some cases, a neighboring subventricular zone. The cell bodies of these neurons migrate away from the ventricular region to varying degrees and in varying numbers. Different patterns of neuron-cell migration result in the formation of either cortex or nuclei, which are important to distinguish for a number of functional reasons.

A cortex (**Figure 1**(**b**)) consists of several different populations of neurons that lie in layers and that thus can receive somewhat different inputs (afferent connections) and give rise to somewhat different outputs (efferent projections). In a cortex, unlike in a nucleus, the receptive portions of some or all of the neurons of one layer, their dendrites, can extend into the territory of another population, and thus sample the inputs arriving there as well.

Nuclei (**Figure 1**(**c**)) are discrete groups of similarly connected neuron cell bodies that are not cortically laminated, the crucial distinction being that in a nucleus, the dendritic arborizations of all of the neurons, their receptive portion, are confined within the boundary of the nucleus. Some nuclei are laminated, but in that case, the dendritic arborizations of a neuron cell body in a specific lamina remain within the boundaries of that lamina. The neurons of both nuclei and cortex can have local, internal connectivity via the axons of their local circuit neurons, which are usually inhibitory, as well as long, efferent projections to other neuron cell groups, that lie some distance away, either nuclear or cortical in structure.

During embryological development, patterning genes that are active in different regions of the neuraxis, the rostrocaudal axis of the neural tube, result in differentiation of various regions in that dimension. Likewise, other patterning genes specify dorsoventral differentiation into a dorsally lying alar plate and a ventrally lying basal plate, which each give rise to a set of structures in the adult brain. Among the derivatives of the basal plate are the efferent motor neurons of the nervous system, particularly the motor nuclei of cranial nerves in the brainstem and spinal

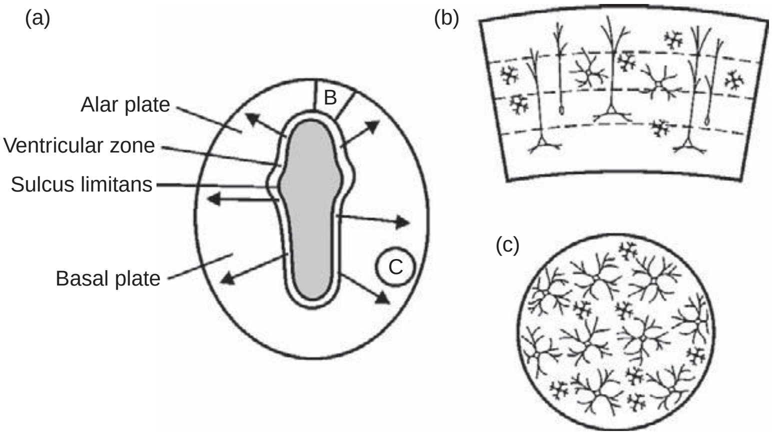

Figure 1 (a) Drawing of the developing neural tube to show the ventricular zone, which surrounds the ventricular space (gray shading). Neuron cell bodies generated in the ventricular zone migrate radially, as indicated by arrows (or, in some cases, tangentially). They form either laminated cortices, as shown in (b), or nuclei, as in (c). In (b), the glutamatergic pyramidal neurons, which give rise to long projections, are shown with vertically extending apical dendrites and basal dendrites arising from their triangular-shaped cell bodies. Multipolar larger and smaller local-circuit (locally projecting), GABAergic inhibitory neurons are also shown. In (c), large, multipolar, glutamatergic projection neurons are intermingled with small, local-circuit, GABAergic interneurons.

cord that innervate muscles or are the preganglionic neurons (first in a two-neuron chain) of the autonomic nervous system, while the alar plate is more sensory in nature, including feedback information from motor system actions.

Much of the variability across taxa, whether among fishes or across all vertebrates, involves the number of nuclei present, the degree to which they migrate away from their germinal zone along the ventricular surface in a radial (or, in some cases, tangential) direction, and the degree to which they develop in size. Variation in the morphological features of the dendritic tree of various neurons also occurs, giving rise to many diverse phenotypes, and, likewise, major variation occurs in the differentiation into multiple different neurotransmitter and neuromodulator phenotypes. The number of afferent and efferent projections of nuclei and cortical areas at various locations along the neuraxis and how elaborate the cortical areas are, also contribute to the variability. Most of this variation arises from variations in the degree and elaborateness of development of alar plate-derived structures, while basal plate-derived structures vary to a substantially lesser degree. While both the basal and alar plates give rise to nuclei, all cortical structures are alar plate derivatives.

Like the brains of other vertebrates, the brains of fishes comprise a caudal hindbrain region, an intermediate region called the midbrain, and a rostrally lying forebrain. The major parts of the brain of a gar (*Lepisosteus osseus*) are shown in **Figure 2**(**A**). The hindbrain contains the caudal part of the brainstem, the medulla, and the cerebellum; the midbrain contains the more rostral part of the brainstem and a roof region, the tectum; and the forebrain consists of the more caudally lying diencephalon and the more rostrally lying telencephalon, which comprises a dorsally lying pallium and a ventrally lying subpallium (**Figure 2**(**B**)) as well as the olfactory bulbs. The hindbrain and midbrain contain the basal plate-derived motor neurons for the various motor cranial nerves that innervate the muscles of the head and the preganglionic neurons that form part of the parasympathetic system for both head and body, as well as a number of alar plate-derived sensory nuclei in which peripheral sensory nerves synapse. They also both have alar plate-derived cortical regions, such as the cerebellum of the hindbrain and the tectal region of the midbrain, which includes the visually dominated optic tectum (**Figure 2**(**C**)) and the auditory tectum called the torus semicircularis. The forebrain also contains sensory-receptive nuclei as well as many nuclei that are part of multisynaptic ascending and descending pathways. Across fishes, the upper (i.e., dorsal) part of the telencephalon, the pallium, varies in its degree of development from a relatively simple lamina of neurons that remain near the ventricular surface to having multiple migrated nuclear areas, as is the case for the gar (**Figure 2**(**C**)). In some species, such as squirrelfish, among the ray-finned fishes, the pallium is elaborated to the extent that some cortical, or at least cortical-like, regions are formed. The lower (i.e., ventral) part of the telencephalon, the subpallium, contains only nuclei.

Historical Perspective

For decades and through the first half of the twentieth century, it was thought that fish brains were merely smell brains, dominated by the sense of smell to the exclusion of other sensory systems. While the anatomical organization of fish brains had been studied by the early comparative neuroanatomists, little was understood that had functional

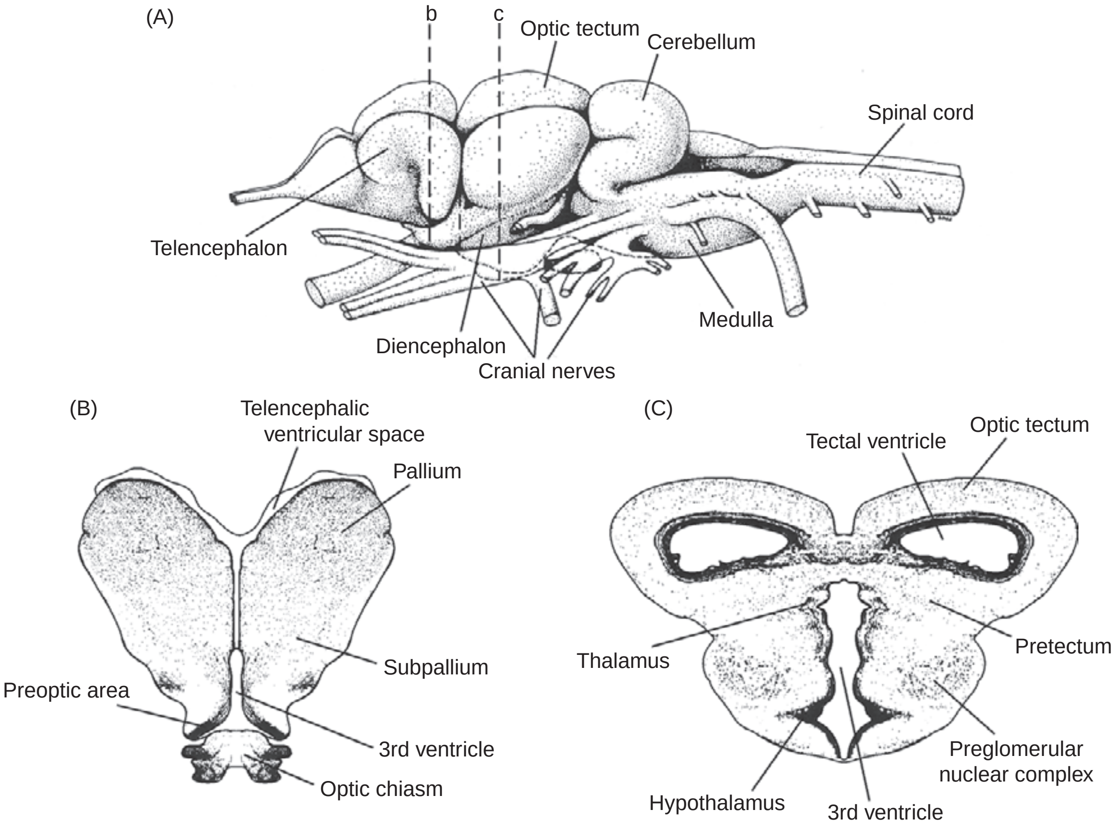

Figure 2 (A) Side view of the brain of a gar, with some of the various major parts lebeled. The dashed lines b and c indicate the levels at which the sections shown in parts (B) and (C) are taken. The section in (B) is through the telencephalon, showing the pallium dorsally and the subpallium ventral to it. The section in (C) is through the midbrain roof, showing the tectum, which is cortical in structure, dorsally and the various nuclei of the caudal part of the diencephalon, ventrally.

relevance. Beginning in the early 1960s, the Dutch neuroscientist Rudolf Nieuwenhuys provided new insights into the organization of fish brains, including seminal observations on the topology of the pallial areas in ray-finned fishes, which develops in a rather unique manner as compared with most other fishes and land vertebrates, and thus has been particularly challenging to understand.

A second breakthrough came with the work of the Swedish-American neuroscientists Sven Ebbesson and Lennart Heimer, who showed that the olfactory projections in sharks are restricted to only a small part of the telencephalon and that visual and other sensory information was relayed to other, separate areas of the telencephalon. These seminal findings engendered interest in the overall organization of fish brains and ushered in a new era of research activity. The organization of the various sensory systems, including the mechanosensory lateral line, electrosensory lateral line (where present), auditory, visual, gustatory, and olfactory systems and, to some extent, the descending motor pathways, have been elucidated over the past several decades. The remarkable degree of variation in brain structure and in the degree of elaboration of the various systems is addressed across the major taxa of fishes in this section.

Variation in Brain Structure across the Taxa

In the article **Brain and Nervous System**: Functional Morphology of the Brains of Agnathans, the marked differences in brain structure between lampreys and hagfishes are considered. While pathway tracing and histochemical methods allow identification of many of the major brain regions, many of the homologous relationships with the brains of jawed fishes have yet to be established, particularly concerning the very divergent morphology evinced in hagfishes. The article **Brain and Nervous System**: Functional Morphology of the Brains of Cartilaginous Fishes details the major brain regions in members of this diverse taxon. In many respects, including pallial organization, cartilaginous fishes have brains that are more like those of land vertebrates than any other extant fish taxon. The article **Brain and Nervous System**: Functional Morphology of the Brains of Ray-Finned

Fishes deals with the extreme variability in brain structure across this very large and highly diverse taxon. As noted above, pallial organization differs in marked respects from that in other vertebrate taxon even though comparable ascending sensory-system pathways can be identified. Additional information on the major pallial component of the midbrain, the optic tectum, in ray-finned fishes can be found in the article **Vision**: Optic Tectum. The article **Brain and Nervous System**: Functional Morphology of the Brains of Sarcopterygian Fishes: Lungfishes and Latimeria turns to the sarcopterygian radiation. Recent histochemical work has provided new insights into brain organization in this taxon and allowed for more detailed comparison with tetrapods than previously possible.

Five additional chapters cover other evolutionary aspects of nervous-system organization in fishes. The article **Brain and Nervous System**: Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern details the evolution of the nerves in the context of the components present in invertebrate deuterostomes. The article **Brain and Nervous System**: Physiology of the Mauthner Cell: Discovery and Properties highlights the use of this unique motor neuron as a model neuron system for general physiological properties, while the companion article **Brain and Nervous System**: Physiology of the Mauthner Cell: Function details the specific physiological and behavioral aspects of the system. The article **Brain and Nervous System**: Motor Control Systems of Fish discusses the Mauthner cell system, but in the context of other aspects of motor behaviors. Finally, the autonomic nervous system is discussed in the article **Brain and Nervous System**: Autonomic Nervous System of Fishes.

Glossary

Basic helix–loop–helix (bHLH) proteins They bind as heterodimers to specific promoter-binding sites (so-called M-box) to induce expression or repression of specific genes involved in cell differentiation. Important members of this family are Neurogenin, atonal/Atoh1, and Neurod.

Bone morphogenetic protein (BMP) A group of diffusible proteins that bind to the BMP receptor to elicit intracellular signals that are important for brain, heart, cartilage, and bone development.

Central nervous system (CNS) An internal aggregation of neurons involved in processing information obtained from sensors and eliciting appropriate motor responses. Depending on the systematic relationships, the CNS has been suggested to have evolved only once in bilaterians (nephrozoa) or, a position taken here, multiple times out of a diffuse nerve net that is shared among diploblasts and basal triploblasts.

Decapentaplegic (Dpp) The fruit fly homolog of BMP with a somewhat similar function, except for bone and cartilage.

Fibroblast growth factors (Fgfs) Diffusible factors that signal through their Fgf receptors and are involved not only in proliferation regulation but also in differentiation, such as legs and CNS.

Forkhead genes (Foxg1) They play major roles in proliferation regulation. For example, forebrain growth and cellular diversity is extremely stunted in Foxg1 null mice.

Homology Indicates similarities due to inheritance, is used for homologous structures (e.g., limbs) or homologous gene sequences.

Hox genes A set of genes which contain the homeodomain sequence and are involved in patterning, and in some species in patterning of specific antero-posterior compartments of the body (segments) or brain (rhombomeres).

Metamere and metameric Repeated units (compartments) and their formation.

Micro-RNA (miR) A set of small single-stranded RNA molecules which can bind to specific messenger RNAs and essentially remove them from being translated into proteins. Many miRs co-evolved with increasing complexity of multicellular organisms and are currently perceived as mediating in part this complexity through differential regulation of gene-product translation. Specific miRs have been identified which co-evolve with neurons and sensory systems and are crucial for their development.

Neural crest A transient developmental tissue at the interface between ectoderm and neuroectoderm found in craniates which gives rise to numerous adult tissues, for example, peripheral sensory neurons, melanocytes, and skeletal cells.

Neurogenic placodes Embryonic ectodermal thickenings that give rise to neurons and sensory cells such as the ear, lateral line and olfactory organs, and, in some cases, cranial nerves.

Olfactores A grouping of chordates comprising urochordates and craniates but excluding cephalochordates.

Orthodenticle-like 1 (Otx1) Like Foxg1, orthodenticle genes play a major role in the differentiation of forebrain and sensory organs.

Placode A plate-like thickened area of embryonic ectoderm which gives rise to sensory organs.

Peripheral nervous system (PNS) A set of nerve tracks with or without neurons which connect the centralized CNS with sensory input and effector organs.

Rhombomere Transverse compartments of the hindbrain.

Synapomorph A shared derived (apomorphic) feature found only in this group, for example, a lower jaw is a synapomorphy of all jawed vertebrates.

Introduction

Understanding how the vertebrate's body and head, with its nervous system and craniate senses, evolved requires a broad perspective taking into account the evolution of multicellular animals. A brief overview of animal evolution is therefore needed here to set the stage for our discussion of how the original, diffuse nervous systems, organized as nerve nets with no centralized nervous or sensory component, differentiated over time into complex brains interconnected to the peripheral sensory organs and effector systems with peripheral sensory and motor nerves.

A new theory has recently emerged based on the insight that all multicellular organisms were derived from single-celled organisms called choanoflagellates, so named for their single flagellum surrounded by a collar of microvilli. The flagellum propels food caught by and ingested at the base of the microvilli. Aside from sponges (Porifera) and an odd species of an amorphous colony-like aggregation of single-celled organisms (Placozoa), multicellular animals can be divided into two great clades (**Figure 1**), which are based on the type of body symmetry and the number of primary tissue layers:

1. Radially symmetrical animals are diploblasts. They have two primary tissue layers, the outer ectoderm and the inner endoderm. They include jellyfish and their relatives (Cnidaria) and the comb jellies (Ctenophora).
2. Bilaterally symmetrical animals are triploblasts. They have three primary tissue layers (intermediate layer of mesoderm in addition to the ectoderm and endoderm), and include all bilaterally symmetrical invertebrates and vertebrates. Among triploblasts, a group of flatworms lacking a gut are referred to as acoelomate flatworms (Acoela, **Figure 1**). These animals are no longer considered to be true flatworms (the phylum Platyhelminthes) but rather are viewed as basal triploblasts. The rest of the bilaterally symmetrical animals, the Nephrozoa (animals with kidneys), comprise the Protostomes and Deuterostomes. The former include most species of invertebrates (including the 'true' flatworms, Platyhelminthes), while the latter include the vertebrates and their deuterostome invertebrate relatives. The most basal extant deuterostomes (**Figure 1**) are of the genus *Xenoturbella*, which comprises two species of marine worms, and the newly recognized clade Ambulacraria, which contains the echinoderms (starfish, sea urchins, etc.) and the hemichordates (acorn worms, with cylindrical bodies, and pterobranchs, with vase-shaped bodies). Chordates comprise those animals which have a notochord at some point in their lifecycle and are divided into three major extant clades: the cephalochordates (amphioxus), the urochordates (sea squirts or tunicates), and the craniates (vertebrates) (**Figure 1**).

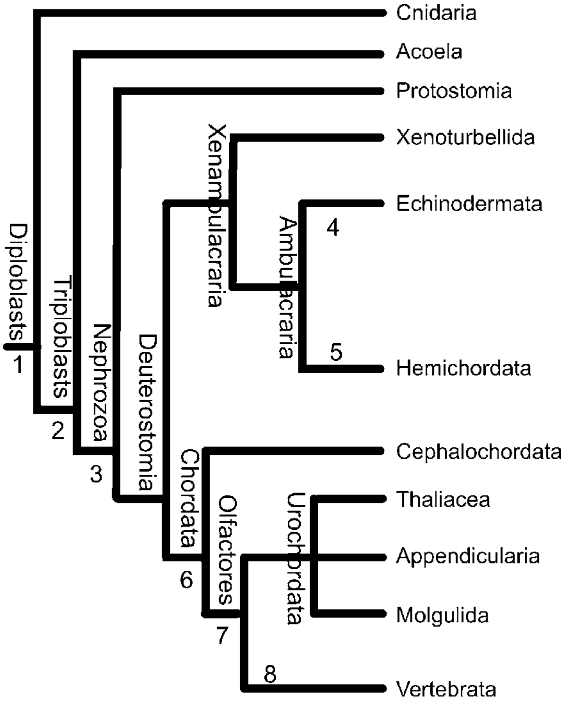

Figure 1 The simplified cladistic relationships of animals and some critical events concerning the evolution of neurons and sensory systems: (1) diffuse epithelial nerve net; (2) miR-124 specific for neurons appear; (3) miR-183 specific for sensory cells appear; (4) formation of a pentameric nerve net with rudimentary sensory organs; (5) partial dorsal invagination of the epithelial plexus and appearance of localized sensory cells; (6) neurons are concentrated in a dorsal neural tube and composite sensory organs appear. Sensory neurons are inside the neural tube and motor neuron(s) are ventral in the neural tube. Possible precursors of neural crest, branchial motor neuron(s), and somatic motor neuron(s) appear; (7) branchial motor neuron(s) are present, first appearance of neural crest and possibly placodes; (8) placode-derived sensory systems, cranial branchial motor neuron(s), and spinal somatic motor neuron(s) appear. Eyes, ears, nose, taste buds, lateral line, electroreceptive ampullary organs, and ocular muscles appear.

Of the numerous theories about the origin of the craniate head, brain, and peripheral nerves which have been proposed over the past 150 years, most assumed a transformation of either an amphioxus-like (cephalochordate) organism into a craniate with a clearly delineated head (the new head hypothesis), or that tunicates (urochordates) form the outgroup of craniates and consequently, many head organs, jaws, and the craniate spinal cord had to evolve anew. Ideas that the last common bilaterian ancestor of nephrozoans had a highly developed central nervous system (CNS) and was segmentally organized require the assumption that many basal protostomes and deuterostomes have secondarily lost all of these features and devolved into a more ancestral-like organization.

As all multicellular organisms derive from single-celled choanoflagellates, they share molecular synapomorphies at the level of diploblasts and triploblasts, indicating that the ectodermal nerve net found in diploblasts may also have been the primitive state in basal triploblasts. In fact, within basal deuterostomes, the marine worm in the genus *Xenoturbella* has an epithelial nerve plexus with no recognizable sensory system. Among Ambulacralia, acorn worms (hemichordates, **Figure 1**) have some centralization of nervous elements without formation of a true CNS and single sensory cells instead of sensory organs. Likewise, what appears to be basal protostomes, the arrow worms (Chaetognathans), mostly have an epidermal nerve plexus with little concentration into a ganglion, similar to basal triploblasts, the acoel worms. The wide phylogenetic distribution of these shared features indicates that the common triploblast ancestor, and therefore likely also the common deuterostome ancestor, may have had an epithelial nerve plexus with little, if any, metameric (segmental) organization. If the morphology of the nervous system in *Xenoturbella* is indeed close to the basal deuterostome organization and not secondarily derived through regressive evolution, the ancestor of craniates could have had a nerve net, avoiding the need to transform an already existing CNS, as in amphioxus or tunicate larvae, into a craniate-like CNS (**Figure 1**).

For this article, we assume that the deuterostome and craniate ancestor had a nerve net very much like the *Xenoturbella's* unorganized nerve net with little to no metameric organization. It seems unlikely that a metameric organization of a well-developed CNS devolved to form the epithelial nerve nets now found in diploblasts and basal triploblasts.

Following already well-entrenched arguments for the evolution of eyes and ears, the different patterns of nervous system found in deuterostomes are considered here to be independently derived forms reflecting either different and independent steps in forming a CNS (acorn worms, cephalochordates, urochordates, and craniates) or a transformation into a pentameric (five-portioned) nerve net (echinoderms). A consequence of this hypothesis is that many problems in establishing homology of peripheral nerves and sensory organs across deuterostomes become obsolete, leading to the more parsimonious idea that the formation of a CNS comes about by aggregating a subepidermal nerve net and condensation of distributed sensory cells into sensory organs. Such centralization may have happened at least twice in deuterostomes (acorn worms, chordates) and at least twice in protostomes (insects and related species; mollusks, and related species).

A consequence of this condensation is the formation of connecting strands of the emerging CNS with effector and sensory organs, referred to here as 'nerves'. Obviously, in order to communicate with the remaining parts of the body, such nerves have to carry both afferents (for sensory input from the periphery) and efferents (for motor output to the periphery). A by-product of this condensation of the CNS out of a diffuse nerve net is the condensation of various sensory cells with more or less discrete segregation of sensory input into organs dedicated to a specific set of stimuli such as photic, mechanical, or chemical stimulation as well as the evolution of the neural crest (embryonic tissue giving rise to most of the peripheral nervous system (PNS).

For this idea to be true, each of the deuterostomes having a CNS will have to show certain similarities in its overall development and its molecular basis which in part will reflect the patterning already found in the more or less centralized nerve plexus of acorn worms. In particular, genes related to neurulation should be common among all deuterostomes with a CNS, but may reflect common co-option or a prototypical partial aggregation into a CNS that does not reach the level of obvious homology. Apparently, only craniates achieved the aggregation of all neurons into a CNS, aggregated all peripheral sensory systems into discrete sensory organs, and developed a unique set of innervations via neural-crest-derived sensory neurons and neurogenic-placode-derived sensory organs. Neurogenic placodes, like neural crest, are ectodermally derived structures but are present only in the head; along with neural crest, they produce the sensory neurons of the PNS in the head region. The formation of these special embryonic tissues – neurogenic placodes and neural crest – is the newly evolved developmental mechanism which achieves this aggregation of sensory cells in craniates' embryos.

Whereas much work has concentrated on the specific gene networks promoting embryonic formation of placodes or neural crest, few studies have been focusing on the molecular mechanism of suppression of neuronal fate determination in the remaining ectoderm. In other words, the ectoderm in a developing embryo will become nervous-system tissue unless this fate is repressed; in the parts of the ectoderm where this repression occurs, the ectoderm forms epidermis, the outer layer of the skin. It is now clear that fibroblast growth factor (Fgf) upregulation, combined with limited to no expression of bone morphogenetic proteins (BMPs) induce a neuronal fate in the ectoderm of chordates (i.e., it becomes neuroectoderm) but apparently not in *Xenoturbella.* That the default state of ectoderm for chordates is indeed neurogenic has been demonstrated by overexpressing proneuronal basic helix-loop-helix (bHLH) genes in the ectoderm, revealing a transformation into neurons.

Another emerging concept is the importance of microRNA (miR) for the development of neurons and sensory cells. Recent data have shown that specific miRs (miR-124) are evolutionary conserved and evolved first with triploblasts. MiR-124 has been shown to be essential for neuronal development through the regulation of chromatin remodeling and absence of miR-124 (and other miR species) causes rapid degeneration of developing neurons. Another set of miR, miR-183,182, and 96, is evolutionary conserved among nephrozoa (i.e., bilaterians excluding acorn worms). It has been shown to be associated with mature sensory cells and is crucial for their development. In fact, even single-base mutations in miR-96 lead to deafness. Obviously, the ability of miR to regulate large sets of transcription factors could be perceived as a prerequisite for the evolution of a more complex neuronal and sensory system.

This article provides an overview of the evolutionary steps and their underlying developmental transformations toward the formation of a PNS such as the spinal and cranial sensory nerves, molecular mechanisms of suppressing neurogenesis in the ectoderm, invagination of the neuroectoderm, and induction and initial differentiation of placodes and of neural crest. It is organized to reflect the currently accepted phylogenetic relationships among deuterostomes, with *Xenoturbella* (**Figure 1**) as a likely ancestor type for all deuterostomes as far as its nerve organization is concerned – it has a simple epithelial nerve net with no evidence of concentration of neurons or sensory cells. Unfortunately, beyond the knowledge of an unusual Hox code, no molecular data exist on these animals to illustrate what might be the original molecular code for the development of a nerve net.

The Acorn Worm CNS and the Molecular Basis for Its Development

C. Lowe has demonstrated that many patterning genes thought to be associated with craniates' CNS neuromeres (repetitive compartments of the developing brain) exist in the ectoderm of these animals and may play a distinct role in developmental patterning. Comparative expression data provide strong molecular evidence indicating that the basic organization of repetitive neuronal elements, as well as the evolution of neuromeric boundaries which can be molecularly dissected, are discrete steps in deuterostome and chordate evolution and that these elements progress from a more basic, non-neuromeric organization to a fully developed craniate organization with clear association with compartmental boundaries. For example, lampreys have three paralogous Hox-groups while jawed vertebrates have four. In addition, the trigeminal motor neurons extend from r2 to the first half of r4 in lampreys while it extends from r2 to r3 in jawed vertebrates. While the overall similarities in expression domains and neuronal organization between flies and gnathostomes have long been understood and used to indicate a possible homology at the molecular and structural level across phyla, it appears more likely in light of these more substantial data that the limited molecular toolbox used across phyla provides for a molecularly homologous basis for anatomically analogous organs and their organization. In fact, detailed analysis of cellular elements contributing to what have been viewed by some as possibly homologous peripheral nerves has long pointed out this problem at the cellular identity level. Clearly, basal protostomia and deuterostomia do not have metamerically organized 'nerves' radiating out in a specific pattern from the basically epithelial nerve plexus (the CNS of these animals). In fact, the asymmetric but metameric organization of nerves in cephalochordates and basal chordates may reflect as much an independently derived peripheral nerve reorganization as the molecular basis of boundary formation in the CNS reflects a step-wise evolution of neuromeric boundaries and their underlying molecular basis. Likewise, the dorso-ventral patterning differences now recognized in flies, acorn worms, and craniates may reflect different anatomic solutions driven largely by similar molecules and distributions.

Inducing a CNS and Suppressing Neuronal Capacity in General Ectoderm: A Common Theme Shared among Chordates but Not With All Hemichordates?

It is now well known that key early steps in CNS and ectodermal placode formation involve the transformation of ectoderm into neuroectoderm. A key player across phyla is the decapentaplegic (Dpp)/BMP pathway. However, chordates require the additional action of Fgfs, which apparently play little role in this process in arthropods and hemichordates. It remains unclear if this Fgf dependence is linked to the apparent dorso-ventral patterning difference in nervous-system induction which has so long been a source of a general body-plan-reversal ideas. These ideas have been questioned by several lines of evidence – the neural tube is ventral in protostomes but dorsal in craniates, and while the acorn worms shows both a dorsal collar region and ventral trunk nerve cord. The most parsimonious interpretation is to assume that the dorsal and ventral position of the CNS in protostomes and deuterostomes is an independent condensation of the ancestral nerve net making obsolete the apparent need for a dorsal–ventral position reversal.

In the absence of understanding all the genes involved in these processes and their interactions, it appears most parsimonious to assume that the already known differences are likely to indicate a nonhomologous origin of a

CNS based on partially homologous transcription-factor actions to transform an epidermal plexus-like PNS, as was initially proposed for the acorn worm. Other known similarities such as the use of different and similar sets of bHLH genes, the ubiquitous use of the delta-notch system (a signaling pathway involved in cellular differentiation through lateral inhibition), and certain molecular aspects of proliferation regulation could reflect their similar functions not in the common triploblast ancestor but in the common diploblast ancestor. What needs to be clarified now is how the diffuse nerve net of a diploblast ancestor, most likely also present in the common triploblast ancestor, has been tied into the emerging and the differing general embryonic-patterning mechanisms to elicit a local upregulation of specific neural inducers resulting in a dorsal or ventral CNS. The currently available data suggest that hemichordates and chordates differ in that respect.

Motor Neuron(s), The Ancient Efferent Communication of All Nerves to Induce Muscle Movements for Locomotion

The nervous system derives from the ectoderm and has to get access to the mesoderm-derived muscle fibers to execute movements. Interestingly, diploblastic organisms have bHLH genes with both a proneural and promyogenic capacity, indicating that the developmental lines giving rise to muscle and neuronal cells in these organisms might be shared, as implied by the existence of neuromuscular cells which are both receptor and effector. However, with the formation of triploblastic organisms and the evolution of a developmental novelty, the mesoderm, muscle fibers, and neurons derive from different germ layers. This, therefore, requires that motor neuron(s) have the capability of accessing those muscle cells through the basement membrane. Apparently, at an early stage in triploblast evolution, muscle fibers acquired cholinergic receptors and most motor neuron(s) became cholinergic.

With the progressive concentration of the nerve net toward the dorsal side of the animal in deuterostomes, motor neuron(s) or muscle fibers had to develop elongated processes to reach each other for function. As those processes extended in development from or toward the mesoderm-derived target, initially random tracks formed carrying the majority of those processes. The assumption here is that the evolutionary-stabilized appearance of such tracks eventually encoded for discrete tracks – the repetitive peripheral nerves now recognized among craniates. These tracks of motorneuron axons could either have contained only motorneuron axons or could have been associated with sensory fibers, either derived from intraspinal sensory cells or consisting of the axons from peripheral sensory cells. The various hypothetical mixes can be found in various nerves among chordates and hemichordates with different arrangements with respect to the motorneuron exit from the nerve cord as either ventral (most cases) or dorsal (some cases). An additional change found among chordates is that motorneuron axonal tracks can run alone or associate at a certain distance away from the nerve chord with sensory fibers. With this theoretical concept in mind, we can now investigate the organization and content of various nerves found in deuterostomes.

Acorn Worms (Hemichordates)

There is no clear formation of aggregated peripheral nerves in acorn worms, but there is an occasional aggregation of the net to form strands of fibers. As expected by the network-like organization of the epithelial nerve plexus, information might flow through the net to reach the effector organs possibly via short nerves containing motorneuron axons. However, this possibility is highly speculative and based on data dating back to the era prior to modern tracing and neurochemical staining techniques and it requires more work to be solidified. Most interesting here is that the general organization of the dorsal nerve chord seems to resemble very much the craniate spinal-cord organization with the neurons grouped near a central lumen, surrounded by a peripheral neuropil. As with craniates, motor neuron(s) appear to be ventral in the dorsal nerve cord. Clearly, a detailed analysis using modern tracing techniques, *in situ* hybridization, and immunohistochemistry is needed to evaluate the organization of the PNS and its relationship to the partial formation of a CNS in these animals.

Amphioxus (Cephalochordates)

At least three kinds of peripheral nerves (very loosely defined) are found in amphioxus, associated with three different types of motor neuron(s). Amphioxus has an unusual notochord consisting of muscle plates. Processes of the muscle fibers of these notochord muscle plates extend as short ‘ventral roots’ to the spinal cord to form cholinergic synapses on the notochord with a subset of poorly characterized motor neuron(s). The second set of peripheral nerves are the muscle processes of the metameric muscle packages reaching toward the intramedullary motor neuron(s), which have axons that extend rostrocaudally along the nerve chord but do not exit the CNS. Among deuterostomes, this situation is highly specialized but it is also found in nematodes within the protostomes. Whether this situation is indeed uniquely derived or reflects a general property of basic triploblasts requires additional analysis in more basal triploblasts, paying attention to the emerging cladistic relationships. Despite the unusual morphology, the synaptic transmitter appears to be acetylcholine, indicating that motor neuron(s) with acetylcholine as a transmitter are at least deuterostome commonalities and are shared with many protostomes. Of note, the muscle-process bundles of both sets of motor nerves, which formally can be compared to ventral roots of craniates, do not contain sensory fibers.

The dorsal root nerve fibers are composed of processes of multiple intraspinal sensory neurons, of various single or aggregated sensory cells, and of one specific type of motorneuron. There are certain resemblances in the content of these dorsal nerves with the cranial nerves of basal chordates (dorsal exit of motor neuron(s), fibers of intramedullary sensory neurons, and placode-derived nerves to sensory cells), but it is unclear if these similarities are a case of convergent evolution with the nerves of craniates or reflect an ancestral organization of this basal chordate.

Tunicates (Urochordates)

The overall organization of both peripheral nerves and the CNS differs dramatically among the various tunicate lineages reflecting their deeply rooted divergence. In one lineage, the spinal cord contains almost no neurons and is a transient larval structure that is lost during metamorphosis when the larva turns into a sessile adult. motor neuron(s) are only present in what will become the central ganglion of the sessile adult, and their fibers project along the spinal cord to form either pure motor nerves or mixed nerves as they exit. These motor neuron(s) have been homologized based on their organization with the branchial (gill arches) motor neuron(s) of craniates. Interestingly, recent molecular data have confirmed and extended this suggestion by showing that a unique set of genes (Phox2) associated only with craniate oculomotor and branchial/visceral motor neuron(s) show expression in these motor neuron(s). In addition, these motor neuron(s) persist past metamorphosis and thus identify the origin of branchial motor neuron(s) already in urochordates. It remains to be seen whether this approach can be expanded to cephalochordates and hemichordates. In appendicularians (a class of free-swimming tunicates which retains the larval body form into adulthood), the spinal cord contains motor neuron(s) which project first along the spinal cord but eventually exit the spinal cord through ventral roots containing only the motor neuron axons adjacent to the muscle cells they innervate. The latter organization resembles that of the ventral roots in craniates.

The origin of sensory nerve components in chordates is also yet to be fully understood. Despite the presence of certain molecular structures indicative of a neural crest and the presence of most genes now identified with the formation of the neural crest, the entire molecular cascade used to generate neural crest in craniates is not clearly assembled as yet. Likewise, while specific components indicative of neurogenic placodes have been identified and associated with putative placodal structures, it is clear that the entire molecular basis of placode induction has not been elucidated in noncraniate chordates. It is very possible that the final assessment will show an incomplete assembly of the molecular pathways comparable to those of neuromeric boundaries in chordates, in particular the midbrain/hindbrain boundary, rendering molecular homology as tentative as cellular homology and patterning signal homology. In fact, a recent analysis of sensory components in developing *Ciona* (a tunicate with a sessile adult form) shows cells and their distribution which are difficult to reconcile with those found in cephalochordates or craniates.

Craniate (Vertebrate) Chordates

Both jawless and jawed craniates have three different kinds of motor neuron(s): (1) the ventrally exiting somatic motor neuron(s) of the spinal cord; (2) the dorsally exiting branchial motor neuron(s) of the hindbrain targeted for muscle of the branchial arches (hence the name branchial motor neuron(s)); and (3) a unique set of motor neuron(s) innervating the ocular muscles which are present in all craniates except the hagfish, either as primitive absence or due to secondary loss (**Figure 2**). The ocular motor neuron(s) can change their axonal trajectory to exit either dorsally or ventrally, thus resembling somewhat somatic motor neuron(s) associated with the spinal cord. The branchial and oculomotor motor neuron(s) are unique in that they express a specific combination of Phox2 genes not found in the spinal cord. In addition, craniates have a unique set of inner-ear efferent neurons which have been shown to derive from the facial (cranial nerve VII) branchial motor neuron(s). Due to the absence of a recognizable ear in noncraniate chordates, this motorneuron population must be considered as a uniquely derived feature of chordates which coevolved with the evolution of the craniate ear.

All craniates have cranial and spinal sensory nerves which differ in their composition. For example, the lampreys' cranial nerves seem to have only placodal-derived neurons – neural crest does not contribute to them. In addition, those nerves contain axons of intramedullary neurons which appear to be functionally equivalent to the mesencephalic trigeminal sensory neurons of jawed craniates. In contrast to the latter, all cranial nerves in lampreys seem to have some contribution of these intramedullary neurons. Limited embryological evidence suggests that at least the mesencephalic trigeminal sensory neurons are neural crest derived and the intramedullary sensory neurons of lampreys and hagfish may represent such a neural-crest precursor. In the spinal cord,

Eyes (no ocular muscles or nerves), ears (torus with single canal, no cupula) lateral line placodes with limited differentiation, seven cranial nerves, no epibranchial placodes? 'taste buds' innervated by all nerves, spinal dorsal root neurons derived from neural crest?
Intramedullary sensory and motor neurons, branchial motor neurons, traces of placodes and neural crest, no distinct spinal or cranial nerve pathways, no distinct sensory organs

Figure 2 The cladogram shows some of the major changes in the nerve organization and sensory systems in the clade olfactores as discussed in the text. Note that the phylogenetic position of hagfish tends to fall together with lampreys to form a monophyletic taxon based on molecular data. However, most morphological data suggest that hagfish are distinct from lampreys. If indeed hagfish and lampreys are monophyletic, then hagfish have to be extremely derived beyond any such chances encountered in any other vertebrates showing regressive evolution.

jawless craniates differ in their ventral root/dorsal root organization and show asymmetry of dorsal and ventral root exits. In fact, the fusion of dorsal and ventral roots into a common root in hagfish is considered to be independently derived. Most importantly, neither hagfish nor lampreys have spinal or cranial visceral motor neurons and lack both sympathetic and parasympathetic ganglia, the latter being neural-crest derivatives. Interestingly, in hagfish and possibly unique to them, is the innervation of the widespread taste-bud-like Schreiner's organs by all cranial and spinal ganglia. This is in stark contrast to lampreys' taste buds restricted to the branchial arches and innervated only by cranial nerves and jawed craniates whose taste buds are always innervated by epibranchial placode-derived neurons (i.e., placodes forming at the gill arches) requiring Neurogenin2 for their development. Clearly, spinal dorsal root ganglia use both Neurogenin 1 and 2 for development, but it is unclear how widespread this dual use extends among craniates and whether or not the innervations of the hagfish Schreiner's organ is coming from Neurogenin-2-specified dorsal root ganglia, thus presenting a unifying theme of taste-bud innervation with an apparent shift between epibranchial placode-derived cells to neural-crest-derived cells. Whether or not the hagfish spinal dorsal root ganglia develop via placodes like lamprey's cranial ganglia or develop from neural crest as in jawed craniates remains to be demonstrated in hagfish embryos.

Jawed Craniates (Vertebrates)

All jawed craniates are characterized by a set of apomorphies (evolutionary specializations) in their peripheral nervous system:

1. They all have in the caudal midbrain, a set of sensory neurons innervating the muscle of mastication, the mesencephalic trigeminal nucleus. How and why the medullary sensory neurons of lampreys and hagfish were replaced by mesencephalic sensory neurons remains unclear. It can only be speculated that this event somehow correlates with the molecular specification of the gnathostome (jawed craniate) midbrain–hindbrain boundary and the evolution of the cerebellum.
2. They all have spinal sympathetic ganglia innervating the viscera and have somatomotor-derived sympathetic visceral motor neuron(s) which segregate through expression of specific Lim-domain genes from somatic motor neuron(s) and innervate the neural-crest-derived sympathetic and parasympathetic ganglia.
3. They all have dorsal and ventral roots exiting at intersegmental spaces and fusing to form a mixed peripheral nerve. It is likely that the molecular basis of development for these sensory components (the various bHLH genes) is conserved in expression and cell-fate decision, but more basal-jawed craniates as well as jawless outgroups need to be investigated to solidify this assumption.
4. Trigeminal motor neuron(s) (cranial nerve V) project exclusively through the mandibular branch of the trigeminal nerves whereas they also contribute to the maxillary division in lampreys, and this issue remains to be explored in hagfish.
5. All jawed craniates have a vagus (cranial nerve X), accessory nerve (XI), and hypoglossal nerve (XII). However, it is unclear how the lampreys' exclusively spinal somatic motor neuron(s) became reorganized to form the intramedullary hypoglossal motor neuron(s), how vagal motor neuron(s) gained access to the heart and bowel for parasympathetic control, and how the accessory motor neuron(s) evolved from caudal intramedullary branchial motor neuron(s) to form the rostral spinal branchiomotor-like motor neuron(s) of jawed craniates.

Despite this high level of conservation, there were other surprising reorganizations of existing, functional systems into a new pattern at the transition from jawless to jawed craniates and within jawed craniates. Foremost is the reorganization of the ocular motor and vestibular system. Lampreys have 6 eye (ocular) muscles but the pattern of innervation by ocular motor neuron(s) is different from that of jawed craniates: two ocular muscles are innervated by the abducens (cranial nerve VI) in lampreys whereas only one ocular muscle is innervated by the abducens in jawed craniates. This difference suggests either a reorganization of the ocular muscles from a functional eye-movement system into an equally functional system with a different organization combined with a concomitant reorganization of the input mechanisms or a parallel evolution from a possibly seven-ocular muscle ancestor. Instead of reorganizing a lamprey-like into a gnathostome-like six-ocular muscle pattern, a more parsimonious but somewhat speculative idea would be to assume a hypothetical seven-ocular muscle ancestor. If such an ancestor exists, this would not require reorganization of one existing and functional system into another one. Instead, the two lineages would have lost one oculomotor and one abducens innervated muscle in the lamprey and gnathostome lineage, respectively, converting a seven-ocular muscle ancestral pattern into the two derived systems now found in vertebrates. Interestingly, one of those inputs, the vestibular system, evolved from a two-semicircular canal system (lampreys and hagfish) into a three canal system (jawed craniates) through the evolutionary addition of the horizontal (lateral) canal. More recent data suggest that at least two molecular changes underlie this reorganization: orthodenticle-like 1 (Otx1) is needed to form the horizontal canal proper whereas Foxg1 is needed for the formation of the horizontal canal crista containing the sensory part of the horizontal canal system. Another major change is the evolution of cranial and caudal parasympathetic ganglia and their specialized parasympathetic visceral motor neuron(s) which are apparently found only in jawed craniates. Consequently, there is no ciliary ganglion-mediating lens movements in lampreys, which have evolved a different accommodation mechanism. Thus, the eye underwent numerous changes in terms of its ocular muscles, intraocular muscles, and the retina (change in position of the retinal ganglion cells) at the transition from jawless to jawed craniates. Molecular data for the formation of parasympathetic ganglia are beginning to appear in the literature and may help to understand the evolutionary history of this complex system.

While neurogenic placodes are the basis for all craniate sensory systems and their molecular basis is beginning to emerge, it remains unclear how the neurogenic placodes have been molecularly changed to produce the various craniate ears, the various taste-bud neurons, lateral line and electroreceptive organs, and neurons. Most importantly, there is clear experimental evidence indicating that at least the ampullary electroreceptors of Axolotl (a salamander) are derived from the same lateral-line placodes generating the mechanosensory lateral-line organs. Another molecularly unresolved problem of craniate sensory evolution is the generation of the novel auditory sense for which we are just beginning to understand the molecular basis, and the loss of the mechanosensory lateral line and electroreceptive ampullary organs and their placodes in land vertebrates, leaving numerous open issues both for vertebrate neurosensory progressive and regressive evolution of neurosensory systems, including gain and loss of entire sensory epithelia such as the auditory system (amphibian papilla, basilar papilla/cochlea) and the lagena.

The view presented here assumes that the original deuterostome PNS was a nerve plexus closely resembling that of modern diploblasts and basal triploblasts, without aggregation of sensory cells into discrete organs. The evolution of the PNSs and sensory organs in deuterostomes shows certain similarities at the level of single genes and even cells embedded in an overall changing system. The nervous system of deuterostomes may have evolved, hypothetically, from initial peripheral nerve ramifications and rudimentary sensory-cell aggregations into molecularly precise specified systems which, once established, limited evolutionary changes among gnathostomes. Still, while the overall pattern is conserved, even the gnathostome PNS shows remarkable system and cellular evolution for which we do not yet understand the molecular basis. In conclusion, it appears that evolutionary developmental transformation of a nerve net retains peripheral motor nerves which can be modified by various sensory additions derived from intramedullary neurons, neural crest, or placodes to evolve into the almost stereotyped patterns found in all vertebrates.

Summary and Conclusion

Projecting crown-group organization, such as mammalian cranial and spinal nerve organization, onto a putative ancestor biases any attempt to understand the evolution of neural systems. Modern molecular analysis, instead, has demonstrated the expression of homologous molecules and cellular resemblances in analogous parts of peripheral nervous and sensory system such as eyes and ears, organs which are anatomically rather different. This cellular and molecular homology, which can occasionally be established across a wide diversity of phyla, suggests that cellular and molecular identity predates the evolution of complex sensory systems. Different sensory and nervous systems may present examples of convergent evolution with homologous cellular and molecular bases in an analogous organ.

Glossary

Agnathans Vertebrates (fishes) without jaws (a = without; gnathos = jaw).

Ammocoete Alternate name for the larval stage of the lamprey life cycle.

Cyclostomes Animals with round mouth (cyclo = round; stoma = mouth). Synonym of agnathans.

Monorhinic Animals having a single nasal sac, such as agnathans.

Neuromeres Segments or transversal bands of the developing neural tube exhibiting specific properties, such as prosomeres in the forebrain (prosencephalon) or rhombomeres in the hindbrain (rhombencephalon).

Neuromeric model Morphological interpretation of the brain based on the restricted expression pattern of regulatory genes and a segmental conception of brain organization, besides considering four longitudinal subdivisions (floor, basal, alar, and roof plates) throughout the entire longitudinal axis.

Vertebrates As used here, a synonym of craniates, the clade that includes agnathans and gnathostomes; alternately defined by some authors as excluding hagfishes, reserving the term craniates for all agnathans and jawed vertebrates.

Introduction

Lampreys, together with hagfishes, are the only living jawless fishes included in one of the two major taxa of the craniate lineage: the agnathans or cyclostomes; they arose about 500 million years ago and, since then, have evolved independently. The species of this group are of interest for studying the shared characters with gnathostomes and for reconstructing the anatomy of the brain of the common ancestor of craniates. Therefore, the study of their central nervous system (CNS) offers an excellent starting point to understand the development, structure, and function of the craniate neuraxis.

Lampreys (Petromyzontoidea or petromyzontids) belong to the cephalaspidomorphi class that comprises a single family Petromyzontidae (including 9 genera and 41 species), whereas hagfish (Myxinoidea or myxinoids) are included in the Myxini class that comprises two families: Eptatretidae and Myxinidae (with 5 genera and about 60 species). These two classes of craniates share many features such as the absence of jaws, scales, or paired fins (**Figures 1**(**a**) and **1**(**b**)). In addition, they have an elongated eel-like body, a cartilaginous skeleton (without bones), a single nostril (monorhinic), a tongue-like structure bearing sharp denticles, pore-like gill openings, and the ability to exude copious quantities of slime or mucus. However, there are some other features that differ considerably between them, such as the presence of seven pairs of gill openings, a round sucking mouth with many teeth, and two dorsal fins in lampreys. By contrast, hagfishes have a variable number of gill openings, ranging from 2 to 14 pairs, and posses several tentacle-like barbels located around the mouth and the nostril. Another marked difference between the two groups relates to their lifecycles: lampreys have a complex lifecycle that comprises a very long freshwater larval phase (3–5 or more years), followed by a metamorphosis. During the adult stage many of them, but not all, are predators of other fishes. Those that are predacious can complete their lifecycle in freshwater or migrate to the sea and return to freshwater streams for reproduction before dying. Hagfishes are benthic marine organisms that live in relatively cold water at depths ranging from ten to several hundred meters and have no larval stage (**see also Hagfishes and Lamprey**: Hagfishes; Lampreys: Energetics and Development; **Cellular, Molecular, Genomics, and Biomedical Approaches**: Culture of Fish Cell Lines).

At the brain level, lampreys and hagfishes have remarkable differences but also many similarities. In

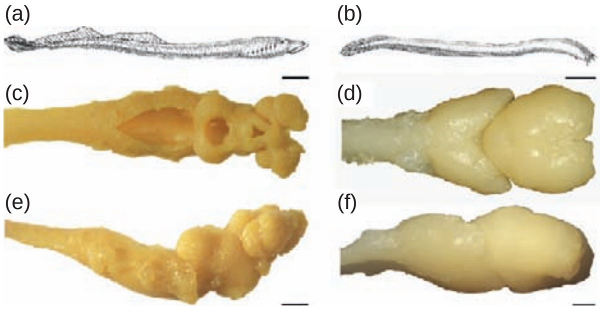

Figure 1 Drawings of lateral views of a lamprey, *Lampetra fluviatilis* (a) and a hagfish, *Myxine glutinosa* (b), as well as dorsal (c, d) and lateral (e, f) views of their brains. Scale bars = 35 mm (a), 90 mm (b), and 1 mm (c–f).

contrast to amphioxus (a cephalochordate), they have a number of special sense organs that convey information over the cranial nerves toward specific centers of the CNS. As in all craniates, their brains consist of a hindbrain or rombencephalon caudally, a midbrain or mesencephalon, and a forebrain or prosencephalon rostrally, with the latter classically thought to consist of a telencephalon and a diencephalon. The adult neural tube of agnathans has a minimal morphogenetic deformation (cephalic flexure) that occurs at the level of the rostral end of the notochord (which persists in the adult stage). This anatomical feature helps establishing particular transversal boundaries and understanding its topology better.

The adult lamprey brain is slender, elongated, and very small (8 mm in length and 2.3 mm width, with the smallest proportion in relation to the body mass among the vertebrates), with an ample mesencephalic ventricle (**Figures 1**(**c**) and **1**(**e**)). The adult hagfish brain is larger (8.4 mm in length and 3 mm width) and unusually compact (**Figures 1**(**d**) and **1**(**f**)). There are no choroidal plexuses in hagfishes, but they cover most of the dorsal part of the brain in lampreys and, together with the ample ventricular cavities, make up for the absence of vascularization in the larval brain and spinal cord as well as in the adult spinal cord.

The eyes in hagfishes are degenerate in that they are not externally visible, and a lens and extraocular muscles are absent; therefore, they have no somatomotor nerves (III, IV, and VI) innervating the eye orbit. Nonetheless, hagfishes do have small optic nerves that arise from the eyes and project centrally. Lampreys, like jawed vertebrates, have fully developed eyes and extrinsic musculature. Some of the lamprey extraocular muscles, however, are differently arranged than their gnathostome counterparts. From a histological point of view, there are also striking differences between lamprey and hagfish brains; in hagfishes, most neurons migrate away from the ventricular surface (where they originated) and are highly organized and particularly arranged in some areas, whereas in lampreys the majority of cells are densely packed in a periventricular position.

Some specific differences with gnathostomes are that the dura mater, arachnoid, and pia mater are absent in the cyclostomes, where the CNS is protected by one undifferentiated meninx, the meninx primitive, which is covered by perimeningeal tissue formed of mucoid cells. In addition, agnathans apparently lack a true cerebellum and have no oligodendroglia; therefore, myelin-sheaths are not developed.

Research to understand the organization and evolutionary development of the agnathan brain has intensified over the last decades. As lampreys have a relatively simple nervous system, with a basic structural organization similar to that of the rest of vertebrates, there are many functional studies. This research has benefitted from the ability to maintain an *in vitro* preparation of its CNS for several days, with attached peripheral nerves and muscles if needed. Many pioneering studies involved the largest reticulospinal neurons, which can be seen without histological preparation because the walls of the brain are translucent. However, the availability of embryonic stages of the various species of hagfishes has hampered progress.

Concerning the nomenclature of the brain, a new paradigm of prosencephalic organization in vertebrates, including lampreys, has been developed in the last two decades. This implies the redistribution of some nuclei and the definition of morphological landmarks between different zones that allow for establishing new homologies.

Hindbrain

The hindbrain or rhombencephalon represents about half of the length of the whole brain and is well developed. It continues rostrally with the midbrain and caudally with the spinal cord by a transition zone or obex that is located at the level of the first spinal root. In hagfishes, its rostral boundary is delineated dorsally by the isthmic fissure and ventrally by the plica encephali ventralis. In lampreys, only the dorsal limit is externally marked by a deep sulcus.

The hindbrain can be subdivided into four longitudinal regions: roof and alar plates dorsally and basal and floor plates ventrally. The internal cavity or fourth ventricle is much more ample in lampreys, where it is covered dorsally by an extensive and richly folded choroidal plexus (roof plate, **Figure 2**(**a**)), whereas in hagfishes it is rather narrow but slightly enlarged in its rostral part. Most of the agnathan alar plate is formed by the octavolateral area, which can be subdivided into dorsal, medial, and ventral nuclei (**Figures 2**(**a**)–**2**(**d**), **2**(**h**), and **2**(**i**)). The dorsal nucleus in lampreys, as in other craniates, receives electroreceptive inputs; however, in hagfishes, which have no electroreceptive lateral line system, this nucleus receives ascending spinal

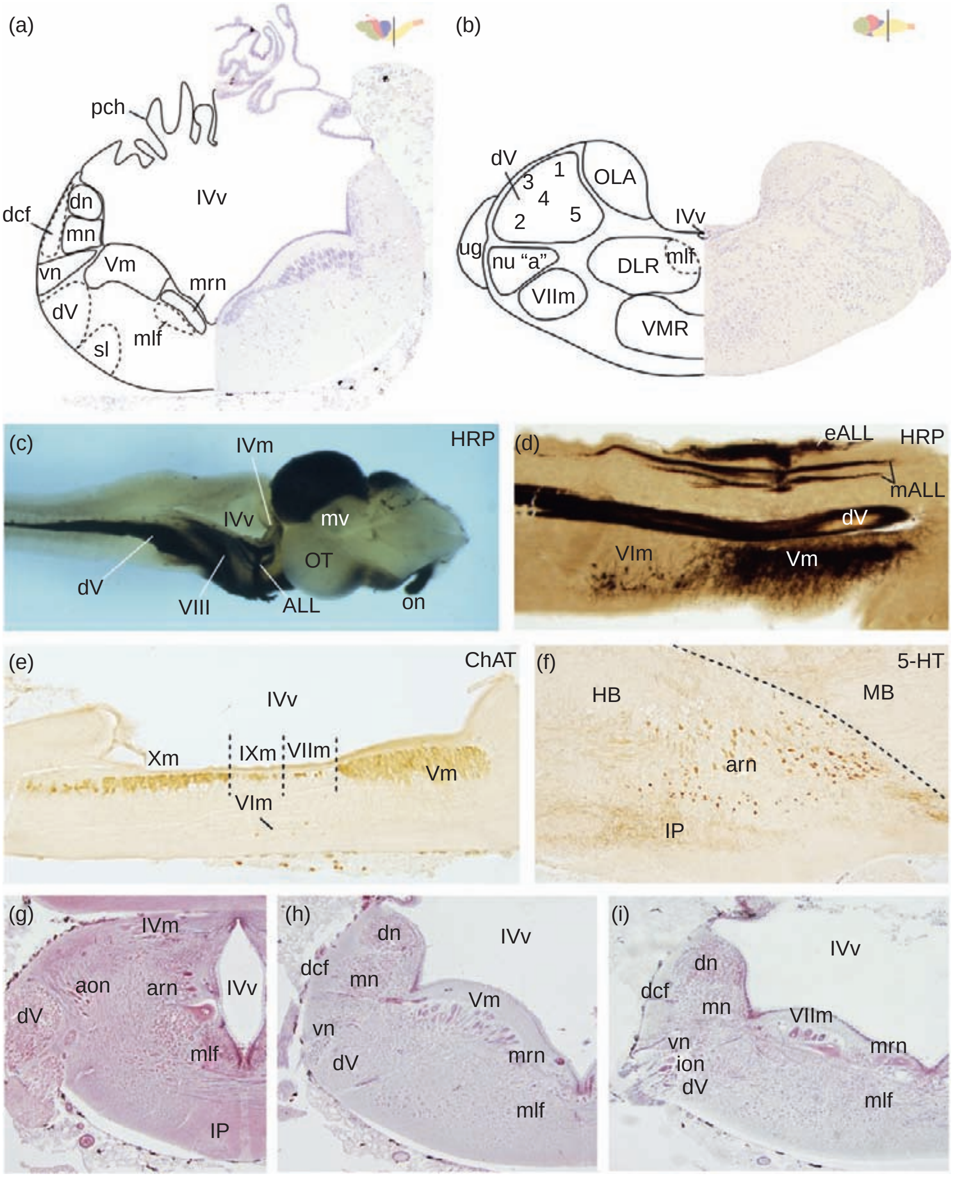

Figure 2 Representative transverse sections through the hindbrain of *L. fluviatilis* (a) and *M. glutinosa* (b). Hematoxylin-stained sections are shown in the right side; the identified areas and nuclei (solid lines), and major tracts (dashed lines) are shown in the left side. projections through the dorsal column pathway. The medial nucleus is innervated by mechanoreceptive lateral line fibers. The ventral nucleus receives vestibular afferents through the octaval (VIII) nerve. In lampreys, three (anterior, intermediate, and posterior) octavomotor nuclei are readily distinguished by their cell body size (**Figures 2(g)** and **2(i)**) and their vestibulo-ocular and vestibulo-spinal connections. In hagfishes, an octaval region is present but is more diffusely organized. A small efferent projection to the labyrinth is also present in lampreys.

The sensory complex of the trigeminal nerve (**Figure 2**(**b**)) and its area of termination are prominent in hagfishes. In lampreys, this sensory system is also well developed (**Figures 2**(**a**), **2**(**c**), **2**(**d**), and **2**(**g**)–**2**(**i**)), with most of its fibers reaching the rostral portion of the spinal cord. The sensory fibers are topographically arranged, and in hagfishes they are segregated into five columns surrounded by cell bodies. The second-order neurons of the sensory trigeminal nucleus have crossed axons projecting to different targets. Remarkably, agnathans have no ascending primary trigeminal fibers, and a principal and a mesencephalic sensory nuclei are apparently lacking. However, lampreys and *Eptatretus stouti* have a number of large intramedullary sensory cells (identified as dorsal cells) with peripheral branches associated with the trigeminal nerve, which are regarded as homologs of the mesencephalic trigeminal nucleus of gnathostomes. In *E. stouti*, these cells are located in the ventral portion of the sensory trigeminal nucleus. In lampreys, they are located periventricularly in the octavolateral area. At the caudal end of the rhombencephalic alar plate, there is another common element of the somatosensory zone, the dorsal column nuclei, which project to the contralateral optic tectum.

In lampreys, a narrow viscerosensory zone is located medial to the descending trigeminal tract and, based on its chemical properties, a nucleus of the solitary tract has been recently identified. In hagfishes, this column is mostly represented by the sensory nucleus of the vagus, which occupies a particular submeningeal location. They also have a nucleus located between the sensory and motor zone called nucleus ‘a’ of Kusunoki (**Figure 2**(**b**)) that cannot yet be homologized with any other craniate nucleus.

The cerebellum has not been convincingly defined in agnathans. Classically, a small and simple ridge or plate between the right and left octavolateral area at the isthmus level is considered as the agnathan cerebellum in lampreys. However, recent experimental results question its existence. Of interest is that the main nuclei related to the gnathostome cerebellum, such as those derived from the rhombic lip (pontine nuclei and the olivary complex) or a nucleus ruber (red nucleus), have not been identified in agnathans.

In the lamprey isthmus, a locus coeruleus has been tentatively identified based on the presence of some catecholaminergic cells projecting rostrally to the striatum. In addition, a nucleus isthmus was identified rostral to the trochlear nucleus by its reciprocal connections with the optic tectum and by the cholinergic nature of its cells. Caudal to this nucleus, there is another radially oriented cholinergic cell population whose periventricular component was considered homologous to the pedunculopontine tegmental nucleus; the superficial portion could correspond to the laterodorsal tegmental nucleus of amniotes. Recent studies suggest that the region of the pedunculopontine tegmental nucleus is the counterpart of the mammalian mesencephalic locomotor region (MLR). Although the MLR is frequently ascribed to the mammalian midbrain, it is located topologically caudal to the trochlear motor nucleus and thus clearly corresponds to the isthmus. None of these isthmic nuclei have been investigated in hagfishes.

The motor nuclei are the most conspicuous nuclei of the rhombencephalic basal plate, and their topographical distribution is relatively well known in agnathans, where they mostly constitute a prominent and rather continuous column of cells along the hindbrain (**Figures 2**(**a**)–**2**(**e**), and **2**(**g**)–**2**(**i**)). In lampreys, the branchiomotor nuclei are located periventricularly, whereas in hagfishes they migrate to the ventrolateral part of the rhombencephalon. These include the nuclei of the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagal (X) cranial nerves, whose motoneurons are located at the same dorsoventral level.

The trigeminal nerve innervates all the periphery of the mouth, and its motor nucleus is strongly developed in lampreys, where the very large motoneurons protrude toward the fourth ventricle. Contrary to the situation in gnathostomes, the facial complex lacks internal mandibular and pharyngeal branches, whose targets are innervated instead by the trigeminal nerve, whereas the glossopharyngeal and vagal nerves are thought to innervate motor and sensory components of the pharyngeal region and viscera. An unresolved issue in agnathans is the distinction of branchiomeric from visceral (preganglionic parasympathetic) cell populations. Assuming that the facial, glossopharyngeal, and vagal nerves carry both components, they cannot be distinguished from each other.

Concerning the lamprey somatomotor column, the abducens motoneurons are located caudal to the trigeminal motor nucleus and adjacent to the floor plate (**Figures 2**(**d**) and **2**(**e**)). In contrast to gnathostomes, these motoneurons innervate two muscles, the ipsilateral inferior and posterior rectus muscles. Their axons course rostrally and exit the brain in an atypical lateral position, together with the trigeminal roots. The motoneurons of the nucleus of the trochlear (IV) nerve innervate the caudal oblique extraocular muscle; most of these motoneurons are located quite dorsally at the isthmus level (**Figures 2**(**c**) and **2**(**g**)), where the majority of their axons cross the midline at the velum medullare anterius to exit the brain dorsally. In addition, agnathans have a spino-occipital motor nucleus, which is considered to be the counterpart of the hypoglossal nucleus of tetrapods. This nucleus innervates the floor of the pharynx and the posterior region of the buccal funnel.

The lamprey reticular system is composed of some very large cells (identified as Múller and Mauthner cells) that are not present in hagfishes. The seven pairs of Múller cells have conserved positions: three rostral to the hindbrain (see below), one in the isthmus, and the remaining three pairs in the rhombencephalon proper. They possess uncrossed axons that course in the medial longitudinal fasciculus to the spinal cord. In addition, lampreys have one or two pairs of Mauthner cells, characterized by their position near the vestibular nerve and by their crossed spinal-projecting axons. The agnathan reticular system is usually subdivided into three portions, namely anterior (superior), intermediate (medius), and posterior (inferior) rhombencephalic reticular nuclei (**Figures 2**(**a**) and **2**(**f**)–**2**(**i**)), and it is mostly composed of glutamatergic cells, but possesses numerous serotonin-immunoreactive cells as well (**Figure 2**(**f**)). These nuclei receive inputs from several systems and project to the spinal cord. Spinal-projecting raphe nuclei are also present, but in hagfishes are only two in number.

An interpeduncular nucleus exists in both hagfishes and lampreys (**Figures 2**(**f**) and **2**(**g**)) based on a prominent input from the habenula through the fasciculus retroflexus. In addition, there are some prominent ascending and descending fiber tracts. The dorsal column tract is located in the alar plate, whereas three main fiber bundles can be distinguished in the basal plate: the medial longitudinal fasciculus, the tecto-bulbo-spinal tract, and the spinal lemniscal fasciculus (**Figures 2**(**a**), **2**(**b**), and **2**(**g**)–**2**(**i**)).

Midbrain

The agnathan midbrain or mesencephalon extends dorsally in the rostro-caudal direction from the posterior commissure to the isthmic region, but ventrally it is very narrow. A unique feature of the lamprey mesencephalon is the presence of an ample ventricular cavity, covered dorsally by the corresponding choroid plexuses. It is subdivided in two main areas: one dorsal, constituted by the optic tectum (OT) and torus semicircularis, and other ventral, called the mesencephalic tegmentum (**Figure 3**).

In lampreys, most of the dorsal portion of the mesencephalic wall corresponds to a well-developed and stratified OT that is subdivided into four major layers: superficial, optic, central, and periventricular strata, with

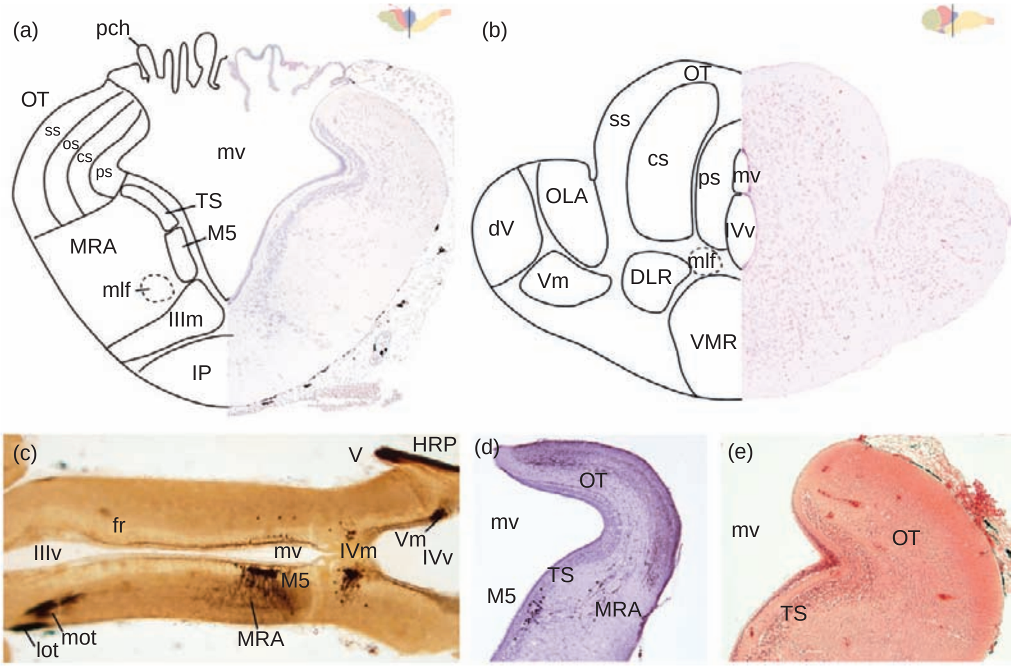

Figure 3 Representative transverse sections through the midbrain and rostral hindbrain of *L. fluviatilis* (a) and *M. glutinosa* (b). Hematoxylin-stained sections are shown in the right side; the identified areas and nuclei (solid lines), and major tracts (dashed lines) are shown in the left side. Some horseradish peroxidase staining (HRP)-labeled structures from the eye orbit are shown in a horizontal section of a larva (c) and a transverse section of an adult (d) lamprey brain. (e) Bodian-stained transverse section of the optic tectum (OT) and the torus semicircularis (TS). cs, central stratum (optic tectum); DLR, dorsolateral reticular nucleus; dV, descending trigeminal tract; fr, fasciculus retroflexus; IIIm, oculomotor nucleus; IIIv, third (diencephalic) ventricle; IP, interpeduncular nucleus; IVm, trochlear nucleus; IVv, fourth (rhombencephalic) ventricle; lot, lateral optic tract; M5, nucleus M5 of Schóber; mlf, medial longitudinal fasciculus; mot, medial optic tract; MRA, mesencephalic reticular area; mv, mesencephalic ventricle; OLA, octavolateral area; os, optic stratum (optic tectum); pch, choroidal plexus; ps, periventricular stratum (optic tectum); ss, superficial stratum (optic tectum); V, trigeminal nerve; Vm, trigeminal motor nucleus; VMR, ventromedial reticular nucleus.

most cell bodies located periventricularly. Although externally visible, the hagfish midbrain is very small and poorly developed. The OT is less developed than in lampreys and generally subdivided in three main layers: superficial (molecular), central, and periventricular cell layers. The major input to the agnathan OT arises from the contralateral retina, but many other sources have also been described.

Ventral to the lamprey OT is a torus semicircularis with ample number of connections, such as ascending lateral line and octaval fibers. This nucleus appears to be absent in hagfishes. In the alar plate of lampreys there are two prominent retinopetal nuclei, that is, the M5 nucleus of Schóber (periventricularly) and the mesencephalic reticular area (displaced laterally and dorsally) (**Figure 3**). Similar retinopetal cells have also been reported in the rostral mesencephalon of hagfishes but identified as the nucleus of the posterior commissure, suggesting that it may actually be diencephalic. The mesencephalic tegmentum of hagfishes is usually subdivided into a dorsal and a ventral tegmental nucleus. On the other hand, the lamprey mesencephalic tegmentum contains the mesencephalic reticular nucleus (which includes the third pair of Múller cells) and the oculomotor (somatomotor) motoneurons. In these animals, only three extraocular muscles (dorsal rectus contralaterally, and rostral rectus and rostral oblique ipsilaterally) are innervated by the third cranial nerve.

An area homologous to the mesencephalic substantia nigra of other vertebrates has been described in lampreys based on its immunoreactivity for dopamine and its projections to the striatum, but it is located farther rostrally in the diencephalon (nucleus of the posterior tuberculum). Such nucleus could also be present in hagfishes.

Forebrain

The forebrain or prosencephalon is the rostral part of the brain. Following the prosomeric model, the forebrain of vertebrates consists of two main parts, the diencephalon and the secondary prosencephalon. This model has been successfully applied in lampreys where, similar to other craniates, the diencephalon can be further divided into three prosomeres (p1, p2, and p3), which are numbered in a caudal to rostral order (**Figure 4**). In addition, two hypothalamic subdivisions (hp1 or prepeduncular and hp2 or peduncular) have recently been proposed in the secondary prosencephalon. As this model is not yet tested in hagfishes, the organization of the forebrain will be commented on following the general lamprey schema, with reference to hagfishes when appropriate. The hagfish diencephalon is dorsally separated from the midbrain by the di-mesencephalic sulcus and from the telencephalon by the sulcus telo-diencephalicus. Inside the hagfish forebrain, there is a complex and prominent central prosencephalic nucleus that can be subdivided into several subnuclei of uncertain homologies with amniotes.

Diencephalon

The pretectal region or pretectum represents the alar plate of the first prosomere (p1) (**Figures 4**(**c**) and **4**(**d**)). In lampreys it is subdivided into a rostral precommissural, an intermediate juxtacommissural, and a caudal commissural region. In agnathans, the most important nuclei of this region are the pretectal nuclei, which receive a substantial retinal projection and are involved in visuomotor behaviors, and the nuclei of the posterior commissure. Below the rostral part of the posterior commissure, there is a well-developed subcommissural organ that is paired in lampreys. The secretory material of this organ forms the so-called Reissner's fiber that runs caudally through the ventricular system to the end of the spinal cord.

The alar plate of the second prosomere (p2) is constituted by the epithalamus and the thalamus (the latter corresponding to the classic dorsal thalamus). The epithalamus consists of the epiphysis (or pineal complex that is only present in lampreys) and the habenular complex. The lamprey pineal complex is well developed and consists of two photosensitive organs (pineal and parapineal) (**Figures 4**(**e**) and **5**(**a**)). They have ample connections with the fore- and midbrain, and some parapineal efferent fibers reach the left habenula. The agnathan habenular complex is well developed and possesses a massive commissure. As in other craniates, it is highly asymmetric with the right habenula being much larger than the left (they are fused in hagfishes) (**Figures 4**(**a**), **4**(**b**), and **4**(**d**)). Its major efferent tract is the habenulo-interpeduncular tract or fasciculus retroflexus that is also asymmetric and mostly courses to the interpeduncular nucleus of the rostral hindbrain. Most of the habenular afferents originate rostrally in the secondary prosencephalon and course via the stria medullaris.

In the lamprey thalamus, which is characterized by the presence of many calretinin immunoreactive cells (**Figure 4**(**f**)), two zones dominate, a periventricular compact gray substance and an external (lateral) zone with dispersed cells that correspond to the primordium of the lateral geniculate nucleus.

In the third prosomere (p3), the main component of the alar plate is the prethalamus (which includes the classic ventral thalamus). Furthermore, the prethalamus is divided into dorsal (including the Bellonci nucleus), medial (including the ventral geniculate nucleus), and ventral portions. A prethalamic nucleus involved in the control of locomotion exists in lampreys, which corresponds to the diencephalic locomotor region of amniote vertebrates.

The hagfish thalamus is relatively small, but contains several nuclei: anterior, internal, external, and subhabenular

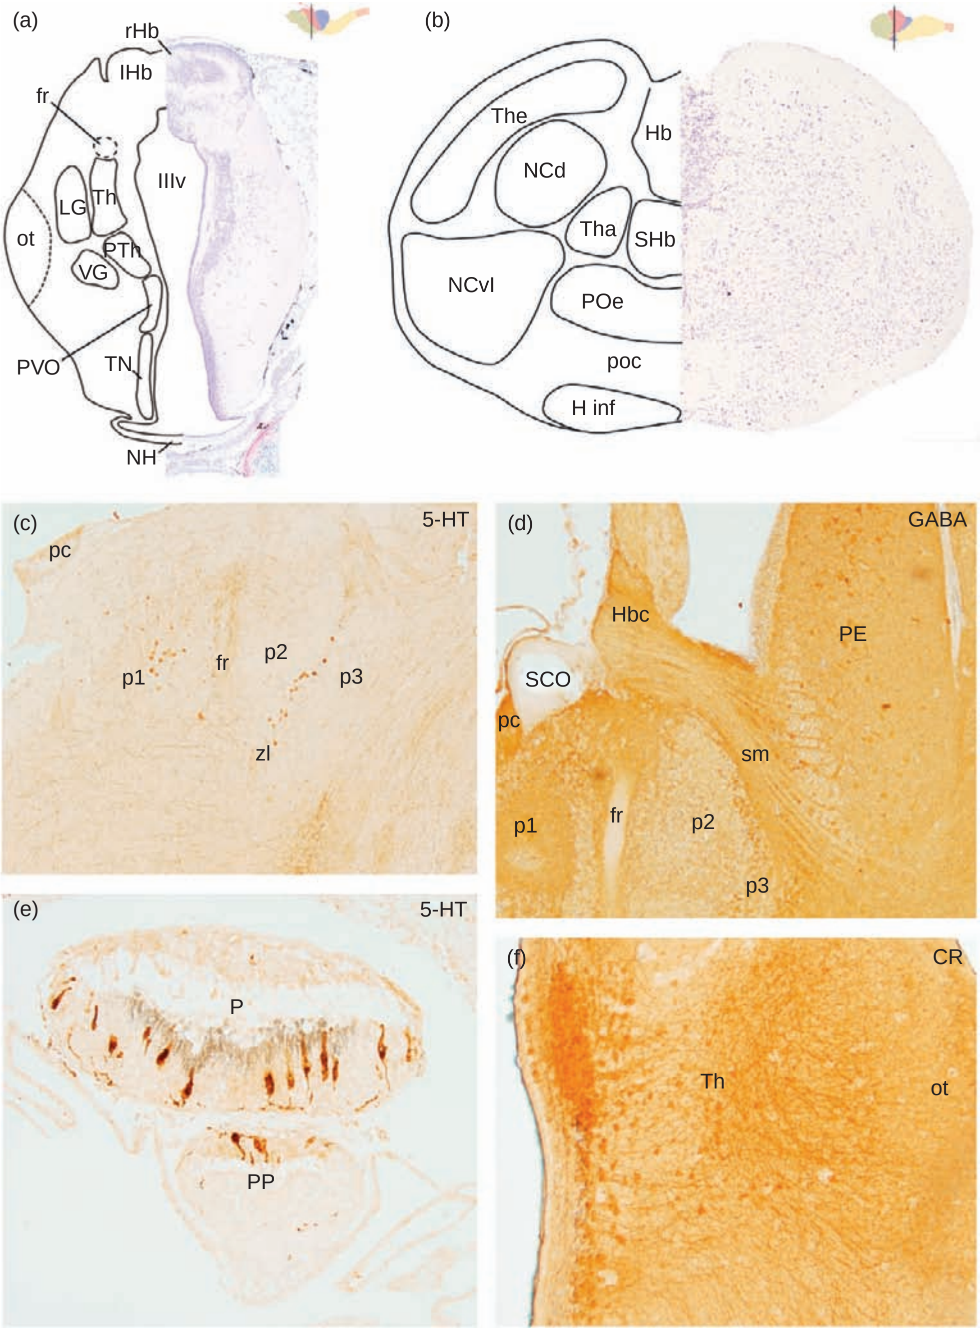

Figure 4 Representative transverse sections through the forebrain (diencephalon) of *L. fluviatilis* (a) and *M. glutinosa* (b). Hematoxylin-stained sections are shown in the right side; the identified areas and nuclei (solid lines), and major tracts (dashed lines) are shown in the left side. thalamic nuclei (**Figure 4**(**b**)), triangular thalamic nucleus, intracommissural thalamic nucleus, paracommissural thalamic nucleus, and diffuse nucleus of the thalamus, with the first receiving retinal projections. Whether these nuclei are components of the thalamus or the prethalamus is uncertain.

The basal diencephalic tegmentum is poorly developed in agnathans. The nucleus of the medial longitudinal fascicle in the subpretectal tegmentum has ipsilateral descending projections to the spinal cord. The huge M1 and M2 Múller cells of lampreys, previously included in the mesencephalic reticular nucleus, are now considered to lie within the subpretectal tegmentum. The agnathan rostral (p2/p3) diencephalic basal plate is formed by the nucleus of the tuberculum posterior, where some catecholaminergic cells with ascending telencephalic projections are located. In fact, the dopaminergic striatal innervation in lampreys originates in this region.

Secondary Prosencephalon

The alar plate of the secondary prosencephalon contains the telencephalon, with the preoptic area included in the molecularly defined subpallium, and part of the hypothalamus, whereas the remaining parts of the hypothalamus constitute its basal plate component.

The agnathan telencephalon comprises two well-developed olfactory bulbs, two relatively large cerebral hemispheres (more prominent in hagfishes), and a nonevaginated portion (**Figure 5**). The two latter parts are subdivided into pallial and subpallial regions. In the evaginated portion, the olfactory lobe is externally demarcated from the telencephalic hemisphere by a circular fissura. In lampreys, the telencephalic ventricle expands laterally from the third ventricle with which it is connected through the interventricular foramen; then, it divides into two portions (Y-shaped cavity): a rostral portion that continues forward into the olfactory bulb (forming its ventricle), and a caudal portion that extends backward into the telencephalic hemisphere (thus corresponding to the lateral ventricle). In hagfishes, the rostral ventricular system has two or three (preoptic, infundibular, and subhabenular) isolated cavities, depending on the species and partial obliteration during development.

The agnathans median, unpaired olfactory organ, located in an internal duct that opens to the exterior by a single nostril, is an exceptional feature among craniates. Paired olfactory nerves enter the olfactory bulb in lampreys, but they are numerous (approximately ten per side) in hagfishes. The proportionately fairly large olfactory bulbs of agnathans are sessile and are interconnected by an interbulbar commissure. The following cytoarchitectonic layers can be discerned in lampreys: a superficial fiber layer with primary olfactory afferents that ramify in relation to the terminals of the mitral cells inside the olfactory glomeruli of the glomerular layer. Close to the glomeruli, there is a noncontinuous row of large mitral cells. Internally, there is a thick granular layer composed of intermingled medium-sized and smaller cells. In hagfishes, the superficial primary olfactory afferents terminate within the deeper glomeruli. Numerous periglomerular cells, including some glomerular cells, invade the glomerular layer. Below, a cell-poor molecular layer is followed caudally by a region of large mitral cells that merges with the internal granular layer. In addition, primary fibers from the accessory olfactory organ project to the ventromedial part of the lamprey olfactory bulb, whereas a dorsal accessory olfactory bulb has been suggested in hagfishes.

The pallial region in lampreys is classically subdivided into four zones without general agreement regarding their correspondence with those identified in other vertebrates. Some authors recognize a lateral pallium, including a primordium pallii dorsalis and a primordium piriforme, a subhipocampal lobe, and a primordium hippocampi. Others identify a lateral pallium, including dorsal and ventral parts, a dorsal pallium, and a medial pallium. Finally, the unevaginated dorso-medial portion has been variously regarded as part of the pallium, thus representing the hippocampal primordium, or as part of the diencephalic prethalamic eminentia (**Figure 5**(**a**)). The pallium of hagfishes is very large, consists of five layers, and is highly differentiated from a cytoarchitectural point of view (**Figure 5**(**b**)). In addition to abundant olfactory inputs, it possesses reciprocal connections with the thalamus; however, no direct correspondence has been established with the pallial subdivisions of gnathostomes.

The agnathan subpallium contains a medial septum, a striatum, and a preoptic region. A putative pallidum has been recognized lateroventral to the striatum. The lamprey striatum (**Figures 5**(**c**) and **5**(**d**)) is basically constituted by a cell layer, which is partially evaginated, and a prominent periventricular neuropil. The hagfish subpallium is poorly differentiated and contains an unpaired septum and a putative striatal region associated with the lateral forebrain bundle. The lamprey preoptic area is constituted by a compact layer of cells located close to the surface of the ventricle. As in hagfishes, it consists of several nuclei. The optic chiasm, where some retinopetal and most of retinofugal axons cross the midline, is larger in lampreys. Slightly caudally to it, there is a conspicuous postoptic commissure.

The hypothalamus, which is classically considered as the basal plate of the diencephalon, is currently interpreted as the ventral portion (including the whole basal and part of the alar pate) of the secondary prosencephalon. This region is slightly differentiated in hagfishes, where the infundibular part of the third

ventricle has a medial hypophyseal recess and two caudal and lateral recesses. Cytoarchitectonically, some cerebrospinal fluid-contacting (CSF-c) neurons are present in the preoptic and infundibular ventricular cavities, as well as a lateral migrated infundibular hypothalamic nucleus. In lampreys, there are many subventricular CSF-c neurons covering most of the infundibular walls and the mammillary recess (**Figures 5**(**e**) and **5**(**f**)). Some of these cells are present in the neurosecretory nuclei of the alar hypothalamus that projects to the neurohypophysis. The periventricular hypothalamic organ also possesses numerous CSF-c cells that are immunoreactive to dopamine, serotonin, and other substances. Some other nuclei were tentatively identified in the basal hypothalamus, of which we emphasized the nucleus of the tract of the postoptic commissure, the tuberal nucleus, and the mammillary region. The most ventral part of the secondary prosencephalon is the neurohypophysis. An interesting feature of the agnathan hypothalamus is that there is no saccus vasculosus.

Glossary

Amniotes Vertebrates whose embryonic development takes place in a fluid-filled sac called amnion that is responsible for keeping the embryo moist. Reptiles, birds, and mammals are amniotes.

Anamniotes Vertebrates that do not form an amnion in the embryonic stage. Fishes and amphibians are anamniotes.

Brainstem A variably defined term that includes the brain regions where most cranial nerves have their origin and/or termination, i.e., the hindbrain and midbrain. Alternatively, the base of the brain extending forward from the spinal cord and including the medulla oblongata and midbrain.

Cerebrospinal fluid (CSF)-contacting neurons Periventricular neurons that contact the CSF by a dendritic process ending in a bulbous protrusion bearing sensory-type cilia.

Circumventricular organs Specialized ventricular regions that contain CSF-contacting neurons among the glial cells. In these regions, the blood–brain barrier (i.e., the cellular barrier that restricts the passage of substances between the blood and the neuronal tissue) is incomplete.

Gnathostomes Vertebrates with true jaws (cartilaginous fish, bony fish, and tetrapods).

Neuromeres Segments or transversal bands of the developing neural tube exhibiting specific properties, such as prosomeres in the forebrain (prosencephalon) or rhombomeres in the hindbrain (rhombencephalon).

Vertebrates As used here, a synonym of craniates, the clade that includes agnathans (hagfishes and lampreys) and gnathostomes; alternately defined by some as excluding hagfishes, reserving the term craniates for all agnathans and jawed vertebrates.

Introduction

Cartilaginous fishes (chondrichthyans) represent an ancient radiation of the gnathostome vertebrates characterized by having calcified cartilage but little or no bone internally, and rarely any in their scales. This group includes sharks, skates, and rays (Elasmobranchs), and chimaeras (Holocephali). Skates and rays show characteristic flat bodies and are grouped together as batoids. Most sharks have a streamlined body and are divided into two groups, squalomorphs (the most primitive group of living sharks) and galeomorphs (includes most of living sharks – advanced sharks), while sharks with flattened bodies are squatinomorphs or angel sharks. Chondrichthyans are currently considered the sister group of the Teleostomi, that is, the group of gnathostomes with a bony skeleton that gave rise to land vertebrates, including mammals. This position as an out-group to all other living jawed vertebrates makes chondrichthyans essential in assessing the ancestral vertebrate condition of brain organization. However, this does not mean they have a more primitive or unspecialized brain. On the contrary, they have well-developed, large brains whose size is comparable to those of birds and mammals with equivalent body weights, and they also have relatively larger brain sizes than the other major taxa of fishes, agnathans (**see also Brain and Nervous System**: Functional Morphology of the Brains of Agnathans) and ray-finned fishes (**see also Brain and Nervous System**: Functional Morphology of the Brains of Ray-Finned Fishes), as well as the sarcopterygian fishes (**see also Brain and Nervous System**: Functional Morphology of the Brains of Sarcopterygian Fishes: Lungfishes and Latimeria).

Differences are noted among chondrichthyans regarding the organization of mature/differentiated neuronal populations with respect to the periventricular matrix. Squatinomorph and squalomorph sharks, together with holocephala, have laminar (type I) brains, a pattern of brain organization characterized by the location of most of the neuronal cell bodies close to the region where they originate, the periventricular region (most neurons remain periventricular, i.e., close to the place along the ventricular surface where they proliferated), which implies the scarce migration of these neurons. In contrast, galeomorph sharks, skates, and rays (similar to those of teleosts and amniotes) show elaborated (type II) brains, that is, brains in which the neuronal cell bodies migrate away from the periventricular matrix during development and form more or less distinct cell groups.

During the early development of the elasmobranch brain, as in other vertebrates, two prominent external constrictions divide the brain into three main vesicles related to the basic structure of the adult brain, which represent the fundamental anteroposterior (i.e., rostrocaudal) vertebrate subdivisions: hindbrain (or rhombencephalon), midbrain (or mesencephalon), and forebrain (or prosencephalon) (**Figure 1**). These brain vesicles become subdivided into more or less evident transverse bands called neuromeres, which have fixed relations with structures of the head and the peripheral nervous system, being very useful as reference points in comparative studies. Simultaneously with the formation of transverse bands, four longitudinal zones with clear morphological and functional identity are seen along the brain axis. The hindbrain presents four longitudinal columns: ventral and ventrolateral columns (together forming the basal plate), and dorsolateral and dorsal columns (together forming the alar plate), which represent four functional longitudinal subzones: alar-plate-derived somato- and viscerosensory columns and basal-plate-derived viscero- and somatomotor columns, as prototypically present in the spinal cord. The ventral column does not extend rostrally beyond the midbrain, and the dorsal column is limited to the hindbrain. Bearing in mind the developmental patterns in longitudinal bands and transverse subunits, the anatomical structure of the adults may be classified not only according to the longitudinal bands but also in terms of their segmentary units. The hindbrain and midbrain tegmenti, the area of the nucleus of the medial longitudinal fascicle, the posterior tubercle, and the hypothalamus have been considered to be derived from the ventral and ventrolateral columns. In contrast, the cerebellum, optic tectum, pretectal area, thalamus (also called dorsal thalamus), prethalamus (or ventral thalamus), preoptic region, and telencephalon have been considered to derive from the dorsolateral and dorsal columns. The understanding of the segmentation of the brain has become essential for comparative neuroanatomical studies. Two flexures, the cervical between the spinal cord and hindbrain and the cephalic between midbrain and forebrain, result in an early bending of the anteroposterior axis and thus distort some anatomical relationships as development proceeds.

Hindbrain

The organization of the hindbrain is very similar in all elasmobranchs except for the existence of well-developed electric lobes in electric rays, most of them members of the genus *Torpedo* (**Figure 2**). These lobes contain electromotoneurons whose axons innervate the electric organs located in the head disk. These axons form electromotor nerves, which are special branches of the facial, glossopharyngeal, and vagal nerves (**see also Brain and Nervous System**: Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern). Neurons within a nucleus located in the hindbrain tegmentum that is called the 'oval nucleus' are responsible for the rhythmic discharge of the electric lobes and electric organ.

The caudal limit of the hindbrain is in a transition area corresponding to the obex (the point where the spinal canal ends and the hindbrain ventricle begins), but a clear landmark is not recognized. The rostral limit is the isthmus, the hindbrain region with the smallest ventricle which forms the boundary between hindbrain and midbrain. The roof of the ventricular cavity of the hindbrain (the fourth ventricle) is covered caudally by the choroid plexus, a thin membranous structure, and rostrally by the cerebellum. The ventral parts of the hindbrain derive from the basal plate and contain efferent ('motor') centers (**see also Brain and Nervous System**: Motor Control Systems of Fish and Physiology of the Mauthner Cell: Discovery and Properties), whereas the lateral walls of the ventricle are made up of the alar plate and contain afferent ('sensory') centers. A conspicuous ventricular groove called the sulcus limitans of His (a nineteenth-century embryologist and neuroanatomist) is currently considered the landmark between the basal and alar plates. Visceral and somatic areas are recognized both in alar and basal plates, which appear, to some extent, as longitudinal columns (somatomotor, visceromotor, viscerosensory, and somatosensory).

The basal plate contains a ventral (medial) area with somatomotor centers and an intermedioventral (lateral) area where visceromotor centers are located. In addition, during development, prominent ventricular bulges and sulci divide the hindbrain into transverse segmental units called rhombomeres. In adults, the rhombomeres are no longer visible, but the segmental disposition remains in some hindbrain centers as the motor nuclei and reticular formation. The ventral (medial) area (somatomotor) region contains the fasciculus longitudinalis medialis, a large fiber bundle which carries fibers that connect anterior and posterior regions of the brain. It is one of the earliest longitudinal pathways that appear during development. Caudally in the ventral (medial) area, the neurons of the spino-occipital nerves (i.e., the hypoglossal nerve homologs) form a continuous column with the motoneurons of the ventral horn of the spinal cord (spinal motor column). The motoneurons of the abducens nerve (somatomotor) occupy an intermediate medial location in the ventral (medial) area of the hindbrain (**see also Brain and Nervous System**: Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern).

Also related to somatomotor function is the reticular formation, a set of scattered cell populations that forms superior and inferior groups, each containing several subgroups located medially (raphe groups) and laterally (reticular groups). Large neurons of the reticular formation project to somatomotor centers in the spinal cord via the fasciculus longitudinalis medialis. The cholinergic nature of these large reticulospinal cells has been reported. Cells of the reticular formation also project to the cerebellum and tectum mesencephali and receive inputs from these regions as well as from the spinal cord and the telencephalon. The superior and inferior groups are organized in an apparent segmental pattern in relation to the segmental disposition of the hindbrain neuromeres (called rhombomeres). The reticular formation contains abundant serotoninergic cells and, to a lesser extent, enkephalinergic, catecholaminergic, and cholinergic cells. The serotoninergic cells arise close to the floor plate, and most populations migrate ventrally and mediolaterally to organize distinct medial (raphe) and laterally migrated (reticular) groups. The ventral (medial) area is also occupied by nuclei/centers not related to somatomotor function, such as the inferior olive, which projects to the cerebellum. At rostral levels, the ventral (medial) area continues with the medial parts of the isthmic, midbrain, and synencephalic tegmenti (basal plate). The intermedioventral area contains the visceromotor column formed by the motor nuclei of the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagal (X) nerves. While traditionally designated as 'visceral' in classification, it should be noted that the muscles of the head that are innervated by components of V, VII, IX, and X are in fact striated somatic muscles, derived from the same embryological source (the epimere component of the mesoderm) as the external eye and tongue muscles, which are correctly classified as somatic.

In the alar plate, two longitudinally arranged cell zones that form elongated intraventricular protrusions can be recognized, the area intermediodorsalis and the area dorsalis. The area intermediodorsalis (viscerosensory zone) is the center of termination for visceral afferent fibers which enter the brain by means of the nerves VII, IX, and X. This center of fiber termination forms a longitudinal protrusion of the lateral wall of the fourth ventricle called the viscerosensory column or vagal lobe. In cartilaginous fishes, there is no clear separation between nuclei specific for taste or general visceral sensibility, as in other fishes. Some of the primary viscerosensory fibers do not terminate in the lobe but course caudally forming the fasciculus solitarius. The general somatosensory nucleus of the trigeminal nerve is found in the superficial part of the intermediodorsal zone. The area intermediodorsalis contains centers which are not related to viscerosensory function, such as the nucleus octavomagnocellularis, a special somatosensory center that receives direct afferents fibers of the octaval nerve (for hearing and vestibular senses). This nucleus octavomagnocellularis contains efferent cells that project directly to somatic efferent centers in the spinal cord. These efferent cells of the octavolateral system are located near the fourth ventricle associated with the median fascicle of Stieda (a nineteenth-century German neuroanatomist).

The area dorsalis is entirely occupied by two large lateral line centers that are unique to chondrichthyans. They are cerebellar-like structures that form two longitudinal nuclear columns: the dorsal and medial octavolateral nuclei that receive primary afferents from the lateral line nerves and may be designated as a special somatosensory zone. The two longitudinal nuclear columns are covered by a thick layer called the cerebellar crest, because it resembles the molecular layer of the cerebellum. Actually, the cerebellar crest is continuous over the two longitudinal columns and extends rostrally toward the cerebellar auricles, which also are continuous with the molecular layer of the cerebellar body. Characteristically, the cerebellar crest contains large cells with spiny dendrites that are called Purkinje-like cells. These spiny dendrites are contacted by a large number of parallel fibers that originate in the granule cells of the auricles (see below).

The isthmic tegmentum contains the motoneurons of the somatomotor nucleus of the trochlear (IV) nerve, which innervate the extrinsic superior oblique muscle of the eye, and other centers not related to somatomotor function, such as the interpeduncular nucleus and the griseum centralis whose efferent connections are unknown.

Cerebellum

The cerebellum is an evolutionary innovation of gnathostomes that is unambiguously recognized in chondrichthyans. The cerebellum of these fishes contains the same kind of elements as the mammalian cerebellum and has similar interactions, being also involved in the modulation of motor control. It has four types of neurons (Purkinje cells, granule cells, Golgi cells, and stellate cells), and it exhibits the basic cerebellar circuitry typical of vertebrates. Its large cavity represents an expansion of the fourth ventricle. It is relatively larger than that of most teleosts and has been related to the need of coordination of more complex movements during swimming. The elasmobranch cerebellum is formed by a cerebellar body and the auricles (**Figure 3**). The cerebellar body is well developed and in squalomorphs is smooth, without fissures, but in batoids and galeomorphs it varies from slight to considerably convoluted, respectively (**Figure 1**). The

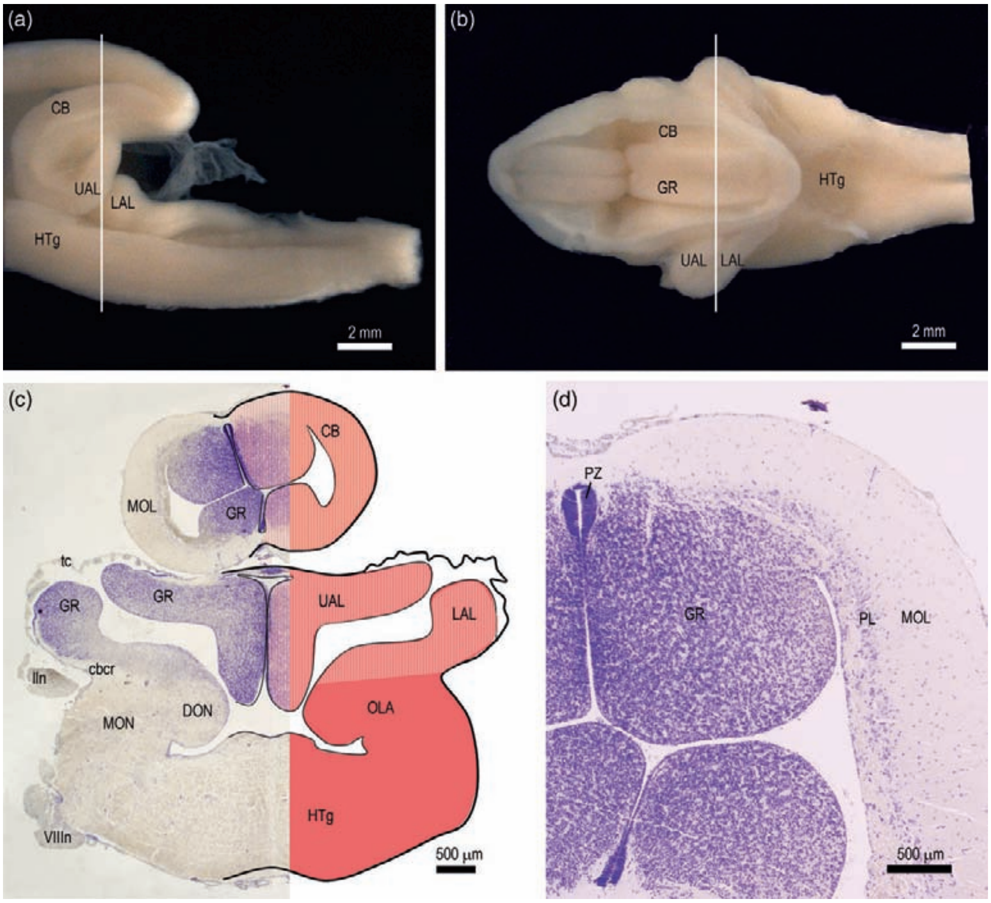

Figure 3 Hindbrain of the galeomorph shark *Scyliorhinus canicula* sectioned longitudinally (a), horizontally (b), and transversally (c) at the level indicated by the white line in (a) and (b); the dorsal part of the cerebellar body has been removed in (b). (d) Detail of the cerebellar body; (c) (left part) and (d) are hematoxilin–eosin stained sections. For abbreviations, see **Figure 2**.

auricles are paired and form large ear-shaped lobes closely related to the lateral line centers, which have a cerebellar-like organization. The basal part of the cerebellar body forms a distinct stalk, the peduncle, which joins rostrally with the tectum of the midbrain by the velum medullare anterius and caudally with the auricles. A cerebellar nucleus located within the cerebellar peduncle is considered the equivalent to the deep cerebellar nuclei of mammals.

The cerebellar body is a well-recognized cortical structure, because there is a clear cellular segregation that allows distinguishing the outer molecular layer, which contains stellate cells, the layer of Purkinje cells, and the deep layer that contains granule cells. In elasmobranchs, this granular layer forms two characteristic paramedian longitudinal ridges called the granular eminences, which protrude into the ventricle of the cerebellar body. During the cerebellar development, a granule cell layer is recognized at the lateral walls of the cerebellar body, as in other vertebrates, but in adults these cells are congregated in the paramedian eminences. Besides granule cells, there are other types of neurons in the granular eminences, such as the Golgi cells that are similar to those of mammals but simpler in their morphology. In the cerebellum of sharks, the proliferative activity remains active during the whole lifespan. This proliferative activity in adult sharks is located in a ventricular zone located medially within the longitudinal granular eminences.

The auricular lobes are covered by the tela choroidea of the fourth ventricle and are formed by upper and lower leaves. The lower leaf is contiguous caudally with the area octavolateralis, while the upper leaves unite medially to bridge the fourth ventricle. These regions differ in their internal organization and connections. The lower lip shows a typical cerebellar organization, with the granule cells concentrated in the paramedian eminences that are continuous with those of the cerebellar body and with the granule cells of the upper leaves. The lateral portion of the upper leaf is composed exclusively of granule cells and perhaps Golgi cells, and it is not covered by a molecular layer. Only a few Purkinje cells are found in the lower leaf, but in the lower lip they form a well-defined layer.

Midbrain

The alar plate of the midbrain is strongly developed and it consists of a pair of bilateral hemispherical lobes that enclose the midbrain ventricle (**Figures 4(a)–4(c)**), which is largely reduced in batoids. It is named optic tectum because it is the main center of termination for retinofugal fibers and the primary center for the perception of vision, but it also receives fibers from centers in the telencephalon (dorsal pallium), diencephalon (pretectum, thalamus, and prethalamus), hindbrain (octavolateral and vestibular areas), and spinal cord. There are tectal efferent pathways ascending to the pretectum and thalamus and descending to the reticular formation. The organization pattern of the elasmobranch retinal projections displays a high degree of complexity similar to that found in some actinopterygians and amniote vertebrates. It is thought that the evolution of the primary visual system in cartilaginous fishes has occurred due to architectonic modifications of the projection zones related to an increase of neuronal density rather than an increase in the number of projection zones. The tectum is organized in at least five layers or strata, distinguished by the different distribution of cells and fibers (**Figures 4(b)** and **4(c)**). The superficial layers are the

main recipients of visual inputs, whereas the deep tectal layers receive nonvisual information. Tectal neurons not only respond to light but also to mechanical and acoustic stimuli, as well as to electric currents. Retinotectal fibers and electrosense are spatiotopically organized. Ventral to the optic tectum, but also derived from the midbrain alar plate, are several nuclei that correspond to the torus semicircularis of other anamniotes; they receive ascending auditory and lateral-line inputs.

In the elasmobranch tectum, there is a band of the large primary sensory neurons that form the mesencephalic trigeminal nucleus. These cells form a strip in the periventricular region of the tectum. Ventral to the tectum is the midbrain tegmentum, which is continuous caudally with the hindbrain tegmentum. The midbrain tegmentum does not exhibit a clear zonal pattern, but there is a motor zone containing the neurons that innervate the extrinsic muscles of the eye, that is, the nucleus of the oculomotor (III) nerve (somatomotor). This motor nucleus is located in the medial part of the tegmentum. Also at a medial level, but located more dorsally, is the Edinger-Westphal nucleus, which is the rostral-most component of the visceromotor column; it is the origin of the cholinergic visceromotor fibers that course along nerve III to innervate the iris and ciliary body of the eye. In contrast to the situation in bony fish, two distinct cell populations have been recognized in the midbrain tegmentum of batoids and sharks, a dense medial group (ventral tegmental area) and a scarcer lateral one (substantia nigra), with neurons that contain the catecholaminergic neurotransmitter dopamine. These cell masses extend rostrally along the basal part of the caudal diencephalon (see below).

Forebrain

The forebrain is divided into diencephalon and a secondary prosencephalon that includes the hypothalamus, preoptic region, and telencephalon.

Diencephalon

Along the diencephalon, the limit between alar and basal territories is less conspicuous than in the midbrain and hindbrain, and some transverse boundaries are also recognizable. The exit of the oculomotor nerve sets the ventral limit between midbrain and forebrain. Dorsally, the midbrain is separated from the forebrain by a constriction at the level of posterior commissure. The cell masses of the diencephalon have a more diffuse arrangement and contain neurons of more uniform size than those of the brainstem. In the alar plate, the epithalamus (which comprises the habenula and the epiphysis or pineal organ), the thalamus (also called dorsal thalamus), and the prethalamus (or ventral thalamus) are distinguished. The most caudal segment of the diencephalon is called the synencephalon. Its dorsal/alar part is occupied by the pretectum, which encloses a retinorecipient center, the pretectal nucleus. It lies lateral to the posterior commissure.

The pineal organ is well developed in elasmobranchs, although it is lacking in some electric rays. It is a tubular structure that opens into the third ventricle between the habenular and posterior commissures. Its distal part remains under a dorsal window of the cartilaginous skull that covers the telencephalon. It consists of receptor cells, supporting cells, and ganglion cells. GABAergic intrinsic neurons and an extensive GABAergic innervation have been observed in the pineal of some elasmobranchs. The ganglion cells give rise to the pineal tract that courses to the thalamus, pretectal area, posterior tubercle, and midbrain tegmentum. The pineal organ also receives afferent fibers. Pineal neural circuits are involved in the photic control of brain functions. Similarly to retinal photoreceptors, the pineal receptor (sensory) cells have well-developed outer segments related to the photoreceptive capacity of the organ. These pineal photoreceptors are cholinergic, which appears to be a primitive feature of vertebrates. A parapineal organ similar to that observed in other fishes has not been observed in elasmobranchs.

The habenular nuclei are well developed in all chondrichthyans. There is a marked asymmetry as for their size, with the left habenular ganglion being larger than the right one. There are also considerable differences in the arrangement of the neurons and in their most important efferent connection, the fasciculus retroflexus, which terminates in the interpeduncular nucleus. The right and left bundles are asymmetrically developed, with the left bundle containing more myelinated fibers. The afferent pathway to the habenula is the stria medullaris, which carries fibers of telencephalic origin. In addition, afferent connections from tectal and tegmental midbrain regions have been reported.

According to the now widely accepted concept of segmentary subdivision of the caudal forebrain in transverse subunits or prosomeres, the thalamus and prethalamus represent transverse and not longitudinal elements along the anteroposterior brain axis. This means that the thalamus is caudal to the prethalamus and not dorsal. Both regions have a medial part with densely arranged cells, as well as a lateral part with larger scattered cells. The thalamus and prethalamus receive retinal inputs and ascending projections from the spinal cord, cerebellum, and tectum, and also project to the telencephalon. Thus, the thalamic and prethalamic regions represent relay centers for ascending sensory pathways to the telencephalon.

The basal part of the diencephalon is formed caudally by the tegmental part of the synencephalon, and rostrally by the posterior tubercle. The synencephalon contains the nucleus of the fasciculus longitudinalis medialis, which is related to the somatomotor coordinating apparatus. As in other fishes, many catecholaminergic cells occupy the posterior tubercle of elasmobranchs, but unlike cyclostomes and actinopterigyans, catecholaminergic cells also occupy the basal part of the caudal diencephalon and midbrain. It has been considered that this may represent the ancestral vertebrate condition even though these synencephalic/mesencephalic catecholaminergic cell groups are lacking in holocephala (the sister group of elasmobranchs).

Hypothalamus

The hypothalamus is a large forebrain region formed by the walls of the infundibular recess of the infundibulum, which is a ventrocaudal expansion of the third ventricle. Two main regions are distinguished: the medial or tuberal region, intimately related to the hypophysis (the pituitary gland), and the caudal area, which contains the broadest circumventricular organ of the elasmobranch brain. The tuberal hypothalamus contains the hypothalamic-hypophyseal tract along which the axons of classical neurosecretory system and other fibers of aminergic and peptidergic nature course. As in other fishes, the walls of the infundibular recess expand laterally to form the characteristic inferior hypothalamic lobes, related to the control of feeding behavior. In sharks, the walls of these lobes surround wide lateral expansions of the infundibular walls, but they are further reduced or even obliterated in batoids (**Figures 4(d)** and **4(e)**). The caudal hypothalamus is mostly occupied by functionally integrated structures that form two continuous circumventricular organs: the posterior recess organ, caudally, and its rostrolateral continuation, the paraventricular organ. The walls of both organs are characteristically folded and formed by a high density of cerebrospinal fluid (CSF)-contacting neurons of catecholaminergic, serotoninergic, and peptidergic nature (**Figures 4(f)** and **4(g)**). At the caudal hypothalamus is located the saccus vasculosus (SV), an enigmatic specialized circumventricular organ which is also observed in many bony fishes. It is a highly vascularized neuroepithelium formed by a specialized and exclusive cell type, the coronet cells (**Figure 5**). It also contains CSF-contacting neurons and supporting cells. Coronet cells are glial cells characterized by an apical crown of globule-tipped cilia protruding into the ventricle. They are considered responsible for the function(s) of the SV, which include pressure

Figure 5 *Saccus vasculosus*. reception, chemoreception, glucose loading, and ionic regulation of the CSF.

Preoptic Area

The preoptic area is the forebrain region that borders the preoptic recess, that is, a rostroventral expansion of the III ventricle. Morphologically and embryologically, it belongs to the telencephalon, but functionally it is part of the hypothalamus as it contains a neurosecretory nucleus, the magnocellular preoptic nucleus. The axons of this nucleus form a tract (the hypothalamus–hypophyseal tract) that courses along the hypothalamic floor to end in the neurointermediate lobe formed by the association of the hypothalamic neural lobe and the pars intermedia of the hypophysis. The magnocellular preoptic nucleus, the hypothalamus–hypophyseal tract, and the neurointermediate lobe form the classic neurosecretory system. Along its course, the neurosecretory tract shows large dilatations called Herring bodies. Extrahypophysial projections of the magnocellular preoptic nucleus have also been reported: some neurosecretory fibers ascend to the telencephalon while others descend to the spinal cord forming terminal fields in the midbrain tegmentum, isthmus, and the obex region. Besides the cells of the classical neurosecretory system, in the preoptic region there are also neurons containing neurotransmitters such as dopamine and serotonin and neuromodulators that are peptidergic in nature. Most of these cells are CSF-contacting neurons that form a circumventricular organ in the walls of the preoptic recess called the preoptic recess organ. Cells of this organ may regulate the adenohypophyseal functions as some of their axons terminate on portal capillaries that drain toward the adenophypophysis. This neurohemal structure is arranged in the region of the hypothalamic floor named the median eminence.

Telencephalon

The development of the telencephalon in elasmobranchs is very different from that in bony fishes (**see also Brain and Nervous System**: Functional Morphology of the Brains of Ray-Finned Fishes). In elasmobranchs, as in tetrapods, the telencephalon develops by evagination, a morphogenetic process which implies protrusion toward the outside and expansion of the lateral telencephalic walls. The telencephalon is subdivided into telencephalic hemispheres and olfactory bulbs. The telencephalic hemispheres are joined in the midline and share a common ventricle. Among elasmobranchs, the telencephalon differs in the shape and insertion of the olfactory bulb, in the length of olfactory peduncle, and in the extent of the ventricular cavities and hemispheric lobe fusion.

The telencephalic hemispheres are subdivided in a dorsal part, or pallium, and a ventral part, or subpallium, but the limit between both regions is not conspicuous (**Figure 6**). In the pallium, dorsal, medial, and lateral

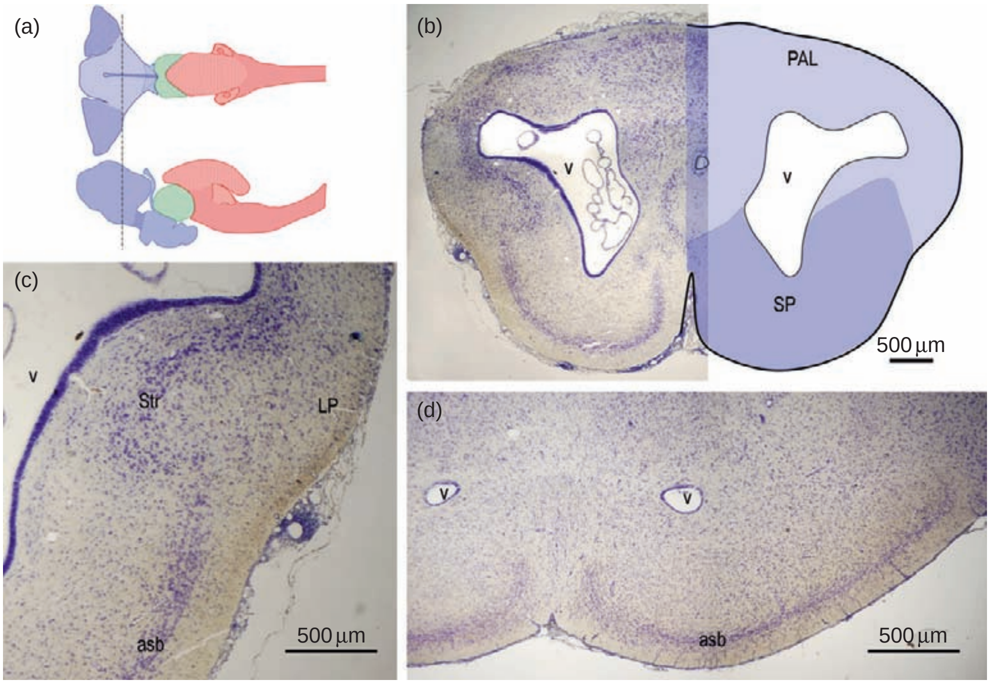

Figure 6 Panoramic view (b) and detail (c) of transverse sections through the telencephalon of *S. canicula* at the level indicated by the dashed line in (a). (d) Subpallium of *Raja undulata*. Note lower dispersion of the cell masses and higher extent of the ventricular cavity in shark (b, c) than in batoid (d). v, telencephalic ventricle. For other abbreviations, see **Figure 2**.

territories are distinguished. The dorsal pallium is a cortical structure that forms the roof of telencephalic hemispheres that presents a more or less stratified organization, with an external superficial part, a central part and an internal periventricular part. The medial pallium is considered the counterpart of the hippocampus of amniotes and it is recognized as the protrusion of the dorsomedial wall into the telencephalic ventricle. The lateral pallium, which receives the main olfactory input, lies dorsolateral to the area superficialis basalis. In batoids, these pallial subdivisions are hardly recognized because of the high dispersion of the cell masses (**Figure 6**). The subpallium is subdivided into a medial part that contains the septal nucleus, and a lateral part occupied by the area superficialis basalis, the striatum, and the area periventricularis ventrolateralis, structures that are related to the striatal and pallidal subdivisions of the basal ganglia of mammals. The area superficialis basalis is a region of densely packed neurons with a laminar organization that may be the equivalent to the pallidum of tetrapods. The striatum, located laterally, and the more medial area periventricularis ventrolateralis may represent the striatal subdivision, probably related to the striatum proper and the nucleus accumbens, respectively. These striatal subdivisions are not identified with certainty in batoids.

Olfactory bulbs are large, well-developed structures that enclose extensions of the lateral ventricles. Irrespective of their shape, four layers are distinguished: the layer of the primary olfactory fibers; the glomerular layer (formed by numerous glomeruli which contain arborizations of primary olfactory fibers), the layer of mitral cells, and the broad granular cell layer. Most of the neuronal elements found in the mammalian olfactory bulb are present in elasmobranchs, but, unlike in mammals, the mitral cells lack basal dendrites and the periglomerular cells are very scarce. In addition, the granular cells, as in lampreys, have axons that contribute to form secondary olfactory fibers together with those of the mitral cells. These structural distinctions imply differences in the circuitry and processing of the olfactory information with respect to mammals.

Classically, the elasmobranch telencephalon was considered simple in organization and exclusively involved in olfaction. This conception has been revised after the finding that the olfactory information reaches only to a restricted part of the telencephalon and that it also receives inputs from visual, auditory, mechanoreceptive, and electroreceptive centers.

Unlike the situation in bony fishes in which the lateral pallium projects directly to the dorsal and/or medial pallium, the lateral pallium of elasmobranchs projects to the subpallium (area superficialis basalis), and from there the information is sent to the dorsal pallium. The dorsomedial pallium of batoids, which receives a strong olfactory input, appears to be the most important relay center of information leaving the telencephalon. At least part of this projection reaches octavolateral centers, which means that olfactory information may reach centers with electrosensory and mechanosensory lateral-line information, perhaps used to detect prey in the substrate.

Glossary

Collothalamic Refers to the set of dorsal thalamic nuclei that receive their predominant input from the midbrain roof (optic tectum or torus semicircularis) and, in turn, project to the pallium and/or subpallium. In ray-finned fish, the collothalamus comprises two nuclei, nucleus centralis posterior and dorsalis posterior. Due to their afferent and efferent connections, the preglomerular nuclei also qualify for the designation of collothalamic.

Eversion Process by which the pallium develops in ray-finned fish, wherein the originally medial-most part of the pallium turns outward and thus comes to lie in the most lateral position topographically in the adult, and the originally lateral-most part of the pallium comes to occupy the medial-most aspect of the pallium in the adult. This is the reverse topography from that seen in most other fish and in land vertebrates.

Lemnothalamic Refers to the set of dorsal thalamic nuclei that receive their predominant input not from the midbrain roof but rather more directly from sensory system centers, such as the retina or, in land vertebrates, the dorsal column nuclei. This direct type of projection can be referred to as lemno-, derived from the word 'lemniscal', which means ribbon like. In ray-finned fish, only one dorsal thalamic nucleus, nucleus anterior, constitutes the lemnothalamus. The projections of nucleus anterior are not fully elucidated in ray-finned fish; in most vertebrate taxa, the lemnothalamus projects to the pallium.

Pallium The more dorsal part of the telencephalon. The projection neurons of the pallium are glutamatergic.

Preglomerular nuclear complex A set of nuclei that lie within the caudal part of the telencephalon and relay sensory information rostrally to the pallium. They resemble dorsal thalamic, sensory relay nuclei in this regard but are located in a more caudal position within the neuraxis. They are developmentally derived from a region called the posterior tuberculum.

Subpallium Ventral part of the telencephalon. The projection neurons of the subpallium are GABAergic.

Vertebrates As used here, the clade that includes agnathans and jawed vertebrates (gnathostomes), alternately defined by some as limited to lampreys and jawed vertebrates, excluding hagfish, with the term craniates used for agnathans and jawed vertebrates.

Introduction

Ray-finned fish (actinopterygians) comprise over 20 000 species. This group includes five major taxa (**Figure 1(a)**): reedfish (Cladistia), sturgeons and paddlefish (Chondrichthyes), gars (Ginglymodi), the bowfin *Amia calva* (Halecomorphi), and the huge radiation of bony fish (Teleostei). The ray-finned fish occupy an extreme diversity of niches (*sensu* George Gaylord Simpson for the entire way of life and relationship to the environment of a species) and exhibit similarly high degrees of diversity in their behavior and in the structure of their brains. Further, they are distinguished from most other vertebrate groups (the term vertebrate is used here to include agnathans and jawed vertebrates) by the way in which the most rostral part of the brain is formed during embryological development. Due to this divergent embryological development and their morphological diversity, ray-finned fish present a large and mostly untapped resource for studying the relationship of neural structure to function.

Hindbrain

As in other vertebrates, the hindbrain of ray-finned fish contains most of the motor and sensory cranial nerve nuclei and the reticular formation. Sometimes included in the latter are the serotoninergic nuclei of the raphe.

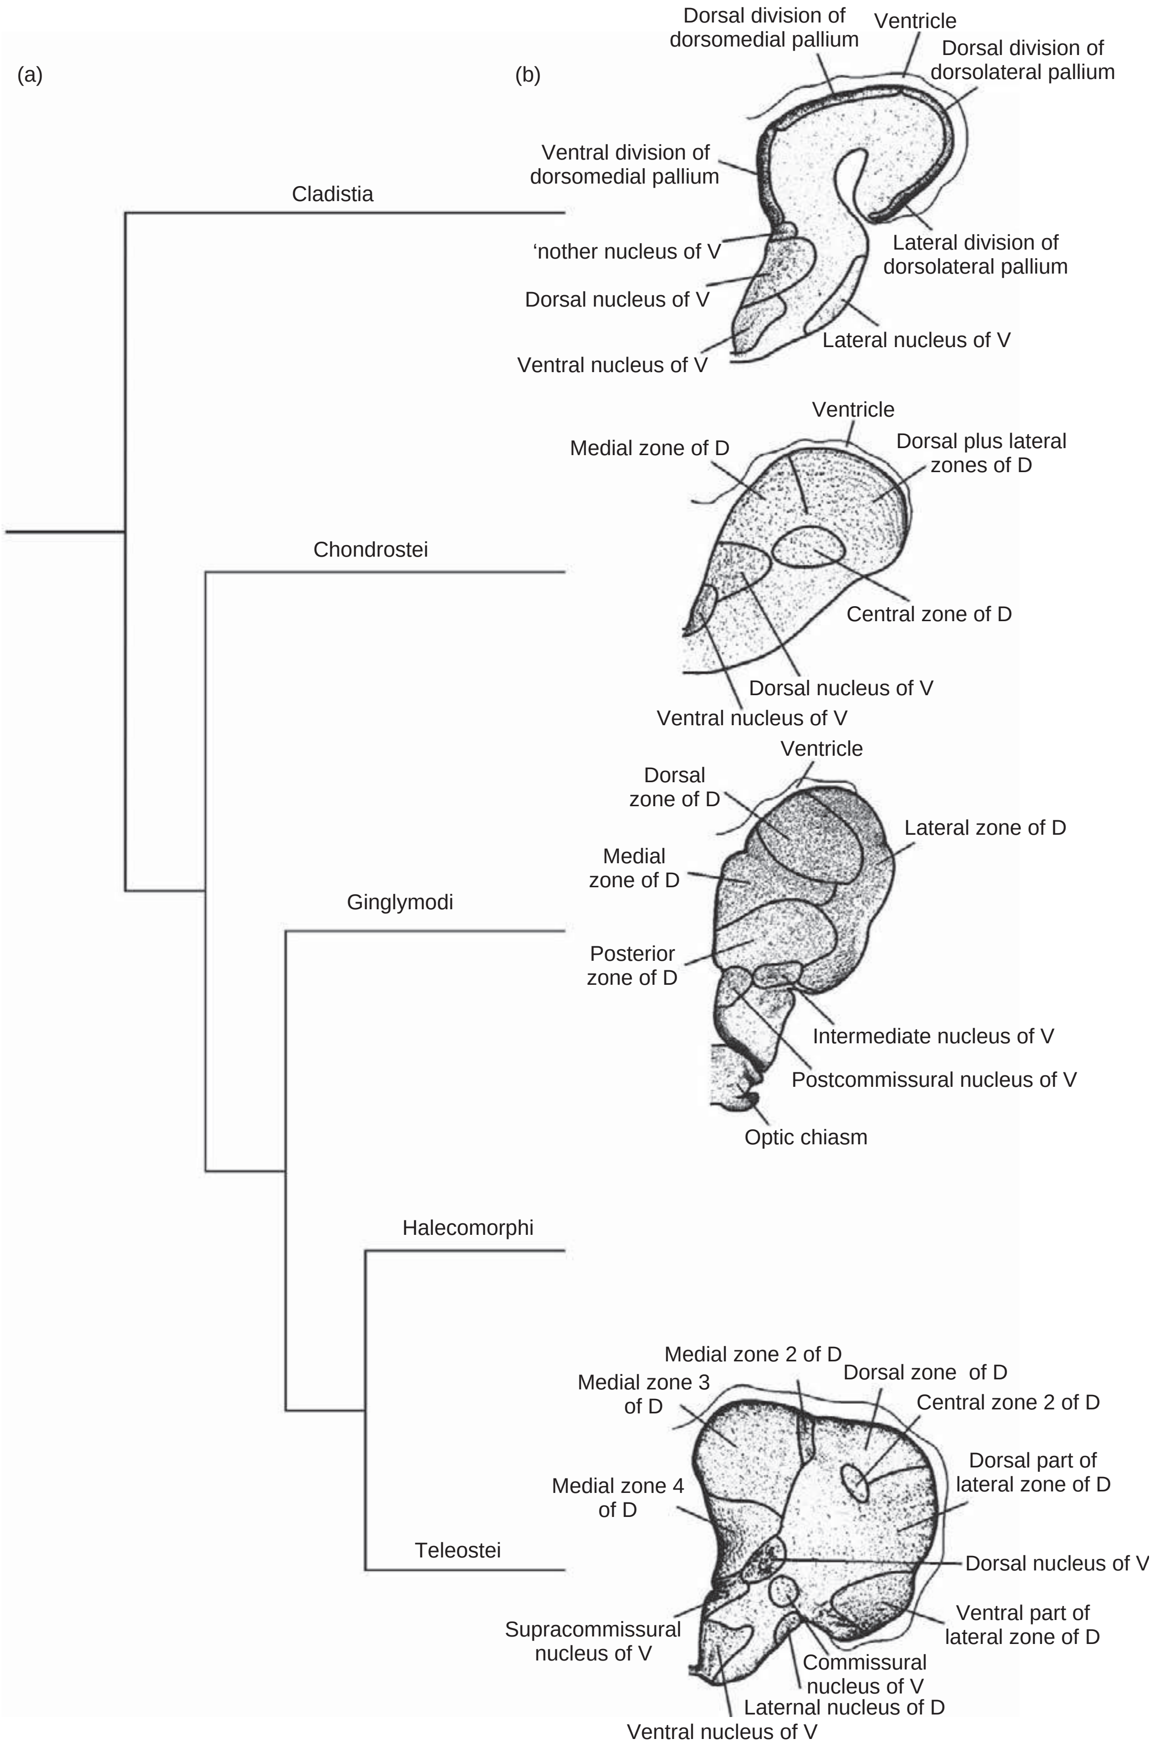

Figure 1 (Continued)

The hindbrain motor nuclei, which all are basal plate derivatives, include the abducens (VI) nucleus, which innervates some of the extraocular musculature, and the branchiomeric (gill arch) series for cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), and X (vagus); the latter can be seen in **Figure 2(g)**. In some ray-finned fish species, as in the other aquatic vertebrate groups and in land vertebrates, the abducens nucleus typically lies in a dorsomedial position. An unusual condition for the abducens nucleus has been documented in goldfish (*Carassius auratus*); however, its neuron cell bodies migrate to occupy a ventromedial position. The number of other ray-finned fish species in which this occurs has not been explored. The branchiomeric motor nuclei in ray-finned fish migrate somewhat ventrolaterally, as is also the case in the other vertebrate taxa. A second variation occurs with the mesencephalic nucleus of the trigeminal nerve (MesV) in tarpons, which are large fish with powerful jaws. In this species, MesV is exceptionally large, consisting of a very large population of neural crest-derived neurons that (as in other vertebrate taxa) migrate into the central nervous system and lie on the outer border of the periventricular (deep) layers of the optic tectum.

The alar-plate-derived sensory structures of the hindbrain include the octaval (VIIIth) cranial nerve for the auditory and vestibular senses (**Figure 2(f)**) as well as several examples of sensory specializations in ray-finned fish. Teleosts that are electroreceptive include notopterids (featherbacks and knifefish) and mormyrids (freshwater elephantfish), both of which are osteoglossomorph teleosts, and siluriforms (catfish) and gymnotids (electric eel and electric knifefish) (**see also Detection and Generation of Electric Signals**: Generation of Electric Signals and Detection and Generation of Electric Signals in Fishes: An Introduction). These teleosts have an electrosensory lateral line lobe that is highly laminated and cytoarchitectonically complex, with up to 15 cell and fiber layers, which differentially receive afferent information and give rise to efferent projections. Likewise, the gustatory system, which is most elaborately developed in catfish and in the nonelectroreceptive cyprinids, such as goldfish, has afferents that terminate in three laminated lobes, the facial, glossopharyngeal, and vagal lobes, rather than in a simple gustatory nucleus as in most vertebrates, including mammals (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction and Neurophysiology of Gustation). Both the electrosensory lateral line lobe and the gustatory lobes are cortical in their cytoarchitecture, indicating that highly complex processing of the sensory information is being carried out within them. There are also ascending pathways that relay this information to the pallium, as is the usual case for sensory systems. In teleosts, most of this information is relayed through part of the diencephalon to the medially lying part of the pallium, an area referred to as Dm (as discussed below).

The cerebellum is also an alar plate derivative and shows considerable variation in the extent to which it is developed across the different groups of ray-finned fish. As is the case in cartilaginous fish, ray-finned fish have a corpus cerebelli (**Figure 2(f)**) with an outer molecular layer, granule cells, and Purkinje cells and a related structure, the cerebellar crest. The corpus cerebelli receives inputs from the electrosensory system in those species with that sense as well as mechanosensory lateral line and octaval (auditory/vestibular) inputs and descending inputs relayed from the telencephalon (**see also Hearing and Lateral Line**: Auditory/Lateral Line CNS: Anatomy). The outputs of the cerebellum are via Purkinje cells, as in other vertebrate taxa, but rather than projecting to deep cerebellar nuclei, the Purkinje cells project to eurydendroid cells that lie within the cerebellar cortex. The eurydendroid cells project to a wide range of targets, such as the reticular formation, red nucleus, and various diencephalic nuclei. An additional cerebellar structure unique to teleosts is the valvula cerebelli, which is an extended part of the corpus cerebelli. In the electroreceptive mormyrids, the valvula is hypertrophied to the extent that it covers the entire dorsal surface of the brain, covering not only the corpus cerebelli but also the tectal roof and the pallial hemispheres.

Mormyrids and other fish that use electrosensory communication also have descending pathways through the brainstem that are involved in the generation of the electric signals (**see also Detection and Generation of Electric Signals**: Generation of Electric Signals). In

Figure 1 (a) Cladogram of ray-finned fish showing the phylogenetic relationships of Teleostei (bony fish), Halecomorphi (the bowfin *Amia*), Ginglymodi (gars), Chondrostei (sturgeons and paddlefish), and Cladistia (reedfish). (b) Nissl-stained photomicrographs of transverse hemisections through the right telencephalon of a cladistian, the bichir *Polypterus senegalus* (top), the sturgeon *Scaphirhynchus platorynchus* (second from top), the gar *Lepisosteus osseus* (third from top), and the sunfish *Lepomis cyanellus* (bottom). The Nissl stain stains the cell bodies of neurons but not their myelinated processes. Thus, each tiny black dot in the photomicrographs represents a neuron cell body. In instances where the cell bodies are very densely packed along the ventricular surface, the staining creates the appearance of a thick black line, as seen in *Polypterus*. Due to the eversion process during embryological development (discussed in the text), the ventricular space overlies the dorsal surface of the pallial areas. D, area dorsalis (= pallium); V, area ventralis (= subpallium). The author thanks R. Glenn Northcutt for generously providing the original photomicrographs shown in this figure and in **Figure 2**.

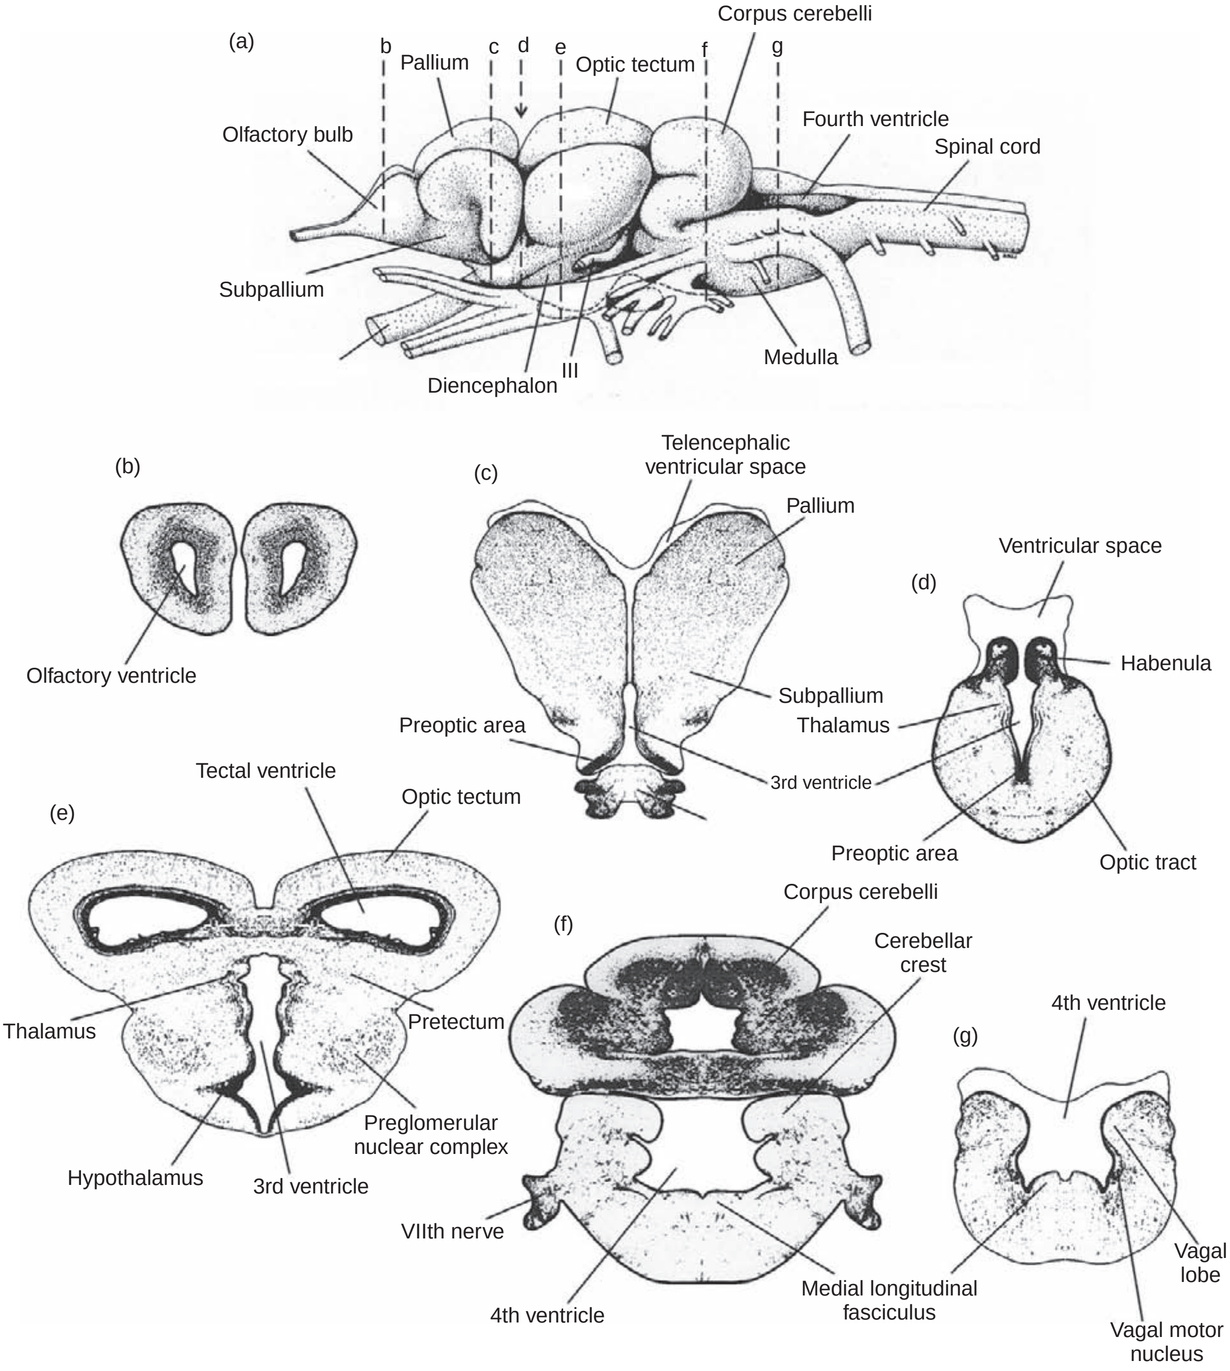

Figure 2 (a) Drawing of a side view of the brain of a gar (*Lepisosteus osseus*), with rostral toward the left. The levels of Nissl-stained sections below are indicated by dashed lines and labeled with corresponding letters (b–g). As seen in (a), the forebrain consists of the diencephalon, to which the optic nerve projects, and the telencephalon; the latter consists of olfactory bulbs rostrally and hemispheres that contain the pallium dorsally and the subpallium ventrally. The midbrain consists of the optic tectum, which also receives optic nerve projections, and the tegmentum (the latter is not visible from the side view). The oculomotor nerve (III), which originates in the midbrain can be seen exiting the brainstem just ventral to the optic tectum. The hindbrain consists of the cerebellum dorsally and the medulla ventrally, which is continuous caudally with the spinal cord. The transverse hemisections are through the olfactory bulbs (b); the telencephalic hemispheres (c), with the ventricular space, equivalent to the lateral ventricles of other vertebrates, between and dorsal to them and the optic chiasm (the crossing, or decussation, of the optic nerves) lying in the ventral midline at this level; the rostral part of the diencephalon (d), with its ventricular space, equivalent to the third ventricle of other vertebrates, between and dorsal to it; the midbrain (e) with the optic tectum dorsally and the caudal parts of the diencephalon present at this level ventrally; the rostral part of the hindbrain (f) with the corpus cerebelli and cerebellar crests dorsal to the fourth ventricle; and the caudal part of the medulla (g).

gymnotids, a prepacemaker nucleus in the diencephalon projects to a pacemaker nucleus in the hindbrain, which in turn relays its outputs to electromotor neurons in the spinal cord that control discharges from the animal's electric organ. A similar pathway in mormyrids involves projections from a pre-command nucleus in the midbrain to a command nucleus and the medullary electromotor relay nucleus in the hindbrain and thence to the spinal cord electromotor relay nucleus, which controls the electric organ discharges.

Midbrain

The hindbrain transitions into the midbrain proper through a region called the isthmus. Rostral to the isthmus is the midbrain tegmentum located ventrally with the tectum, the alar-plate roof structures, dorsal to it. The isthmus and tegmentum contain a number of ascending and descending tracts, like the hindbrain, and also a number of nuclei specific to them. An interpeduncular nucleus is present in the ventromedial aspect of the isthmal midbrain; it is named for its position between the cerebral peduncles of the midbrain in mammals, structures that are absent or less well developed (depending on how one defines them) in fish. It receives projections from the habenula (**Figure 2(d)**), as discussed below. The nuclei of the reticular formation and raphe extend into the midbrain, which also houses the norepinephrine-containing neurons of the locus coeruleus and the motor nuclei for cranial nerves IV (trochlear) and III (oculomotor). These two oculomotor nuclei are interconnected with each other and with the abducens nucleus and vestibular nuclei of the hindbrain via a long tract called the medial longitudinal fasciculus (**Figures 2(f)** and **2(g)**). The oculomotor nuclear complex of III includes somatic motor neurons that innervate the extraocular muscles and also the visceral motor neurons of the Edinger–Westphal nucleus that supply parasympathetic innervation to eye structures. The oculomotor system displays a rather unique specialization related to the electromotor system in the stargazer *Astroscopus* that has an electric organ formed from modified extraocular muscles innervated by a pool of the oculomotor nucleus neurons.

The tectal structures that form the midbrain roof include the optic tectum (**Figure 2(e)**) (the superior colliculus of mammals), which is dominated by visual input but which also receives multisensory (auditory and somatosensory) inputs in its deeper layers, and the torus semicircularis (the inferior colliculus of mammals), which is dominated by auditory inputs and, in some cases, electrosensory inputs. The optic tectum projects rostrally to a nucleus in the dorsal thalamus (**Figures 2(d)** and **2(e)**), the dorsal posterior nucleus, while the torus semicircularis similarly projects to the central posterior nucleus. Of these two structures, the optic tectum has the most elaborate cytoarchitecture, consisting of cortical layers that group into three zones: superficial, central, and periventricular. The visual input is confined to the superficial layers and the somatosensory and auditory inputs are confined to the two deeper zones; the latter also give rise to efferent tectal projections, which, in addition to the ascending input to the dorsal thalamus, also include descending pathways to the reticular formation and other brainstem sites. The optic tectum has a structure unique to ray-finned fish at its medial-most aspect, the torus longitudinalis, with which it is reciprocally connected and which may be interconnected with the cerebellum. It also has reciprocal, topographical connections with a prominent nucleus in the isthmal region, nucleus isthmi, which contains cholinergic neurons. This nucleus interconnects the optic tectum with the pretectum, a caudal part of the diencephalon involved in the control of eye movements. For a more detailed treatment of the optic tectum, the torus longitudinalis, and nucleus isthmi **see also Vision**: Optic Tectum.

Forebrain

The forebrain comprises the diencephalon and the telencephalon. The diencephalon contains the epithalamus, dorsal and ventral thalamic nuclei, hypothalamus, pretectum, and a set of laterally migrated nuclei known as the preglomerular nuclear complex. The telencephalon consists of the pallium in its dorsal part, which mainly receives and integrates sensory information, and the subpallium ventrally, which is involved in motor control and related functions. Except for the hypothalamus, all of the forebrain is derived from the alar plate.

Diencephalon

The pretectum (**Figure 2(e)**) is a caudal part of the diencephalon. It contains multiple nuclei, many of which receive retinal projections. However, unlike the dorsal thalamus (**Figures 2(d)** and **2(e)**) and the preglomerular nucleus (**Figure 2(e)**, discussed below), pretectal nuclei do not project rostrally to telencephalic sites. Instead, they are interconnected with the optic tectum and are involved in multiple functions, including the control of eye movements. There is considerable variation across ray-finned fish in the extent to which the pretectal region is developed. In most ray-finned fish, the nuclei lie in superficial, central, and periventricular zones that are continuous with the same zones of the optic tectum, and several nuclei, including a rather prominent nucleus, the superficial small-celled (parvocellular) pretectal nucleus (PSp), receive direct retinal input. In non-euteleost teleosts, PSp projects to a nucleus of variable size, the posterior pretectal nucleus (PO), which in turn projects to the inferior lobe of the hypothalamus. The latter is involved in feeding behavior. In euteleosts, PO is replaced by two nuclei, which may represent a separation of the neurons that comprise PO, the intermediate superficial nucleus (PSi) and a large, cytoarchitectonically complex nucleus called nucleus glomerulosus (NG). In this case, PSp receives the retinal input but projects to PSi, which in turn projects to NG, and NG then projects to the inferior lobe of the hypothalamus. This circuitry is an example of an increase of complexity in both the number of relay nuclei and their internal cytoarchitecture in a particular system across the phylogenetic spectrum.

The epithalamus generally comprises the pineal gland (and/or other dorsal diencephalic structure) and the habenula. A single dorsal structure, the pineal gland, is present in most ray-finned fish and has rather widespread projections, including to the habenula and to sites within the dorsal and ventral thalamus, pretectum, hypothalamus, and tegmentum. Trout additionally have a parapineal organ, which projects to the habenula. The habenula itself (**Figure 2(d)**) is asymmetrical in size (not apparent in the figure), as in other vertebrates. In addition to pineal (and parapineal) afferent connections, it receives inputs from a subpallial part of the telencephalon, called Vd (the dorsal nucleus of area ventralis) that appears to be homologous to the striatum of other vertebrates. The main efferent projection of the habenula is via the fasciculus retroflexus tract, which is universally present across vertebrates. This tract is alternatively known as the habenulointerpeduncular tract, defining its target as the interpeduncular nucleus, which lies in the medial aspect of the isthmal region of the midbrain tegmentum. In mammals, the interpeduncular nucleus has at least some serotoninergic neuronal components and is known to project to the hippocampus; it may in fact be a rostral component of the raphe system. Its projections in ray-finned fish have not yet been determined, however.

An additional nucleus, nucleus rostrolateralis, which appears to be a component of the epithalamus – possibly a sort of supernumerary habenula – is present in some fish but only in a phylogenetic distribution that is very sporadic, appearing here and there across the phylogeny, being absent or undetectable in many species in between. It receives retinal and tectal afferent projections, is apparently high in its metabolic activity (as evinced by high cytochrome oxidase staining), and may be involved in circuitry for feeding behaviors. Its far-flung phylogenetic distribution but multiple points of similarity may be due to its being produced by the same genetic pathway, inherited from a deep common ancestor, which is only occasionally expressed in the phenotype.

The thalamus and preglomerular nuclear complex are involved in sensory relay pathways to the telencephalic pallium (**Figures 2(a)** and **2(c)**). In tetrapods, the dorsal thalamic nuclei are the only relay sites for ascending sensory pathways, but in ray-finned fish, multiple diencephalic components provide such relay sites. Several ventral thalamic nuclei are present in ray-finned fish and most of them receive retinal as well as other inputs. Unlike the situation in most other vertebrates, at least one of the ventral thalamic nuclei has been reported to project to the telencephalon. They contain inhibitory γ-aminobutyric acid (GABA)ergic neurons as in other vertebrates, but their other connections and their functions have not been studied. The major relay sites involve components of the preglomerular nuclear complex and two of the three dorsal thalamic nuclei (dorsalis posterior and centralis posterior) that receive their inputs predominantly from the midbrain roof and project to the telencephalic pallium, particularly targeting its medial zone (the medial zone of area dorsalis, Dm, see **Figure 1(b)**, bottom). In its circuitry, the preglomerular nuclear complex resembles the dorsal thalamic nuclei of tetrapods and may be a serial (iterative) homolog of these nuclei, that is, a similar structure occurring at a more caudal segmental level. These preglomerular and dorsal thalamic ascending pathways carry visual and multimodal information from the optic tectum and auditory information from the torus semicircularis. Due to the receipt of major projections from the midbrain roof, these groups can be classified as collothalamic ('collo' referring to the mammalian term for the midbrain roof, the 'colliculi'). The preglomerular nuclear complex (**Figure 2(e)**) relays ascending lateral line and gustatory information and appears to be present in cartilaginous fish also. The connections of the remaining dorsal thalamic nucleus, nucleus anterior, which lies at a more rostral level, are less well understood. This nucleus does not receive major midbrain roof projections, instead receiving visual input directly from the retina in a lemniscal (or straight, ribbon-like) fashion, thus classifying this nucleus as the lemnothalamic part of the dorsal thalamus. In cladistians, it does not project directly to the pallium but rather to another diencephalic nucleus (nucleus medianus of the posterior tuberculum), which in turn projects to the dorsal and lateral parts of the pallium. Nucleus anterior has been reported but not confirmed to project to part of the lateral pallium in goldfish. The afferent projections to the lateral pallium also have been difficult to identify, although its dorsal part is metabolically active for visual system inputs in goldfish.

The hypothalamus (**Figure 2(e)**) and its rostral extension, the preoptic area (**Figure 2(d)**), contain a number of distinct nuclear groups. In the preoptic region are anterior and posterior parvocellular (small-celled) nuclei, a magnocellular (large-celled) nucleus, and the suprachiasmatic nucleus. Caudal to these nuclei lies the hypothalamus proper and consists of dorsal and ventral portions that border the third ventricle as well as some more laterally lying nuclei. Most ray-finned fish have an enlarged part of the hypothalamus that lies ventrally and is known as the inferior lobe. The inferior lobe receives descending projections from the telencephalon and from brainstem gustatory nuclei. As noted above, it also receives projections from the pretectal region – the posterior pretectal nucleus in most non-euteleosts and nucleus glomerulosus in teleosts – and has been functionally implicated in feeding behaviors and some other actions, such as circling and chasing, which may be invoked for establishing territorial boundaries. The preoptic area and hypothalamus also give rise to major descending pathways, which, as in other vertebrates, affect the parasympathetic (general visceral motor) centers of the brainstem, as well as to reticular formation sites that relay information to spinal cord sympathetic centers. It should also be noted that the retinal part of the eyes is derived from the central nervous system; the eye stalk that divides to form them during embryological development buds off from the most rostral part of the neural tube in the preoptic region of the hypothalamus.

The hypothalamus and preoptic area also play major roles in endocrine regulation. Various preoptic and hypothalamic nuclei project to the pars nervosa and/or pars intermedia of pituitary gland and regulate the production and/or release of multiple hormones, including melanocyte-stimulating hormone, which controls skin pigmentation and consequently plays a crucial role in vertical banding displays, arginine vasotocin, which functions as a diuretic and to regulate blood pressure, and isotocin, which also contributes to blood pressure regulation and additionally plays a role in the release of eggs or live birth (**see also The Pituitary**: Development of the Hypothalamus-Pituitary-Interrenal Axis). The adenohypophysis also receives hypothalamic innervation and is involved in the release of other hormones, including prolactin, corticotropin, gonadotropin, growth hormone, and thyrotropin. Overall, the hypothalamus is crucial for many different behaviors that range from endocrine control to courtship (nest building and courting rituals), reproductive behaviors (sperm and egg release), feeding behaviors (especially the inferior lobe as noted above), sound production in some species, and the control of respiration and heart rate.

Telencephalon

As in other vertebrates, the telencephalon consists of olfactory bulbs (**Figures 2**(**a**) and **2**(**b**)) and the telencephalic hemispheres, which can be divided into two regions, a ventrally lying subpallium and, dorsal to it, the pallium (**Figures 2**(**a**) and **2**(**c**)). One major distinguishing characteristic of these two regions across all vertebrates is the difference in the neurotransmitter of their projection neurons: pallial projection neurons are glutamatergic, whereas those of the subpallium are GABAergic.

The subpallium contains septal and striatopallidal components. In contrast to other major vertebrate taxa, the striatopallidal component lies in a relatively medial position and both striatal and pallidal cell populations intermingle within a single nucleus, the dorsal nucleus of V (the ventral zone of the telencephalon), as shown in the bichir (Cladistian), sturgeon (Chondrostei), and sunfish (Teleostei) in **Figure 1**. The ventral nucleus of V (shown in the bichir, sturgeon, and sunfish in **Figure 1**) receives gustatory information and may be homologous to part of the septum or other medial subpallial regions of other vertebrates, while a more laterally situated nucleus, the lateral nucleus of V (shown in the bichir and sunfish in **Figure 1**), which contains cholinergic neurons, may be homologous to the medial septal nucleus or the basal nucleus of Meynert.

The pallium in ray-finned fish undergoes a different developmental process than the pallium in most other vertebrates; however, this results in a reversal of the medial-to-lateral topography of its component parts. In most vertebrates – including agnathans, cartilaginous fish, amphibians, and amniotes – pallial development follows a process of evagination in which the two hemispheres expand outwardly, rather like puffing out one's cheeks. In contrast, in ray-finned fish, the process is one of eversion. This process is diagrammed in **Figure 3**. After the initial formation of the neural tube, shown at the left, the dorsal part of the tube thins to form a thin ependymal roof of non-neural, epithelial tissue. The two dorsal parts of the neural tube then turn outward, that is, laterally, and expand in that direction as the ependymal roof extends over them. This process results in having the originally medial part of the neural tube attain the lateral-most position in the adult and vice versa.

Further development of the pallial region varies to a marked degree across the different major clades of ray-finned fish. As also shown in **Figure 3**, the degree to which the eversion process proceeds varies. The outline of the telencephalon of a basal cladistian, in this case the bichir *Polypterus senegalus* (compare with the section shown in **Figure 1**(**b**), top) is shown at the upper right of the figure. In this clade, eversion continues until the origin of the ependymal roof is at approximately 5:00 on the right side. Eversion is less extensive in sturgeons, as in *Scaphirhynchus platorynchus* shown at the lower right (compare to the section shown in **Figure 1**(**b**), second from top), however, reaching to about 3:00 on that side. As can be seen in **Figure 1**(**b**) (third from top), eversion in gars, *Lepisosteus osseus*, is strikingly less than in either cladistians or sturgeons, reaching only to about 1:00 on the right side. Again, in contrast, in some teleosts, such as the sunfish *Lepomis cyanellus*, also shown in **Figure 1**(**b**) (bottom), eversion is more extensive. Thus, the degree of eversion does not fall

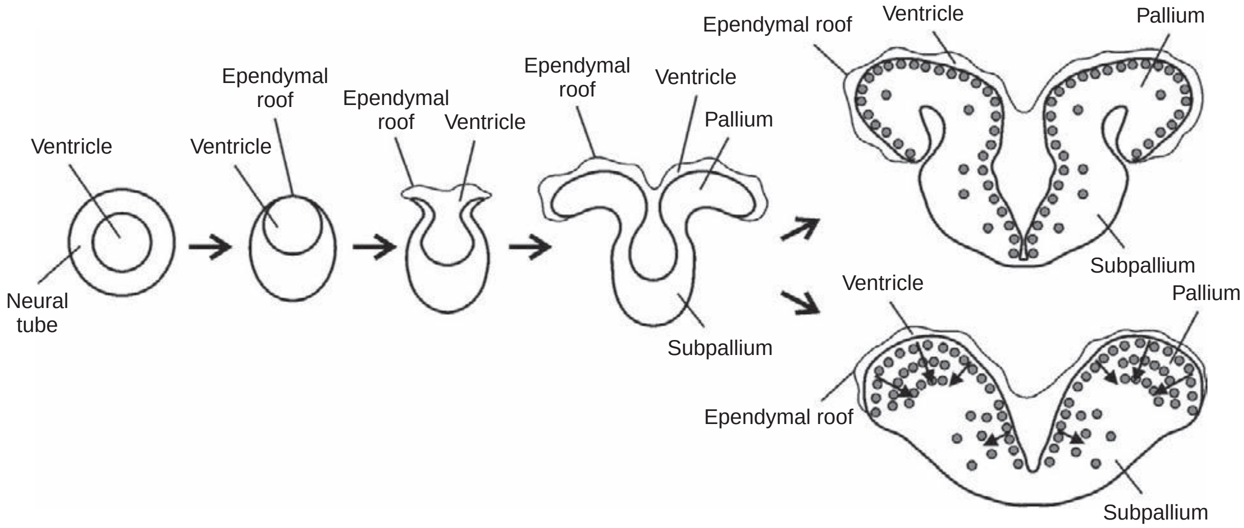

Figure 3 Diagrammatic representation of the eversion process that occurs in telencephalic development in ray-finned fish. As the diagrams show from left to right, the roof of the original round neural tube thins to form a non-neural, ependymal roof, and the upper ends of the neural tube turn outward. Thus, the ventricular space extends between the ependymal roof and the dorsal surface of the pallium. In some ray-finned fish, such as cladistians (*Polypterus senegalus*), shown at the upper right (to compare with its Nissl section in **Figure 1**(**b**), top), there is very little migration of the neuron cell bodies (indicated by large gray dots) away from the proliferative zone along the ventricular surface. In others, there is more proliferation and migration, as shown to a moderate degree here at the lower right in the sturgeon *Scaphirhynchus platorynchus* (to compare with its Nissl section in **Figure 1**(**b**), second from top). In other fish, such as the gar and sunfish shown in **Figure 1**(**b**) (third from top and bottom, respectively), there is much more extensive proliferation and migration. Also, note that the degree of the eversion process, indicated by the lateral point of attachment of the ependyma, varies, being most extensive in some teleosts, such as *Lepomis* (but not in others, such as *Salmo*, not shown), cladistians, and in the halecomorph *Amia* (not shown) and much less in ginglymodi and chondrosteans.

onto a morphocline (a graded series) from basal to crown taxa but rather varies independently across the major clades.

Because the zone of cell proliferation is along the ventricular surface, as is also the case in other vertebrate groups, variation in the degree of eversion results in differing patterns of migration of the newly formed neuronal cell bodies. The extent to which the proliferation and migration processes continue is yet another variable both across and within the different clades. As shown in **Figure 1**(**b**) (and diagrammatically in **Figure 3**), most neuron cell bodies remain very near the ventricular surface in cladistians and show only some migration in wave-like lines in sturgeons but are in much greater abundance and substantially migrated in teleosts, with gars and the bowfin *Amia* having intermediate conditions. These patterns form a continuum of variation, allowing one to somewhat arbitrarily divide the taxa by their type I, or laminar, brains, as in nonteleosts, and the teleost condition of type II, or elaborated brains. (Gars and *Amia* have been classified as type I, but an argument for type II could also be made.) As a result of all these factors – the eversion process itself, the variation in the degree of eversion, and marked variation in the degree of cell proliferation and migration – the identification of comparable pallial areas across ray-finned fish and in comparison to other vertebrate groups is extremely challenging, and consensus on this issue is still far from being achieved. The differential pallial evolution in ray-finned fish in fact presents a natural laboratory of immense opportunity that has only begun to be exploited.

Far from being simple ‘smell brains’, as erroneously thought for decades, some of the true functional capabilities of the actinopterygian pallium have been recently discovered, and the generally larger brain–body ratios of cartilaginous fish imply that such capabilities apply to them as well. In both cartilaginous and ray-finned fish, the olfactory projections have been shown to be limited to a circumscribed region of the pallium, and multiple other ascending sensory inputs to other pallial regions have been traced. Despite the difficulties in identifying pallial areas, some hypotheses have been formulated that are reasonably supported by existing data. In ray-finned fish, the medial zone of D (area dorsalis, which is the pallium) (see **Figure 1**(**b**), bottom), originally lateral in topographical position and which is in receipt of caudal dorsal thalamic and preglomerular projections, has been identified as homologous to the mammalian lateral amygdala, which lies within the lateral-most part of the mammalian pallium and also is in receipt of collothalamic projections relayed from the superior colliculus through the dorsal thalamus. The ventral part of the lateral zone of D (see

Figure 1(b), bottom), originally medial topographically, has been proposed as a homolog of the amniote hippocampus, which can be identified in both mammals and reptiles (including birds) with certainty. Interestingly, while not a criterion for homology, the functional role of this part of the ray-finned fish pallium is intriguingly like the amniote hippocampus in terms of memory and spatial mapping abilities, while the functional role of the medial zone is amygdala-like for fear-conditioning, as discovered by Cosme Salas and his co-workers in goldfish (**see also Sensory Systems, Perception, and Learning**: Fish Learning and Memory). Thus, remarkably, the basic functions of different pallial regions appear to be preserved to some extent despite marked differences in embryological development and also drastic differences in the cytoarchitecture (the lack of specific cell types and their lamination as opposed to the amniote condition). Study of the neuron cellular capacities that underlie these functions in fish has the potential to provide insightful advances in understanding the functions of the comparable regions of mammalian brains.

A recent study in Russ Fernald's laboratory has opened the door to intriguing new questions about the cognitive abilities of fish (**see also Sensory Systems, Perception, and Learning**: Fish Learning and Memory). Male cichlids (*Astatotilapia burtoni*), which have relatively elaborate brains among their euteleost peers, can deduce their individual position in the social hierarchy by serial observation of the behavior of other pairs of males. Such an inductive process has been thought to require working memory – an indication of high-level consciousness subserved by the prefrontal cortex in mammals and previously thought to be unique to them. However, it has now been demonstrated convincingly in birds, and this recent study now also suggests that it may be present in at least some fish. The extreme degree of variation across the brains of extant ray-finned fish, including the high degree of pallial elaboration in some euteleosts and the recent observations of surprising behavioral similarities, at least in general terms, to amniotes, requires reevaluation of fish brain structure and functional capacities.

Glossary

Area octavolateralis This is the area where the VIII cranial nerve and the lateral line nerves terminate in the dorsal alar plate of the rhombencephalon.

Forebrain The forebrain (or prosencephalon) is the rostral-most portion of the brain in vertebrates. During development it separates into the diencephalon and the secondary prosencephalon, which includes the hypothalamus, the preoptic area, and the telencephalon.

Hindbrain The hindbrain is the caudal-most portion of the brain. It includes the large rhombencephalon, which early in development gives rise to the cerebellum rostrally.

Hodological Adjective referring to pathways (axonal connections) in the central nervous system, derived from *hodos*, the Greek word for road or way.

Midbrain The midbrain (or mesencephalon) forms a roof, which consists of an optic tectum and a torus semicircularis, and a floor, which forms the midbrain tegmentum.

Sarcopterygians The Sarcopterygii, or lobe-finned fishes + terrestrial vertebrates, are characterized by having an axial skeleton connecting the pectoral and pelvic regions. Tetrapods comprise the largest living group of sarcopterygians, but two extant groups of fishes are most commonly referred to as the sarcopterygians: the Actinistia or coelacanths (*Latimeria*) and the Dipnoi or lungfishes (*Lepidosiren*, *Neoceratodus*, and *Protopterus*).

Introduction

The lobe-finned fishes (Sarcopterygii) are currently represented by six species of lungfishes (Dipnoi) and two species of coelacanths (Actinistia). The lobe-finned fishes diverged from the ray-finned fishes about 450 million years ago (mya) and were highly successful during the Devonian, when hundreds of species lived in the oceans and rivers of most continents. By the end of the Devonian, 360 mya, the first tetrapods had diverged from the Rhipidistia, an extinct family of lobe-finned fishes, and colonized land. The diversity of all lobe-finned fishes began to decline after the mass extinction in the Permian (290–245 mya). Most recent paleontological analyses support a Dipnoi + Rhipidistia sister group relationship, although Actinistia + Rhipidistia or Dipnoi + Actinistia sister group relationships have also been proposed. Based on molecular data, rather than phenotypic data, however, lungfishes, and not the coelacanths, appear to be the closest living relatives of tetrapods.

Nowadays, lungfishes live in the rivers of Africa (four species of the genus *Protopterus*), South America (*Lepidosiren paradoxa*), and Australia (*Neoceratodus forsteri*). For many years they were considered the only extant lobe-finned fishes until 1938, when a surviving member of the coelacanths, *Latimeria chalumnae*, was caught off the Comoro archipelago near the eastern coast of Africa in the Indian Ocean. A second species, *Latimeria menadoensis*, was discovered in 1999 in Indonesia.

Because they appear to be the closest living relatives to the ancestors of all tetrapods, information on the anatomy and physiology of lobe-finned fishes is critical to any explanation of the origin of land vertebrates. However, the availability of these animals for experimental research has been limited. *Latimeria*, especially, is extremely rare and critically endangered; its population is estimated to consist of fewer than 400 animals alive today. Lungfishes are somewhat more plentiful but are not always easily obtained. In the following sections, we describe the organization of the brain in lungfishes and

Latimeria, based on the information available. For lungfishes, the data from normal histology and experimental hodological techniques have been supplemented with data from immunohistochemistry for the localization of neurotransmitters, neurotransmitter-related molecules, or neuroregulators. For *Latimeria*, the description is necessarily based only on normal histological material.

Macroscopical Anatomy of the Brain in Lungfishes and *Latimeria*

The gross morphology of the brain of a lungfish (*Protopterus*) and the brain of *Latimeria* is shown in **Figure 1**. In both cases the brain is elongated and possesses only small flexures, compared to those seen in most bony fishes. Generally speaking, the brain in lungfishes is similar to that in urodele amphibians. The brain of *Latimeria* is similar to that of lungfishes but is smaller in relation to body size. It occupies only 1% (approximately) of the total cranial volume, being confined to the most caudal division of the skull. As in other vertebrates, lungfishes and *Latimeria* both have three major brain parts, corresponding to the three encephalic vesicles formed during development: the hindbrain, the midbrain, and the forebrain, from caudal to rostral. The hindbrain, with the rhombencephalon and cerebellum, is similar to the hindbrain in other vertebrates, and it shows paired cranial nerves organized in a pattern similar to that seen in most groups of vertebrates. In both lungfishes and *Latimeria*, there are up to six pairs of lateral line nerves. In lungfishes the cerebellum is less well developed than in other fishes, and it has laterally located auriculae that are relatively larger than the medial corpus cerebelli. In *Latimeria* the cerebellum is larger than that in lungfishes. It comprises two extremely large auriculae and an unpaired, evaginated corpus cerebelli. The midbrain develops from the mesencephalic vesicle. In lungfish, it is represented by a small, slender portion of the brain, which caps the rostral rhombencephalon and cerebellum caudally and shows a poorly developed bilateral optic tectum. This region appears better developed in *Latimeria.* The forebrain comprises the diencephalon, hypothalamus, and telencephalon. The diencephalon is small and tubular in both groups of fishes and shows prominent bulges corresponding to the dorsal thalamus. A well-developed tela choroidea forms a particularly large dorsal sac in lungfishes. The hypothalamus shows macroscopical differences among the lungfishes and between them and *Latimeria. Protopterus* and *Lepidosiren* have a caudally directed, long infundibular hypothalamus, whereas this structure is almost vertically oriented in *Neoceratodus.* In contrast, the whole hypothalamus of *Latimeria* bends rostrally. The telencephalon comprises caudal, intermediate, and rostral subdivisions. The caudal portion is a small region known as the telencephalon impar, from which the intermediate telencephalic hemispheres emerge. These are large and evaginated in lungfishes, with a floor (subpallium) that is remarkably bigger than the dorsal (pallial) regions, which in some cases (*Neoceratodus*) are partially reduced to an ependymal tela. In *Latimeria*, the subpallium is thin walled and clearly evaginated, whereas the pallium is a thickened, solid body that is partially covered by a membranous roof, which constitutes an ependymal septum in the median plane. The rostral telencephalic region is formed by the secondarily evaginated olfactory bulbs, which, in lungfishes, can be sessile on the rostral tip of the hemispheres, as in *Protopterus*, or separated for a short distance and connected by hollow peduncles, as in *Neoceratodus.* In *Latimeria*, the olfactory bulbs are directly apposed to the nasal cavity, and very long peduncles connect them to a particular pair of swellings (the rostral bodies) at the rostral tip of the hemispheres.

Histological Features of the Brain in Lungfishes

Hindbrain

As in most brain regions, the cell populations of the hindbrain retain an essentially periventricular arrangement (**Figure 2**), and particular neuronal groups can be distinguished only by experimental techniques, such as tract tracing or immunohistochemistry (**Figure 3**). The wide rhombencephalon shows a largely horizontal basal plate and a vertically oriented alar plate around the fourth ventricle, which is mostly covered by a

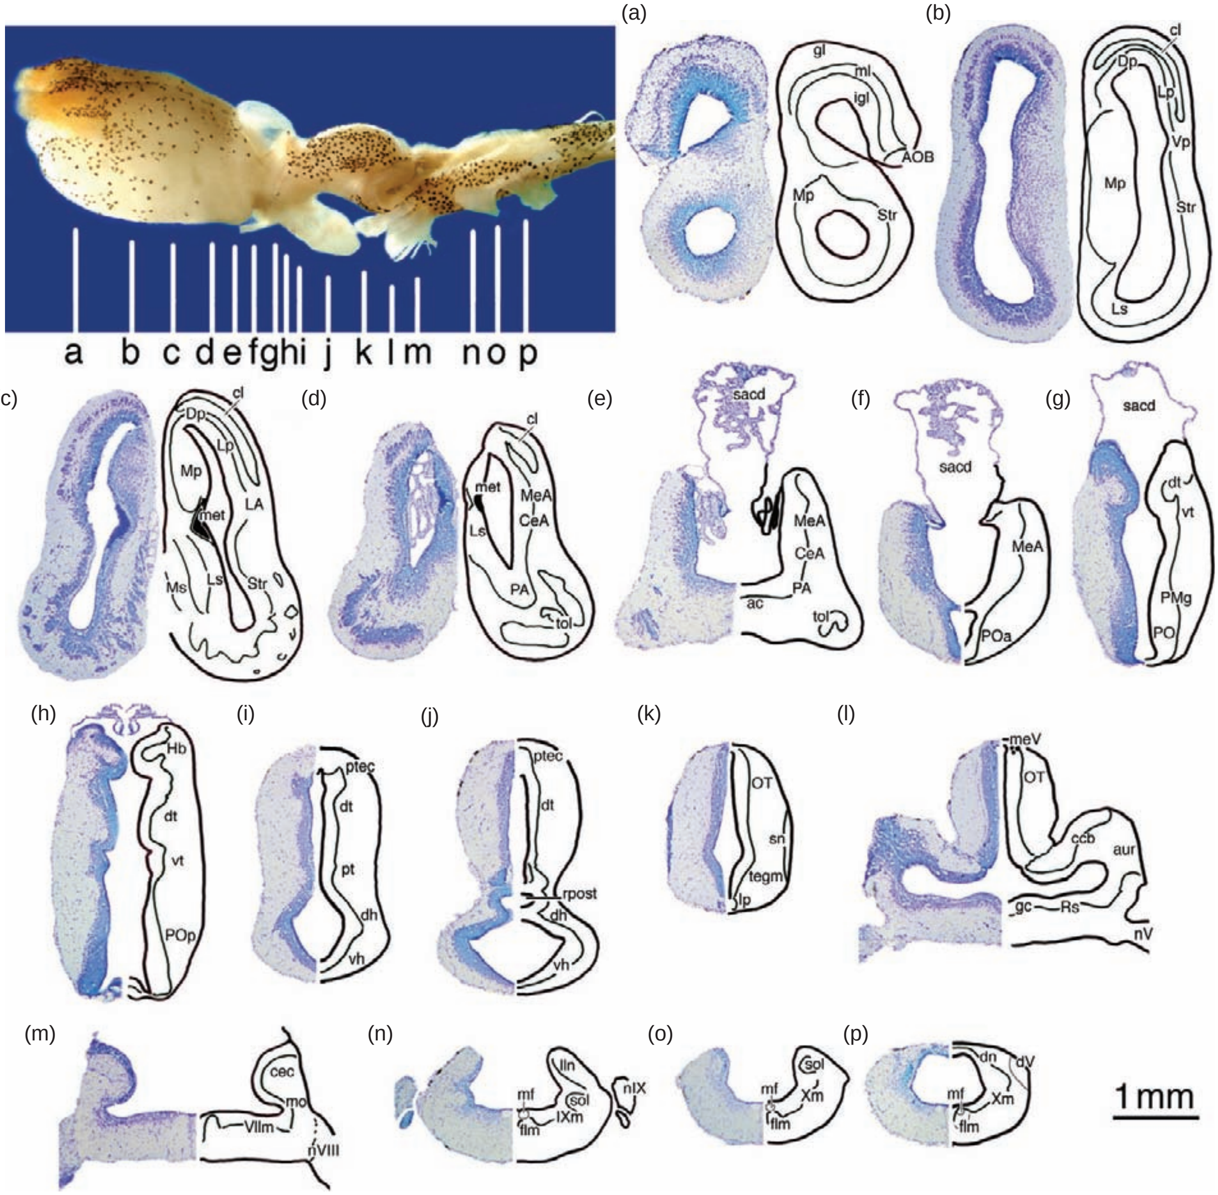

Figure 2 Photomicrographs of transverse hemisections through the brain of *Protopterus dolloi,* stained with cresyl violet, showing the cytoarchitecture (left) and corresponding line drawings indicating the primary structures (right) at the rostrocaudal levels (a–p) indicated on the photograph of the brain in lateral view. Abbreviations: ac, anterior commissure; AOB, accessory olfactory bulb; aur, auricula cerebelli; ccb, corpus cerebelli; CeA, central amygdala; cec, cerebellar crest; cl, cortical layer; dh, dorsal hypothalamus; dn, dorsal column nucleus; Dp, dorsal pallium; dt, dorsal thalamus; dV, descending trigeminal tract; flm, fasciculus longitudinalis medialis; gc, central gray; gl, glomerular layer; Hb, habenula; igl, internal granular layer; Ip, interpeduncular nucleus; IXm, glossopharyngeal motor nucleus; LA, lateral amygdala; lln, lateral line nucleus; Lp, lateral pallium; Ls, lateral septum; MeA, medial amygdala; met, medial ependymal thickening; mf, Mauthner cell fiber; ml, mitral cell layer; mo, median octavolateral nucleus; Mp, medial pallium; Ms, medial septum; nIX, glossopharyngeal nerve; nV, trigeminal nerve; nVIII, octaval nerve; OT, optic tectum; PA, pallidum; PMg, magnocellular preoptic nucleus; PO, preoptic area; POa, anterior preoptic area; Pop, posterior preoptic area; pt, posterior tubercle; ptec, pretectum; rpost, posterior recess; Rs, nucleus reticularis superior; sacd, saccus dorsalis; sn, superficial nucleus; sol, solitary tract; Str, striatum; tegm, tegmentum; tol, tuberculum olfactorium; vh, ventral hypothalamus; VIIm, facial motor nucleus; Vp, ventral pallium; vt, ventral thalamus; Xm, vagal motor nucleus.

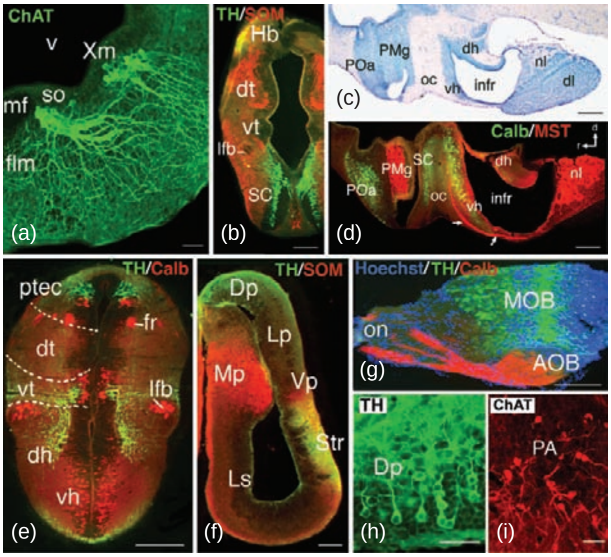

Figure 3 Photomicrographs of sections reacted for immunohistochemistry at different levels of a lungfish brain (*Protopterus dolloi*). (a) Transverse section through the caudal rhombencephalon showing motor nuclei revealed with choline acetyltransferase. (b) Transverse section through the diencephalon and hypothalamus showing distinct structures revealed with somatostatin and tyrosine hydroxylase. (c, d) Adjacent sagittal sections through the hypothalamus and the preoptic area showing the cytoarchitecture revealed by cresyl violet staining (c) and the specific distribution of calbindin and mesotocin (arrows point to the hypophyseal tract). (e) Transverse section through the diencephalon and hypothalamus showing distinct tyrosine hydroxylase and calbindin positive structures. (f) Transverse section through the telencephalic hemisphere showing distinct somatostatin and tyrosine hydroxylase positive structures. (g) Sagittal section through the olfactory bulbs showing structures positive for tyrosine hydroxylase, and the unique calbindin labeling of the putative accessory olfactory bulbs. (h) Cells positive for tyrosine hydroxylase in the dorsal pallium. (i) Cells immunoreactive to choline acetyltransferase in the region of the pallidum. Scale $=100\,\mu$m (a, g), $400\,\mu$m (b–f), $50\,\mu$m (h, i). Abbreviations: AOB, accessory olfactory bulb; dh, dorsal hypothalamus; dl, distal lobe of the hypophysis; Dp, dorsal pallium; dt, dorsal thalamus; flm, fasciculus longitudinalis medialis; fr, fasciculus retroflexus; Hb, habenula; infr, infundibular recess; lfb, lateral forebrain bundle; Lp, lateral pallium; Ls, lateral septum; mf, Mauthner cell fiber; MOB, main olfactory bulb; Mp, medial pallium; nl, neural lobe of the hypophysis; oc, optic chiasm; on, olfactory nerve; PA, pallidum; PMg, magnocellular preoptic nucleus; POa, anterior preoptic area; ptec, pretectum; SC, suprachiasmatic nucleus; so, spino-occipital nucleus; Str, striatum; v, ventricle; vh, ventral hypothalamus; Vp, ventral pallium; vt, ventral thalamus; Xm, vagal motor nucleus.

tela choroidea except for the rostral portion, which is occupied by the cerebellum. Three main longitudinal sulci divide the hindbrain into four longitudinal zones that are imposed over the transversal segments (rhombomeres) formed during development. Traditionally, each column has been considered to serve a specific function, but in many cases cell groups of different functions may occupy positions within a single longitudinal column. We will comment on functional grouping under subdivisions of the motor and sensory modalities.

The rhombencephalon includes most of the motor cell groups that directly innervate the muscles of the head (and upper part of the trunk). The major component of this system is formed by what are classically viewed as the special visceral motor nuclei of the trigeminal (cranial nerve V), facial (VII), glossopharyngeal (IX), and vagal (or vagus X) nerves, which innervate the jaw muscles and muscles of the branchial (gill) arches. However, because this set of muscles has been demonstrated to arise from paraxial mesoderm, the hindbrain motor centers that innervate them are better considered special motor centers. They constitute a column in the lateral half of the rhombencephalic basal plate (**Figures 2**(**m**)–**2**(**p**)), in which the trigeminal motor nucleus is the most rostrally located and separated from the rest of the column by a small gap. Choline acetyltransferase immunohistochemistry reveals that the morphology of these motor cells is characterized by profuse dendritic arborizations (**Figure 3**(**a**)). Close to the rostral motor neurons of the facial nerve, a pair of large Mauthner cells (**see also Brain and Nervous System**: Motor Control Systems of Fish and Physiology of the Mauthner Cell: Discovery and Properties) is located in the reticular formation, adjacent to the entry of the octaval nerve into the rhombencephalon.

Located medially in the basal plate, slightly caudal to the facial nerve root, are the somatic motor neurons that innervate the external rectus eye muscle and constitute a small abducent (or abducens, cranial nerve VI) motor nucleus. In a position that is similar but in the caudal portion of the rhombencephalon are the somatic motoneurons whose axons form two pairs of spino-occipital nerves (**Figure 3**(**a**)) that innervate the hypobranchial muscles of the head.

A third motor modality identified in the rhombencephalon of vertebrates is represented by general visceral motor nuclei of the parasympathetic nervous system. These neurons are generally associated with the facial, glossopharyngeal, and vagal motoneurons, but in lungfishes they are difficult to identify. It is likely, however, that the small cholinergic cells revealed by immunohistochemistry at the lateral aspect of the motor column may represent these neurons.

Peripheral information regarding pain, temperature, and touch reaches the rhombencephalon and contacts somatic sensory centers. This kind of sensory information ascends through the dorsal funiculus of the spinal cord and contacts cells of an incipient dorsal column nucleus located close to the obex (**Figure 2**(**p**)). Sensory fibers of the trigeminal nerve carry similar information from the skin and deeper tissues of the head and reach sensory cells in the rhombencephalon. In lungfishes, as in most vertebrates, fibers carrying touch information would terminate in the principal sensory nucleus, located dorsolateral to the trigeminal motor nucleus. The fibers carrying pain and temperature information would enter the rhombencephalon in the trigeminal nerve and form a long descending tract in the lateral margin of the alar plate. Throughout its course, fibers from the tract would contact scattered cells that, as a group, represent the descending trigeminal nucleus. A third constituent of the trigeminal sensory system is formed by proprioceptive information from the extrinsic eye muscles and jaw muscles conveyed by primary fibers of the mesencephalic trigeminal nucleus that enter the hindbrain in the trigeminal nerve and course toward the mesencephalic tectum, where the large ganglionic somata that constitute the mesencephalic trigeminal nucleus are distributed dorsally along the tectum (**Figure 2**(**l**)).

Visceral sensory information is carried by facial, glossopharyngeal, and vagal fibers, which reach the rhombencephalic alar plate and form a descending tract known as the solitary tract (**Figures 2**(**n**) and **2**(**o**)). In relation to this tract, the nucleus of the solitary tract is formed by a column of cells that extends from the level of the facial nerve root to the obex. At the level of the vagal roots, the solitary tract and nucleus are more conspicuous and form a bulge into the ventricle termed the vagal lobe. Part of the information carried by this tract is gustatory, coming from taste buds that are located in the oropharynx and also externally on the skin of the head.

Most of the dorsal portion of the rhombencephalic alar plate is devoted to octavolateral sensory information. Lungfishes possess a complex inner ear, which is innervated by the octaval cranial nerve (VIII). They also have a series of mechanoreceptive neuromasts and electroreceptive ampullary organs that are innervated by up to six pairs of lateral line nerves. The octaval fibers enter the rhombencephalon together with the facial motor root and terminate in the ventral zone of the octavolateral area. As in most fishes, lungfishes have four nuclei: anterior nucleus, magnocellular nucleus, descending nucleus, and posterior nucleus. Only the magnocellular nucleus is easily recognized, as the other three are less distinct. The lateral line fibers enter the hindbrain in the dorsal portion of the alar plate. The dorsal roots of the anterodorsal and anteroventral lateral line nerves carry electroreceptive information, enter the dorsal portion of the octavolateral area, and form a dense neuropil, lateral to the dorsal nucleus. The ventral roots of the anterodorsal and anteroventral lateral line nerves, and the roots of the posterior lateral line nerve, carry mechanoreceptive information from neuromasts, enter the intermediate region of the alar plate, and end on cells of the medial (or intermediate) nucleus. This nucleus forms a cell column that extends throughout most of the rhombencephalon, and its caudal pole is dorsal to the solitary tract. The caudal part of the medial nucleus receives fibers of the posterior lateral line root, which enters just rostral to the glossopharyngeal root. The rostral two-thirds of the dorsal alar plate contains a typical crista cerebellaris, formed by a fiber layer similar to the molecular layer of the cerebellum, with which it is directly continuous rostrally (**Figures 2**(**l**) and **2**(**m**)).

Cerebellum

In lungfishes, the cerebellum is relatively simple compared to that in other groups of fishes, and it resembles the cerebellum in amphibians more. It comprises a pair of large auriculae that possess upper and lower leaves, the latter in continuation with the octavolateral area. These auriculae contain numerous granule cells and are particularly small in *Neoceratodus*. They are medially joined over the rostral rhombencephalon by the transverse plate of the corpus cerebelli. This region is clearly layered into molecular and granular layers, but the Purkinje cells are irregularly distributed and do not form a continuous layer. The rostroventral part of the cerebellum protrudes into the IV ventricle, forming an eminentia that has been regarded as the cerebellar nucleus, although its connections are unknown. Notably, the corpus cerebelli is particularly small in *Protopterus* and *Lepidosiren,* resembling that in urodele amphibians, and is covered by the midbrain tectum.

Isthmus

As in many vertebrates, the boundary between the hindbrain and midbrain in lungfishes is oblique, and the region between the two is generally known as the isthmic region. Actually, this region constitutes the rostral part of the rhombencephalon, and it contains a series of nuclei with different functions. Immunohistochemistry has revealed a noradrenergic locus coeruleus and cholinergic laterotegmental and isthmic nuclei (with their connections to the optic tectum and the forebrain) in lungfishes, as in amphibians. The ventral tegmentum of the isthmus possesses the rostral part of the serotoninergic raphe column, which continues throughout the rhombencephalon. A small trochlear (IV) motor nucleus, which innervates the superior oblique eye muscle, is also located ventrally in the isthmus. In the midline, just ventral to the trochlear nucleus, there is an interpeduncular nucleus (**Figure 2**(**k**)), which receives information from the habenula via the fasciculus retroflexus. A peculiar cell group found laterally in the isthmus, just in a subpial position, is termed the superficial isthmic nucleus (**Figure 2**(**k**)). Its nature and function are unknown. At least part of it was proposed to be a homolog to the isthmic nucleus of other vertebrates, but its lack of cholinergic cells does not support this contention.

Midbrain

This region of the brain in lungfishes is tubular in shape, and the walls are thick around a vertically oriented ventricle (**Figures 2**(**k**) and **2**(**l**)). The dorsal part, or tectum, is similar to that in urodele amphibians, as it constitutes only a periventricular cell layer and a superficial fiber zone. Recent experimental research, however, has shown that in spite of its simple cytoarchitecture, the tectum in lungfishes has the same heterogeneous cells as in other vertebrates. Tectal neurons containing serotonin, different calcium binding proteins, or nitric oxide synthase all have been demonstrated. In addition, fibers of retinal origin are organized in the superficial zone, whereas other tectal afferents and the efferent axons of tectal neurons are organized in the deeper fiber zones. As noted above, the conspicuous cells of the mesencephalic trigeminal nucleus occupy a long narrow strip on the dorsal portion of the tectum. A small and poorly differentiated torus semicircularis is located beneath the optic tectum and is better developed in *Neoceratodus*. Most likely, it receives mechanosensory information from the octaval and lateral line systems, as in other groups of fishes. Within the midbrain tegmentum, there is a rostral portion of the superficial isthmic cell group, and, medially, the oculomotor (III) nucleus. The latter is difficult to distinguish in normal material but has been demonstrated with experimental techniques. It should be noted that lungfishes, as do chondrichthyans, possess a large dopaminergic cell group in the midbrain tegmentum that is readily comparable to the substantia nigra-ventral tegmental cell groups in amniotes.

Forebrain

As noted above, the diencephalon comprises the caudal portion of the forebrain. Embryologically, this region is constituted by three caudorostral segments, or prosomeres, whose alar plates give rise to the pretectal area, dorsal thalamus (or thalamus), and ventral thalamus (or prethalamus), and whose basal plates form different tegmental regions that are generally smaller than the alar regions. All regions are poorly differentiated cytoarchitectonically, showing only a continuous internal zone of periventricular gray and an external zone of fibers and neuropils (**Figures 2**(**g**)–**2**(**i**)). Immunohistochemical data have highlighted a distinct diencephalic organization, however. In the first (i.e., most caudal) diencephalic segment (also called the synencephalon), several cell groups in the pretectal region have been revealed with specific markers (**Figure 3**(**e**)). As in tetrapods, these cell groups are termed according to their relationship with the posterior commissure: subcommissural, juxtacommissural, and postcommissural. They receive direct retinal information, and are better developed in *Neoceratodus* than in the other lungfishes, as is the rest of the visual system. The tegmental part of this segment houses the large neurons of nucleus fasciculus longitudinalis medialis, whose axons descend to the spinal cord.

The second diencephalic segment (posterior parencephalon) contains the large thalamus, which protrudes into the third ventricle. No subnuclei can be distinguished, although immunohistochemical reactions for different neuropeptides have demonstrated the heterogeneity of this region (**Figure 3**(**b**)). Dorsally in this segment is the large habenula, which contains abundant cholinergic cells in its dorsal part, which give rise to the habenular–interpeduncular tract. Ventrally in this segment, the posterior tubercle shows abundant dopaminergic cells. The third segment of the diencephalon (anterior parencephalon) is narrow and contains distinct cell populations within a poorly differentiated ventral thalamus (or prethalamus) in the alar plate (**Figure 3**(**e**)). The ventral portion of this segment is caudally continuous with the hypothalamic mammillary region and is called the retromammillary zone; in *Protopterus*, this zone shows a unique recess of the III ventricle, also called the posterior recess (**Figure 2**(**j**)).

Hypothalamus and preoptic area

Classically, the hypothalamus was included in the diencephalon, but contemporary neuromeric models, based on developmental data, indicate that the hypothalamus, preoptic area, and telencephalon form a single unit within the forebrain, known as the secondary prosencephalon. The hypothalamus consists of a tuberal (infundibular) portion (which is derived from the basal plate and located caudal (topologically ventral) to the optic chiasm) and an alar portion (which is formed by a suprachiasmatic region). The basal region is traditionally divided into dorsal and ventral hypothalamic parts, with respect to the infundibular ventricle (**Figures 2**(**i**), **2**(**j**), and **3**(**c**)–**3**(**e**)), and both contain immunohistochemically distinct cell populations that are similar to those described in amphibians (**Figures 3**(**c**)–**3**(**e**)). The alar hypothalamic region is mainly comprised of the suprachiasmatic nucleus, an extremely heterogeneous cell group containing distinct populations of catecholaminergic and peptidergic cells with strong projections to the intermediate lobe of the hypophysis.

The preoptic area is located topographically rostral to the suprachiasmatic nucleus. It contains a preoptic recess of the III ventricle, and in its walls cells of the magnocellular nucleus are recognized by their content of the neurohormones vasotocin and mesotocin (**Figure 3**(**d**)). These cells issue a well-developed tract that borders the chiasmatic ridge and courses in the ventral hypothalamus toward the neural lobe of the hypophysis. The rest of the preoptic area is comprised of small cells that form subgroups, distinguished only by immunohistochemistry, such as that for specific calcium-binding proteins (**Figures 3**(**c**) and **3**(**d**)).

Telencephalon

As described above, the olfactory bulbs, the pallial and subpallial regions of the hemispheres, and the telencephalon impar are all considered part of this large forebrain region. The olfactory bulbs are well developed in all lungfishes and show the cell types present in most vertebrates, as well as the organization of granular, mitral, and glomerular cell layers separated by plexiform layers. A much-debated issue regarding the olfactory system in lungfishes has been the possible presence of an accessory olfactory bulb that is cytoarchitectonically indistinct. Only recently have immunohistochemical data, based on specific labeling for calbindin (**Figure 3**(**g**)) and other olfactory markers, clearly indicated the existence of an accessory olfactory system, which may represent an incipiently segregated vomeronasal system in lungfishes, as exists in tetrapods.

The actual extent of the pallial regions in lungfishes has also been the basis for long debate. The telencephalic hemispheres are unusual in Neoceratodus, as a part of the medial wall is reduced to an ependymal membrane. The structures in the medial wall located ventral to this ependymal membrane in *Neoceratodus* and most of the thick medial wall in *Protopterus* and *Lepidosiren* have been believed by some researchers to be homologous to the septum in other vertebrates. Current data on telencephalic organization, however, strongly indicate that the medial telencephalic wall in lungfishes consists of a dorsal medial pallium and a ventral septum, as in other vertebrates. Specific immunohistochemical labeling has identified medial, dorsal, and lateral pallial regions, and, in addition, a new ventral pallial region, as defined in tetrapods (**Figure 3**(**f**)). The medial pallium extends rostrocaudally throughout most of the length of the hemisphere; it is large at rostral levels but progressively reduced at caudal levels, as the ventrally located septum becomes enlarged (**Figures 2**(**b**)–**2**(**d**)). Several immunohistochemical features allow the distinction of ventral, intermediate, and dorsal parts within the medial pallium, as in tetrapods (**Figure 3**(**f**)). Both the dorsal and lateral pallial regions are considerably small and have a periventricular cell layer of nonmigrated neurons and a cortical-like layer of cells detached from the periventricular layer (**Figures 2**(**b**)–**2**(**d**)). A peculiarity of these pallial regions is the large number of catecholaminergic neurons that they possess (**Figure 3**(**h**)). At the boundary between the lateral pallium and the subpallium, a portion of the lateral hemispheric wall has been recognized as the ventral pallium in lungfishes, due to its neurochemical similarity to that area in tetrapods (**Figures 2**(**b**), **2**(**c**), and **3**(**f**)). In amphibians, this pallial region contains the lateral amygdala (the only pallial amygdaloid component), and this is likely true in lungfishes as well.

The striatal and pallidal structures of the basal ganglia are major components of the subpallium in lungfishes. The striatum is located in the ventrolateral part of the telencephalic hemisphere; although its boundaries are unclear, it can be identified by the presence of an abundant neuropil, formed by dopaminergic fibers originating in a mesencephalic tegmental cell group (**Figure 3**(**f**)). It has a dense periventricular cell plate, but in *Protopterus* a ventral lobe is formed at caudal levels by migrated islands of cells (**Figures 2**(**b**)–**2**(**d**)). Classically, these were considered to comprise the olfactory tubercle in lungfishes, but they are at least in part a component of the dorsal striatum, and they project to the mesencephalic tegmentum. The large striatal regions in lungfishes can be divided into dorsal and ventral parts, based on cytoarchitecture. In addition, developmental markers have identified a pallidal structure in the caudoventral telencephalon, and cholinergic neurons of a basal forebrain system are also found among its cells, as in amniotes and amphibians (**Figures 2**(**d**), **2**(**e**), and **3**(**i**)).

The septal complex in lungfishes is restricted to the ventromedial wall of the hemispheres, as in terrestrial vertebrates (**Figures 2**(**c**) and **2**(**d**)). The expression of several developmental markers reveals subregions within the septum, including a large lateral septum, a small medial septum, and a specific ventral septum.

Homologs of the amygdaloid complex in amniotes have been proposed in the telencephalon of lungfishes, mainly on the basis of immunohistochemical features and some hodological data. Three distinct amygdaloid regions are characterized: (1) the lateral amygdala within the ventral pallium, which is related to secondary olfactory fibers; (2) the central amygdala, a striatal component of the amygdala in the subpallium that is mainly related to autonomic brain centers; and (3) the medial amygdala, a region in the caudal telencephalon that includes the dorsal portion of the telencephalon impar above the preoptic area; it receives a subset of olfactory information that may be comparable to that received by the vomeronasal amygdala of tetrapods (**Figures 2**(**c**)–**2**(**f**)).

The Brain of the Coelacanth *Latimeria chalumnae*

Our current knowledge of the organization of the brain in *Latimeria* is based exclusively on nonexperimental histological material, and, as *Latimeria* is both rare and endangered, it is highly unlikely that hodological or other experimental studies will be ever conducted. The general organization of the brain is very conservative, and many cell masses do not require further comment, as they are similar in location and structure to their homologs in

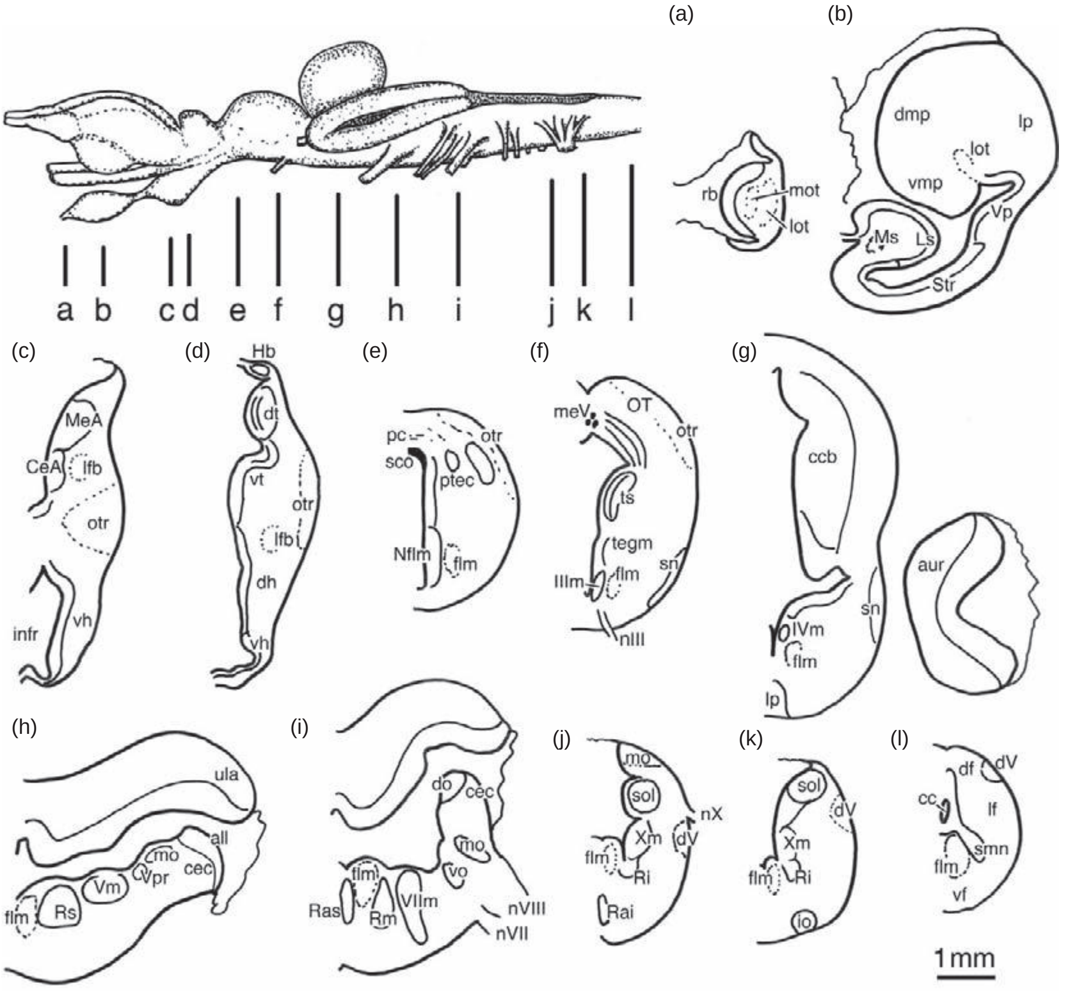

Figure 4 Diagrams of transverse left hemisections, rostral to caudal (a–l), through the brain of *Latimeria chalumnae* at levels indicated in the drawing of the brain in lateral view. Abbreviations: all, lower leaf of the auricle; aur, auricula cerebelli; cc, central canal; ccb, corpus cerebelli; CeA, central amygdala; cec, cerebellar crest; df, dorsal funiculus; dh, dorsal hypothalamus; dmp, dorsal part of medial pallium; do, dorsal octavolateral nucleus; dt, dorsal thalamus; dV, descending trigeminal tract; flm, fasciculus longitudinalis medialis; Hb, habenula; IIIm, oculomotor nucleus; infr, infundibular recess; io, inferior olive; Ip, interpeduncular nucleus; IVm, trochlear nucleus; lf, lateral funiculus; lfb, lateral forebrain bundle; lot, lateral olfactory tract; Ls, lateral septum; MeA, medial amygdala; meV, mesencephalic trigeminal nucleus; mo, median octavolateral nucleus; mot, medial olfactory tract; Ms, medial septum; Nflm, nucleus of the fasciculus longitudinalis medialis; nIII, oculomotor nerve; nX, vagal nerve; OT, optic tectum; otr, optic tract; pc, posterior commissure; ptec, pretectum; Rai, inferior raphe nucleus; Ras, superior raphe nucleus; rb, rostral body; Ri, nucleus reticularis inferior; Rm, nucleus reticularis medius; Rs, nucleus reticularis superior; sco, subcommissural organ; smn, somatomotor neurons; sn, superficial nucleus; sol, solitary tract; Str, striatum; tegm, tegmentum; ts, torus semicircularis; ula, upper leaf of the auricle; vf, ventral funiculus; vh, ventral hypothalamus; VIIm, facial motor nucleus; Vm, trigeminal motor nucleus; vmp, ventral part of medial pallium; vo, ventral octavolateral nucleus; Vp, ventral pallium; Vpr, principal sensory trigeminal nucleus; vt, ventral thalamus; Xm, vagal motor nucleus.

lungfishes and other groups of fishes (**Figure 4**). A peculiar feature of the brain in *Latimeria*, as compared to that in lungfishes, is reflected in its overall histology: in addition to periventricularly arranged nuclei, there are a number of neurons and neuronal groups that occupy peripheral (migrated) positions (**Figure 5**).

Starting from the spinal cord, *Latimeria* shows distinct dorsal and ventral horns, with intermediate gray between them. Large, scattered motoneurons are located in the ventral tip of the ventral horn (**Figures 4**(**l**) and **5**(**a**)). Notably, the spinal cord shows slight pectoral and pelvic enlargements associated with the innervation of the extraordinary paired fins.

The rhombencephalon is characterized by conspicuously developed longitudinal ventricular sulci (**Figures 4**(**j**), **4**(**k**), and **5**(**b**)). Thus, prominent ridges are formed, mainly by the development of large branchiomotor nuclei that form an almost uninterrupted series (**Figures 4**(**h**)–**4**(**k**), 5(**b**), and **5**(**c**)). A peculiarity of *Latimeria* is that the abducent rootlets emerge as ventral roots, caudal to the level of the glossopharyngeal root, and innervate a powerful basicranial muscle present in the well-developed

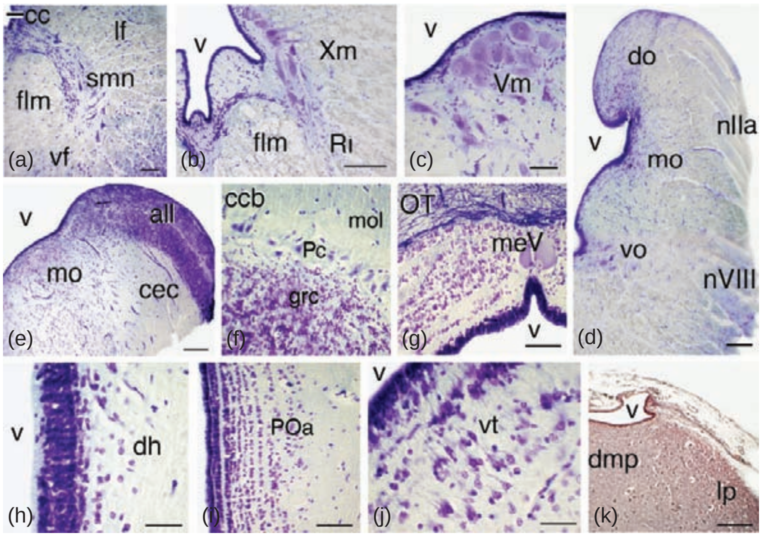

Figure 5 Photomicrographs of transverse sections, caudal to rostral (a–k), through the brain of *Latimeria chalumnae*. (a) The ventral horn of the spinal cord. Scale = 100 μm (a, c, d, f, g, i), 200 μm (b, e, k), 50 μm (j, h). Abbreviations: cc, central canal; dh, dorsal hypothalamus; dmp, dorsal part of medial pallium; do, dorsal octavolateral nucleus; flm, fasciculus longitudinalis medialis; lp, interpeduncular nucleus; lf, lateral funiculus; mo, median octavolateral nucleus; nlla, anterior lateral line nerve; nVIII, octaval nerve; POa, anterior preoptic area; Ri, nucleus reticularis inferior; smn, somatomotor neurons; v, ventricle; vf, ventral funiculus; Vm, trigeminal motor nucleus; vo, ventral octavolateral nucleus; vt, ventral thalamus; Xm, vagal motor nucleus.

intracranial joint that divides the neurocranium. As part of the somatic motor column of the caudal rhombencephalon, a conspicuous spinooccipital nucleus gives rise to three pairs of nerves, the first pair emerging as ventral roots approximately at the level of the last vagal rootlet. These somatic motor neurons are located just lateral to the very conspicuous fasciculus longitudinalis medialis, which constitutes the most important system involved in supraspinal control, because Mauthner cells – which are present in lungfishes and most actinopterygians – are lacking in *Latimeria*.

The octavolateral area consists of three zones, similar to those described for lungfishes: dorsal, intermediate, and ventral (**Figures 4**(**h**), 4(**i**), and **5**(d)). The first two receive their input exclusively from the lateral line nerves. The anterodorsal and anteroventral lateral line nerves have dorsal roots that end only in the dorsal nucleus and carry information from an enigmatic rostral electroreceptive organ, which actually represents a collection of ampullary organs. The intermediate (median) nucleus receives mechanosensory fibers from neuromasts innervated by the ventral roots of the anterodorsal and anteroventral lateral line nerves, as well as the roots of the remaining lateral line nerves. The ventral nucleus comprises three separate cell masses: the anterior, magnocellular, and descending octaval nuclei. In the caudal part of the alar plate, the gustatory afferent fibers form small vagal lobes; together with the lack of a distinct secondary visceral nucleus, this denotes that the gustatory system is poorly developed in *Latimeria*.

The cerebellum is formed by a dome-like corpus and a large vestibulolateral lobe, the lateral parts of which constitute huge auricles with upper and lower leaves (**Figures 4**(**g**)–**4**(**i**)). While the corpus and upper auricular leaves contain the usual three cerebellar layers, the lower leaves contain mainly granule cells (**Figures 5**(**e**) and **5**(**f**)). A superficial isthmic nucleus, obviously a homolog to that in lungfishes, is also found in *Latimeria* (**Figures 4**(**f**) and **4**(**g**)).

In the midbrain, the optic tectum is relatively large and bilobed. Compared to that in lungfishes, it is better laminated, and the large perikarya of the mesencephalic trigeminal nucleus forms a dorsomedian strip in the caudal two-thirds of the tectum (**Figures 4**(**f**) and **5**(**g**)). Also better developed and better laminated is the torus semicircularis (**Figure 4**(**f**)).

A characteristic feature of the caudal forebrain in *Latimeria* is a distortion of the infundibulum, which is directed rostrally. Thus, the postoptic hypothalamus (basal hypothalamus) becomes topographically rostrobasal, located ventral to the chiasmatic ridge and extending below the telencephalon. Similarly, most of the ventricular sulci and cytoarchitectural boundaries in the diencephalon are altered, as evidenced by the rather caudal position of the asymmetrical habenulae, for example. The dorsal thalamus resembles that of *Neoceratodus* in the way it protrudes into the III ventricle and in the way its cell bodies are arranged into distinct laminae. This laminar arrangement continues, and is better specified, in the narrow ventral thalamus (**Figure 5**(**j**)). This contrasts with the ventricular lining of the large hypothalamus, which shows a thick periventricular cell layer (**Figure 5**(**h**)), clearly differing from the layered arrangement seen in the preoptic region (**Figure 5**(**i**)). Apart from the distortion of the infundibulum, the hypothalamic organization in *Latimeria* appears conservative, except for two peculiarities: the location of the eminentia media in the rostrodorsal part in the infundibular wall and the presence of a small sacus vasculosus in its ventrocaudal wall.

The telencephalon is by far the most striking portion of the brain in *Latimeria*. Because of the lack of embryonic material and experimental data, much of its organization is interpreted speculatively. Within the telencephalon impar, central and medial amygdalar nuclei (**Figure 4**(**c**)) can be identified, based on their similarity to the same-named structures recently established in lungfishes and amphibians. The hemispheres consist of a greatly thickened dorsal part (pallium) and a thin-walled ventral part (subpallium). The subpallium is the product of simple evagination, as in lungfishes and amphibians, but the pallium does not participate in this evagination, and it instead suggests the everted pallium in actinopterygians (**Figure 4**(**b**)). The subpallium shows a very simple cytoarchitecture in all its parts; a narrow layer of periventricular cells and a peripheral fiber zone are common features. The lateral part of the subpallium has been considered the striatum, and a distinct change in cell density at its dorsal border may indicate the presence of a ventral pallidum, as in lungfishes and tetrapods (**Figure 4**(**b**)). The medial portion of the subpallium comprises the septum and shows migrated cells from the ventricle that constitutes a medial septal nucleus.

The cell bodies of the pallium are evenly scattered throughout the entire thickness of this solid structure (**Figure 5**(**k**)), and three main fields have been recognized: dorsomedial, ventromedial, and lateral (**Figure 4**(**b**)). Their putative homologies with pallial fields in lungfishes or tetrapods cannot be proposed with any confidence, because of the lack of developmental or neurochemical data. Different hypotheses have been advanced, however, depending on the proposer's interpretation of a total or partial eversion process. Only the ventromedial field that surrounds the large central olfactory tract is directly comparable to the lateral pallium of tetrapods.

As mentioned above, the olfactory bulbs are small. They are located at the posterior extreme of the nasal cavity and connected by long, thin olfactory stalks or peduncles (15–20 cm long) to the so-called rostral bodies (**Figure 4**(**a**)), a pallial formation in *Latimeria* that represents the retrobulbar area in other vertebrates. Overall, given the rather small olfactory bulbs and the limited histological differentiation of the olfactory centers (rostral bodies and ventromedial pallial field), the olfactory system in *Latimeria* would appear to be only moderately developed.

Glossary

Basal ganglia Subcortical forebrain nuclei involved in the control of movements.

Brainstem The interface between the forebrain and the spinal cord.

Calcium-activated potassium channels Potassium channels that open when the intracellular calcium levels increase.

Central pattern generator Neuronal circuits that generate rhythmic motor output for coordination without the aid of sensory feedback.

Cerebellum Structure above the brainstem that is involved in the control of movement.

Climbing fibers Afferent fibers in the cerebellum that originate from the inferior olivary nucleus and may serve as error detectors.

Command signals A signal that can initiate activity in a CPG.

Diencephalon The more caudal of the two divisions of the forebrain. Caudal part of the prosencephalon (forebrain) associated with the third ventricle. The general subdivisions are (from dorsal to ventral): epithalamus, dorsal thalamus, subthalamus, and hypothalamus.

Disinhibition Activation that occurs as a result of a decrease in the level of inhibition.

Eurydendroid cells Efferent cells in the teleost cerebellar cortex, homologous to the deep cerebellar nuclei in mammals, which receive input from Purkinje cells and project to the brainstem and spinal cord.

Glutamatergic Neuron that uses glutamate as transmitter.

Interneurons Neurons with local axonal arborization.

Intrinsic intersegmental connectivity Synaptic interaction within a segment.

Mauthner cells Two giant neurons located in the hindbrain of most fish species. Mauthner cells usually control escape responses. However, non-Mauthner cell escapes also have been reported, and the Mauthner cells may be involved in other behaviors such as post-feeding turns.

Mesopontine Brainstem structures at the border between the mesencephalon and the pons.

Metabotropic Receptors on the postsynaptic membrane that act through G-proteins.

Mossy fibers The major afferent input to the cerebellum, originating from the brainstem and spinal cord.

Motor learning Different movements can be modified through learning.

Optic tectum Structure in the dorsal part of the mesencephalon in which a retinotopic map is formed by afferents from the eye.

Periaqueductal The canal in the mesencephalon that joins the third and the fourth ventricle is called the aqueduct. Periaqueductal refers to the location of cells around the aqueduct.

Premotor The term premotor is used to label interneurons that terminate on motor neurons.

Purkinje cells GABAergic neurons in the cerebellar cortex that constitute the sole output of motor coordination in the cerebellar cortex.

Reticulospinal neurons One of the most important descending pathways in the vertebrate nervous system. They integrate sensory inputs and higher motor commands in the brain to ultimately regulate motor functions in the spinal cord.

Goal-Directed Locomotion – Overview of Neural Control System

The nervous system coordinates different motor acts through a number of dedicated networks or modules that are specialized to coordinate specific motor patterns, be it locomotion, respiration, or eye movements. The locations of the different networks are illustrated in **Figure 1**. Most jawed fish and cyclostomes swim with an undulatory wave of muscle contraction transmitted along the body. The caudally directed movement is generated by a network that activates motor neurons in successive segments with a delay that is proportional to the duration of each movement cycle. Usually, the delay along the entire body

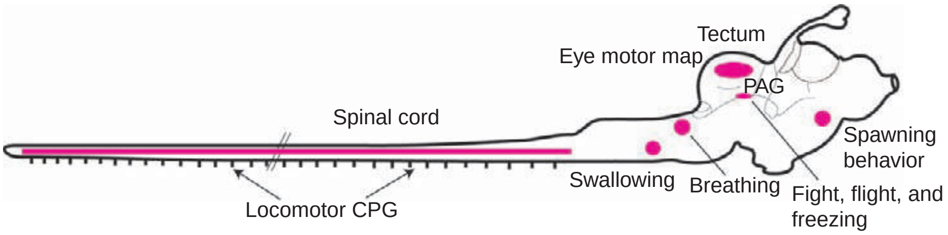

Figure 1 Motor infrastructure in cyclostomes and fish. Along the neuraxis, different motor programs/CPG networks are located that can be recruited when needed, from protective reflexes and locomotor CPG networks in the spinal cord to respiration and the saccadic eye motor map at the brainstem level. Each motor program can be recruited into action by neural mechanisms that determine when a given motor program is selected. More integrated motor patterns can be induced as fight, flight, or freezing behavior from the periaqueductal gray (PAG) and spawning behavior from part of the preopticus nuclei.

corresponds to around one undulatory cycle (**Figure 2**, left). The lag between each segment is described as a phase lag, because it is proportional to the cycle duration, whether it is 0.5 s or 100 ms (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops).

This motor pattern is generated by a central pattern-generating (CPG) network, that is, a spinal network extending throughout the spinal cord (**Figure 1**). The spinal CPG network is controlled by descending reticulospinal neurons from the brainstem, which, in turn, are activated from locomotor command regions in the diencephalon (diencephalic locomotor region (DLR)) and the mesopontine area (mesencephalic locomotor region (MLR)). The command signals issued from the MLR or DLR represent a continuous signal

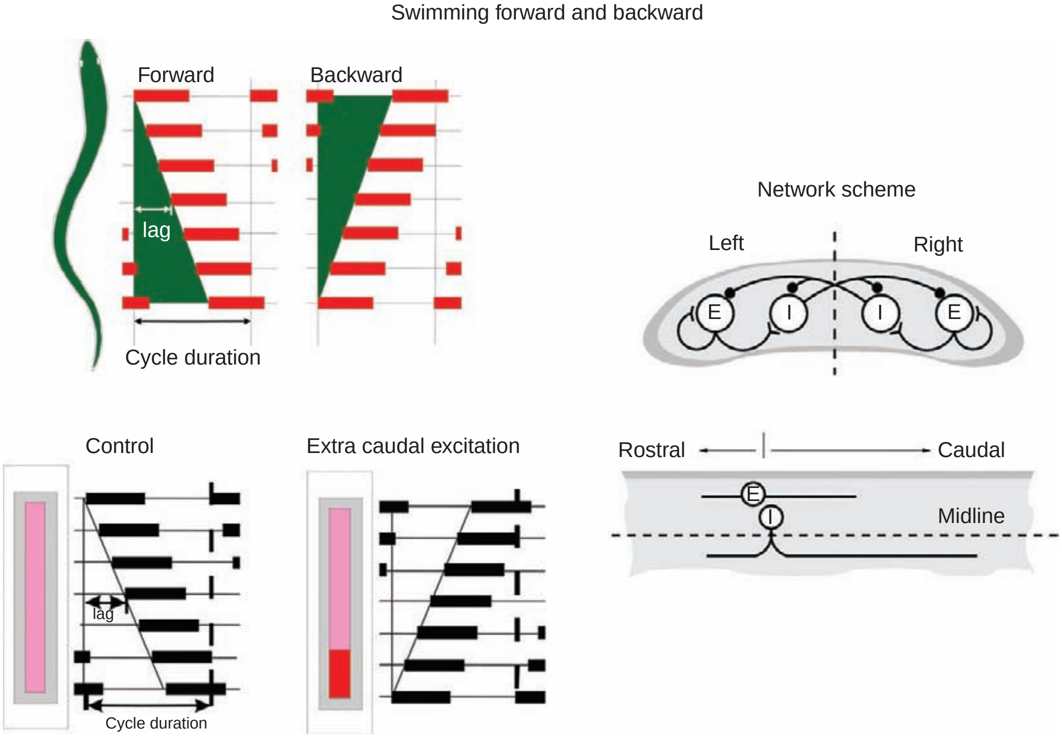

Figure 2 Intersegmental coordination through phase coupling. Cyclostomes, jawed fish, and some amphibians and reptiles swim by producing a mechanical wave that is transmitted along the body. As illustrated during forward locomotion, there is a lag between consecutive segments in the spinal cord. This lag is always a certain proportion of the cycle duration and is therefore referred to as a constant phase lag. During backward locomotion, the wave is instead propagated from tail to head. Below in the isolated spinal cord (control) a rostro-caudal phase lag also can be produced and thus the ability to generate a constant phase lag is inherent within the spinal cord. The pattern can be reversed if extra excitation is added to the caudal spinal cord (right). This is explained by the fact that the segments of the caudal part then get a higher excitability and generate a somewhat higher burst rate that is able to entrain the segmental networks in the rostral part of the spinal cord. The rostral segments have a lower inherent burst rate and are therefore entrained but with a certain lag. The schemes to the right show the connectivity of populations of excitatory (E) and inhibitory (I) interneurons at the segmental level (upper graph), and below the intersegmental connectivity of E and commissural I interneurons.

Figure 3 Goal-directed locomotion – components of the control system. Subsystems are involved in the control of goal-directed locomotion. Selection of a motor program is performed in the basal ganglia, which receives inputs from the cortex (pallium) and the thalamus. The basal ganglia output stage (pallidum) inhibits command centers in the diencephalic locomotor region (DLR) and mesencephalic locomotor region (MLR) during resting conditions. Through a well-controlled inhibition of pallidal regions, the spinal CPG network for locomotion can be activated via the reticulospinal (RS) neurons. In the brainstem, information is further integrated based on visual, sensory, and vestibular inputs to control both steering and posture. In all vertebrates, the spinal cord CPG neurons are modulated by local sensory feedback.

that turns on the network. The level of activity in the command centers determines the degree of activation of the CPG network and thus determines swimming speed (**Figures 3** and **4**). The complex of MLR/DLR, reticulospinal neurons, and the spinal CPG network constitutes the circuit controlling the propulsion itself (**Figure 4**). To be behaviorally meaningful, the locomotor movements also need to be steered toward the goals of different types. The different components of the neural control system are detailed in the following.

Spinal CPG Network and the Locomotor Pattern Generation

Trunk movements

The motor pattern produced by the spinal CPG network during forward locomotion (**Figure 2**) is generated by a network composed of a population of excitatory glutamatergic premotor neurons and inhibitory commissural interneurons (**Figure 4**, left). The intrinsic connections within the segmental pools of excitatory (E) interneurons (red) give rise to the burst activity in each segment, if in addition they are activated from supraspinal sources. The termination of the burst depends on the intrinsic membrane properties of these cells and particularly one subtype of ion channel, the calcium-activated potassium channels that become progressively activated by the calcium entry occurring during each burst (**Figure 4**, right). The coordination of the alternating activity in each segment depends on the commissural inhibitory neurons, which use glycine as their transmitter (inhibitory (I) interneurons (blue), **Figure 4**). When there is burst activity on one side, the commissural inhibitory neurons inhibit the contralateral side, but as the burst terminates, the other side becomes disinhibited and thus starts bursting.

The coordination along the spinal cord results in the progressive activation of successive segments during locomotion and is generated by the intrinsic intersegmental connectivity (**Figure 2**, right) in that both excitatory and inhibitory interneurons have axons projecting over several segments. The isolated spinal cord generates forward locomotor coordination that has been detailed in modeling experiments.

Although the spinal network generates the coordination underlying forward locomotion under ordinary conditions, it can instantaneously switch to backward locomotion with an undulatory wave instead propagated from tail to head (**Figure 2**). How can this be explained? It turns out that the flexibility can be explained by a simple control mechanism; the active spinal cord receives some inhibition of the most rostral segments. Their lower excitability makes them become activated after the segments with higher excitability located in a more caudal direction. Because the spinal cord network functions as a unit, this reverses the phase lag along the entire spinal cord.

Dorsal fins

The dorsal fins increase the lateral surface of the body during swimming, and thereby provide stability but at the expense of increasing drag (**see also Buoyancy, Locomotion, and Movement in Fishes**: Maneuverability). Their position in relation to the body during movement is stabilized by an exclusive set of fin motor neurons that are activated in antiphase with the motor neurons controlling the trunk muscles during locomotion. This is required to stabilize the vertical position of the dorsal fins in relation to the body movement.

In some teleost species, the dorsal fin extends along most of the body (e.g., *Gymnarchus niloticus*), and an undulatory wave can actually be transmitted along the entire dorsal fin, in either a backward or a forward direction, moving the fish in the corresponding direction. Instead of having only one undulatory wave, as in trunk locomotion, there are many small amplitude waves transmitted along the fin.

Figure 4 Locomotor network of the lamprey: schematic representation of the segmental neural circuitry that generates rhythmic locomotor activity. All neuron symbols denote populations rather than single cells. The reticulospinal (RS), glutamatergic neurons excite all classes of spinal interneurons and motor neurons. The excitatory interneurons (E; red) excite all types of spinal neurons, that is, the inhibitory glycinergic interneurons (I: blue) that cross the midline to inhibit all neuron types on the contralateral side, including motor neurons (M). The stretch receptor neurons are of two types – one excitatory (SR-E), which excites ipsilateral neurons, and the other inhibitory (SR-I), which crosses the midline to inhibit contralateral neurons. RS neurons receive excitatory synaptic input from the diencephalic and the mesencephalic locomotor regions (DLR and MLR), which in turn receive input from the basal ganglia as well as visual and olfactory input. In addition, metabotropic receptors are also activated during locomotion and are an integral part of the network (5-HT, GABA, tachykinins (TK), and mGluR). (Right) Several factors contribute to burst termination. Calcium entering via voltage-gated calcium channels during the action potential activates calcium-dependent potassium channels (f KCa) that underlie the postspike after-hyperpolarization (AHP). During the burst, AHP summation leads to frequency adaptation and contributes to burst termination. During *N*-methy-D-aspartic acid (NMDA) receptor activation, KCa channels are also activated by calcium entering through NMDA channels and contribute to NMDA plateau termination. In addition, sodium entry activates sodium-dependent potassium channels (KNa) that may also contribute to burst termination.

Pectoral fins

Whereas the lampreys have no paired fins, elasmobranchs such as sharks and dogfish use their large extended fins to maneuver. By changing the position of the left and right pectoral fins respectively, they can change the instantaneous direction of locomotion and also stabilize their body position. In contrast, rays have pectoral fins enlarged along a large part of the body and swim by propagating an undulatory wave along each fin.

Teleosts have fins that are much more flexible and can be used for very slow locomotion or for positioning themselves in relation to different objects, as when, for instance, they nibble on a piece of seaweed or a snail on a rock. When swimming rapidly, teleost fish generally keep their fins close to the body to reduce drag. The design of the neural networks controlling the pectoral fins has not, as yet, been investigated in any detail, although it should be of major interest as they are a precursor of tetrapod forelimbs (**see also Buoyancy, Locomotion, and Movement in Fishes**: Maneuverability).

Escape swimming

In lamprey, visual stimuli can elicit a rapid change in swimming direction (escape swimming). This rapid response does not depend on processing in the optic tectum, but requires intact pretectal nuclei (see also the dorsal light response below) that, in turn, activate brainstem reticulospinal neurons and Mauthner cells. Escape swimming elicited through other stimuli, such as vibration in the water, is mediated directly at the brainstem level to the very large cells (i.e., the Mauthner cells) with a contralateral axon that projects down the spinal cord to activate contralateral motor neurons along the spinal cord (**see also Brain and Nervous System**: Physiology of the Mauthner Cell: Discovery and Properties and Physiology of the Mauthner Cell: Function). This system provides the fastest avenue to generate a rapid escape response, which is a fast turning to the opposite side combined with fast locomotor movements utilizing the spinal CPG network.

Steering and the Related Orienting and Eye Motor Control

In order for locomotion to be behaviorally meaningful, it must also be steered toward different points of interest. In order to steer the body to the left or the right, the motor activity must be asymmetric, so that the body is bent for a

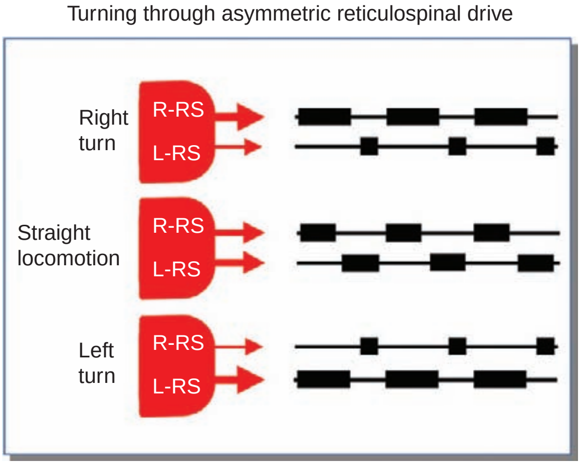

Figure 5 Neural mechanism for steering – asymmetric activation of reticulospinal command. The locomotor command system elicits a symmetric reticulospinal activity on the right (R-RS) and left (L-RS) side (middle trace – straight). A steering command to the right is produced by any signal that enhances the reticulospinal activity on the right side and/or lowers it on the left side (right turn). The converse changes would produce a turn to the left (left turn).

short while to the left or the right side. This is achieved through an asymmetric activation of the reticulospinal neurons, which then in turn activate motor neurons of one side more than the other (**Figure 5**).

If a fish sees something that calls for action such as a prey, there needs to be an interface to the motor system to generate a steering command appropriate to reach the point of interest. In this context, not only vision but also other senses are important (electroreception, input from the lateral line, olfaction, etc.). A structure that is of critical importance in this context is tectum mesencephali (**see also Vision**: Optic Tectum) and the retinotopic map formed in it by the afferents from the optic nerve projecting onto its contralateral superficial layers (**Figure 6**). This mapping is achieved through direct projection from the retinal ganglion cells.

Aligned with the sensory map, there is a motor map in the deeper layers of tectum with efferent neurons projecting out of tectum in the form of a motor map. In the goldfish, important output targets are the vertical and horizontal gaze centers, which are evolutionary conserved structures in all vertebrates. They are activated through interneurons in the cranial eye motor nuclei (no. III, IV, and VI) of both the eyes in a coordinated fashion to produce a movement of the eye directed to any point in the visual space and also the accompanying orienting movements of the trunk mediated via an asymmetric activation of reticulospinal neurons. The latter represent movements of the head and trunk that orient the body toward the point of interest, similar to the human head and neck movements. Orienting movements occurring during ongoing swimming result in turning that steers the body toward the point of interest, that is, it is goal-directed behavior.

If the tectum and the parts of the locomotor system that we just have discussed constituted the entire control system, the fish would automatically swim toward any

■ Type II: downward shift of both the eyes and downward body bending
★ Type IV: orienting response, eye movements neck bending, and locomotion

Figure 6 Retinotopic sensori-motor map – relation to steering. The different parts of retina (color coded) project onto different parts of tectum as indicated in color. The image of the lamprey brainstem is from above with the fourth ventricle in the lower left. The different symbols superimposed on the retinotopic map indicate different motor responses that can be elicited from the different regions as also indicated in the figure. Activation of a certain part of retina results in eye movement and the accompanying orienting movement. If this occurs during locomotion, this steers the movements toward the object of interest. Modified from Jones M, Grillner S, and Robertson B (2009) Selective projection patterns from subtypes of retinal ganglion cells to tectum and pretectum: Distribution and relation to behaviour. *Journal of Comparative Neurology* 517: 257–275.

target that would appear in the retina. This is clearly not the case. One structure that takes part in selecting the appropriate motor behavior in a given instant is the basal ganglia, as discussed separately below.

Control of Body Orientation

All vertebrates from lamprey to man have the ability to control body orientation during movement, mostly with the back maintained in a dorsal position. In contrast, the vertebrate-like amphioxus (Cephalochordate), which has a spinal cord but a poorly evolved brain, is unable to control the position of its body, and swims in a spiral-like fashion, because it lacks the most important sensor in this context, the vestibular apparatus (**see also Hearing and Lateral Line**: Vestibular System Anatomy and Physiology).

The vestibular apparatus compares inputs from the two sides of the body in relation to gravity. The vestibular afferents project to the vestibular nuclei of the brainstem that contain vestibular interneurons projecting to neurons on the ipsi- and contralateral sides. They, in turn, activate reticulospinal neurons that project to spinal motor neurons (**Figure** 7, right). If the body is tilted to one side, the vestibular input from the two sides becomes asymmetric and signal this (via interneurons) to affect the level of activity of the reticulospinal neurons, so that their activity increases on one side and decreases on the other side, as shown by the recordings from reticulospinal cells and the left and right side (**Figure** 7, uppermost). As the body is tilted, the activity of the neurons on one side increases, whereas it decreases on the other side. A tilt to one side leads to a compensatory movement that returns the body to a position with the dorsal side upward. **Figure** 7 (lower right) illustrates the balance between the two sides.

The reticulospinal cells are in fact not one entity, but have four distinct nuclei located in the mesencephalon and the anterior, middle, and posterior nuclei of the rhombencephalon (**Figure** 7, upper left). These four nuclei are activated maximally by different degrees of tilt. Some nuclei are activated at 45° and others at 90° of tilt, while the anterior rhombocephalic nucleus actually is activated when the fish is upside down (180°). This illustrates that these different nuclei are specialized to correct for different tilt angles.

Dorsal light response

Although fish normally stabilize the body with dorsal side up, under particular conditions they stabilize at an angle. Behaviorally this can be explained by the color of the fish body. Predators such as birds find it more difficult to see

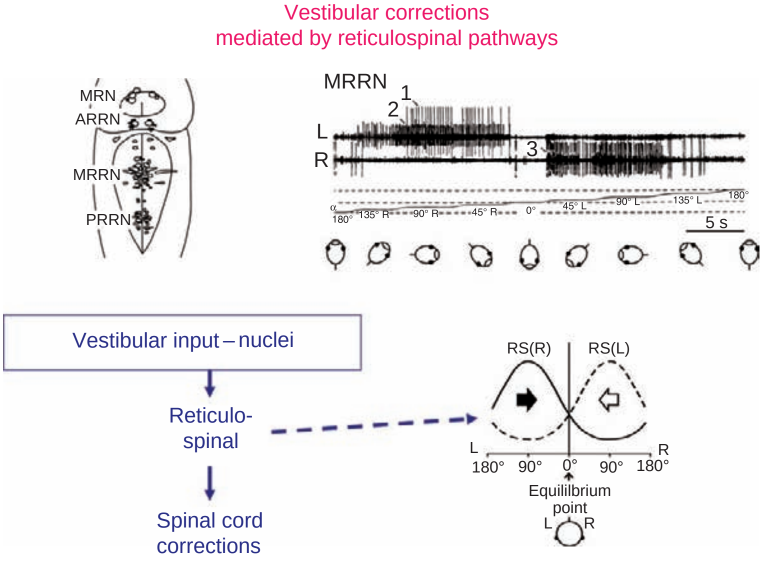

Figure 7 Vestibular corrections mediated by reticulospinal pathways. Schematic representation of the control systems for control of body orientation. The vestibular system plays a key role in the control of body orientation during locomotion. A dorsal view of the brainstem is shown (upper left) with the reticular nuclei (MRN (mesencephalic reticular nuclei), anterior (ARRN), middle (MRRN), and posterior (PRRN) rhombencephalic reticular nuclei). (Right) Simultaneous extracellular recordings from MRRN reticulospinal neurons on the left (L) and right (R), while the brainstem is rotated (full cycle, 360°). Note that when the dorsal side is upward (0), the activity on both sides is similar (low). The gravistatic sensors sense the orientation of the head and thereby detect any deviation of the position of the head from the dorsal side up position. Via vestibular interneurons, they activate reticulospinal neurons. With the dorsal side up, the input from the vestibular receptors is symmetric and thereby the activity of the reticulospinal system. In the diagram, the activity of the reticulospinal populations on the right (RS(R)) and on the left side (RS(L)) are represented. Any deviation to the left or right side leads to an asymmetric activity of the left and right reticulospinal populations. This asymmetry leads to a correction of the body position. Modified from Deliagina TG, Beloozerova IN, Zelenin PV, and Orlovsky GN (2008) Spinal and supraspinal postural networks. *Brain Research Review* 57: 212–221.

fish when viewed from above due to its dark color, while fish predators have the same difficulty from below due to the whitish abdomen (**see also Sensory Systems, Perception, and Learning**: Circadian Rhythms in Fish). However, during sunrise or sunset when light comes from the side, these safety mechanisms are inappropriate, and it is advantageous to rotate the body so that the back faces the sun. This is achieved by changing the balance between the two sides, so that the equilibrium point is stabilized at an angle different from vertical.

The visual input that detects the asymmetry of the incoming light is projected to the pretectum, a small group of nuclei in front of tectum that convey the asymmetry signal to the reticulospinal cells, thereby creating a bias to one side or the other. Most likely, the dorsal light response is a dynamic motor response, because the fish needs to continuously change its orientation as it swims around at sunset or sunrise.

Respiration

The respiratory centers in the brainstem activate motor neurons controlling the respiratory muscles that act primarily via the cranial nerves (no. VII, IX, and X). The respiratory movements differ between groups, such as the gill movements in teleost fish, the water passage through gill slits in elasmobranchs, and movements of water in and out of the seven gill pouches of the lamprey (**see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish).

In lampreys, an enhanced respiratory activity occurs in anticipation of a bout of locomotor activity – the increased respiratory activity in conjunction with the locomotor activity is thus preprogrammed rather than occurring in response to increased metabolic demand.

Details of the control of respiration are covered in a separate article (**see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish).

Jaw Control, Sucker Mouth, and Feeding

Jawed fish can pick up small and large objects, and some fish use their jaws to bite smaller or larger parts out of a prey and bring them into the mouth. Many fish such as sharks can generate exceptionally strong power in their jaw-closer muscles (**see also The Muscles**: Cartilaginous Fishes Cranial Muscles). However, fish, in contrast to mammals, have not developed the ability to chew food. The rich taste receptor innervation in the mouth cavity allows the fish to sense whether the object brought into the mouth is edible, and, if so, it is swallowed but otherwise rejected (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior). Some fish, such as carp and goldfish that feed from detritus and mud in ponds, have developed an intricate intraoral system to filter out inedible particles, while retaining and swallowing the edible ones.

The adult form of some lampreys is parasitic, and they develop the ability to actively suck by applying negative pressure with their sucker mouth, which is equipped with several layers of teeth (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development and Lampreys: Environmental Physiology). In the middle of the mouth there is a stiff and rough tongue that can be moved rhythmically to make a hole in fish skin. The lamprey applies rhythmic suction, resulting in fluid and tissue movements from the prey into its mouth and esophagus. The mechanisms underlying attachment and suction depend on the trigeminal motor system, but the details of the brainstem neural control system remain to be elucidated.

Migration and Spawning

Some fish remain in the same general area throughout life, whereas fish such as eels and salmon migrate thousands of kilometers (**see also Fish Migrations**: Pacific Salmon Migration: Completing the Cycle, Eel Migrations, and Tracking Oceanic Fish). They start from where they hatch to move to feeding grounds far away, and after many years they return to the their birth place. Similarly, many species of lamprey are born in small brooks and spend their first years of life as filter feeders buried in the mud except for the head. After metamorphosis, they migrate down to the mouth of the river and the ocean. Little is known regarding the neural control of these behaviors, but it is well documented that lamprey identify suitable rivers to migrate upward by the detection of species-specific bile acids in the water secreted by young lampreys upstream (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior; **Hagfishes and Lamprey**: Lampreys: Energetics and Development; and Lampreys: Environmental Physiology). These bile acids are detected at very low concentrations, and may also serve to identify the location of potential mates.

Different species of fish display different characteristics and stereotyped spawning behavior (**see also Social and Reproductive Behaviors**: Sexual Behavior in Fish). Electric stimulation in the ventral telencephalon and the preoptic nucleus of sexually primed individuals can instantaneously trigger different steps of the spawning behavior in both male and female salmon. Male and female position themselves in the nest close to each other while vibrating the body at a high frequency – followed by oviposition and sperm release. The neural structures that trigger sexual patterns of behavior when stimulated electrically are rich in gonadotropin-releasing hormone.

Periaqueductal Gray – Fight, Flight, and Freezing Responses

Stimulation of the periaqueductal gray (PAG), which is located in mesencephalon around the cerebral aqueduct (the ventricular canal that joins the third and fourth ventricles), appears to trigger specific patterns of motor behavior. For instance, stimulation of different parts of the PAG in zebrafish can trigger fight, flight, or freezing responses. Neurons in these different PAG compartments can activate different specific motor patterns (e.g., goal-directed locomotion): in the case of fight, a set of aggressive motor patterns must be recruited that need to be adapted to the foe. The PAG areas probably represent downstream command centers that can be used by higher-order control from telencephalic nuclei such as the amygdala, a structure known to be involved in fear (from fish to humans), and hypothalamic involvement can similarly be implied.

Neural Structures of Particular Relevance for the Motor System

In passing, we have noted the importance of different structures in the spinal cord and brainstem, where most of the different motor programs are elicited. What we have not dealt with so far are the mechanisms by which the brain can decide to select, and thereby recruit a given motor program. Here, the basal ganglia appear to play a critical role. We will therefore deal with this structure separately. The second issue that we have not considered is motor learning, which can occur at two levels – learning to calibrate integrated processes such as the vestibulo-ocular reflex and learning specific new motor sequences or associations with what may be required for feeding in a particular location. For the former type, the cerebellum is often involved, and for the second type of motor learning, both the cerebellum and the basal ganglia usually are involved **(see also Sensory Systems, Perception, and Learning**: Fish Learning and Memory**)**.

Basal ganglia

The structure and function of the basal ganglia, located in the forebrain, appear very similar throughout the vertebrates from lamprey to mammals. For the sake of simplicity we consider only the input level, the striatum, and the output level, the pallidum (see **Figure 8**; in reality, each can be subdivided into different components). The output level is unusual in that it consists of tonically active inhibitory neurons (gamma-aminobutyric acid (GABA)) that project to all the different command centers in the brainstem that control different motor programs, such as tectum, DLR, and MLR. The rationale for this is that the different motor programs need to be controlled so that they are not activated accidentally. A precondition for a motor program to be activated is thus to remove the pallidal inhibition. This is the task of striatum, which contains GABAergic neurons that instead are silent at rest. When a group of striatal neurons are activated, however, they will inhibit a subpopulation of pallidal neurons, thereby effectively removing the inhibition from a given motor center, which then becomes free to operate.

What activates the striatum? It receives fast synaptic input from the pallium (analogous to the layered cortex in mammals) and directly from thalamus. These two

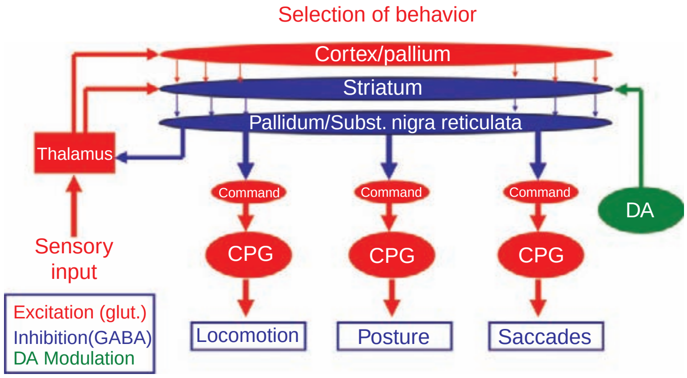

Figure 8 The basal ganglia control CPG activity – schematic diagram. The cerebral cortex in mammals and the corresponding structures in lower vertebrates (pallium) have an excitatory (red) output to striatum, the input layer of the basal ganglia, that is also directly activated by the thalamus. Striatum consists of inhibitory (blue) GABAergic neurons (95% of the extrinsically projecting medium spiny neurons), which have a very high threshold for activation. They are therefore difficult to activate, and may be regarded as a filter for cortical input. The striatum is composed of different subpopulations of neurons. They inhibit the output layer of the basal ganglia, the pallidum, which instead consists of GABAergic neurons with a very high level of resting activity keeping different CPG networks under tonic inhibition. The CPG activity is only released when the appropriate striatal subpopulation is activated and inhibits pallidum, resulting in a disinhibition of the CPG networks. The dopamine (DA) input to striatum has a very powerful effect in controlling the responsiveness of striatal neurons. The basal ganglia thus have a very important role in determining which CPG networks are active at a given instant. This diagram only includes what often is referred to as the indirect loop that the dopamine input inhibits.

excitatory inputs converge onto the striatal output neurons and determine whether they will become activated or not. There is a third factor, however, the dopamine neurons that also innervate striatum, and their effect is to determine the responsiveness of the striatal output neurons. If the dopamine innervation is deficient, it becomes more difficult to activate them and then also to activate the different motor programs. In humans, this condition is known as Parkinson's disease, and similar symptoms occur in fish and lamprey. Both with regard to structure and function, the basal ganglia are thus conserved throughout the vertebrate evolution. All evidences suggest that the striatum plays a prominent role in the selection of which motor programs are turned on at a given instant.

Cerebellum

In lampreys, the cerebellum is very small, whereas it is well developed in jawed fish (**see also Brain and Nervous System**: Functional Morphology of the Brains of Agnathans and Functional Morphology of the Brains of Ray-Finned Fishes). The critical cellular elements are arranged in a similar way in jawed fish as in mammals. Briefly, the input from the spinal cord and brainstem carries information about ongoing movements and activity in central motor circuits. In the general case, the input is of two types – one via mossy fibers that terminate on granular cells that in turn project to the output cells of cerebellum, the Purkinje cells, and the other via climbing fibers that project directly to the Purkinje cell dendrites. The Purkinje cells are inhibitory (GABAergic) and project to the efferent cerebellar nuclei. They, in turn, are excitatory and project to the spinal cord and brainstem nuclei that affect movement. In ray-finned fish, the deep cerebellar nuclei are absent. Cells that may be homologous to them are located within the cortex of the cerebellum and are called eurydendroid cells; they receive input from Purkinje cells and project to spinal cord and brainstem sites.

In many movements such as locomotion, the microcircuit from mossy fibers via Purkinje cells to motor nuclei operates during each movement cycle. This circuit can thus modify the motor pattern. The strength by which this circuit can modify a given movement is changed through synaptic plasticity. An error signal results if a movement is not well calibrated (e.g., if the vision become blurred due to the inappropriate eye movements). A separate set of cerebellar afferents, the climbing fibers, serve as error detectors. Each climbing fiber projects to a small number of Purkinje cells, and a climbing fiber activation affects the entire Purkinje cell and leads to changes in the efficacy of the synaptic input via the mossy fiber pathway (on the granular cell synapse on Purkinje cells). This constitutes the cellular basis of learning in cerebellar cortex; in addition, synaptic plasticity also operates at the level of the cerebellar nuclei. One function of cerebellum appears to take part in the fine tuning (learning) of sensory motor pathways dynamically activated during locomotion and other motor systems.

Concluding Remarks

This brief overview has focused on the neural basis of motor behavior in lamprey and jawed fish. Needless to say, there are a number of adaptations of the motor repertoire in different species, and in this brief article only the most general aspects are included.

Glossary

Antidromic Propagation of an impulse along an axon in a direction that is the reverse of normal. Electrical stimulation either of peripheral nerves or of white matter tracts has long served as a mechanism for electrophysiologically identifying the projections of recorded neurons.

Chemical synapse Modality of synaptic transmission whereby transfer of information from presynaptic neurons is mediated by depolarization-induced release of a neurotransmitter, which in turn activates specific receptors located on the postsynaptic membrane.

Cholinergic A general term pertaining to processes or structures related to acetylcholine. For example, neurons that release acetylcholine as transmitter. Nicotinic and muscarinic receptors are cholinergic receptors because they bind acetylcholine. Cholinergic synapses are found in both the central and peripheral nervous systems.

Electrical synapse Modality of synaptic transmission whereby transfer of information is mediated by intercellular channels known as gap junctions, which provide a pathway of low resistance for the spread of presynaptic electrical currents.

Ephaptic Functional interaction between neighboring neurons where the electrical field generated by one neuron influences the excitability of the second.

Glycinergic Synapse that uses glycine as its neurotransmitter, one of the major inhibitory neurotransmitters in the spinal cord and the brainstem.

Reticulospinal neurons One of the most important descending pathways in the vertebrate nervous system. They integrate sensory inputs and higher motor commands in the brain to ultimately regulate motor functions in the spinal cord.

Rhombomeres Distinct segments of the embryonic neural tube in the area that will eventually become the rhombencephalon, or hindbrain. The neural crest cells from each rhombomere do not intermingle and give rise to different ganglia or groups of neurons.

Time constant Index that expresses how fast the membrane potential of a neuron changes in response to changes in an applied transmembrane current. The time constant (*t*) can be calculated as the product between membrane resistance and membrane capacitance. As with other RC circuits, it expresses the time needed to charge the capacitor through the resistor to ~63% of full charge, or to discharge it to ~37% of its initial voltage (values derived from the mathematical constant *e*). Thus, due to the presence of the membrane capacitance, the voltage across the membrane usually lags behind current injections. Time constants are usually fast in neurons that require high temporal precision.

Introduction

During the nineteenth century, comparative anatomical analyses in fish and amphibians led to major breakthroughs in the understanding of the vertebrate nervous system. As part of this effort, the young Austrian medical student Ludwig Mauthner (**Figure 1(a)**) stumbled upon the presence of two large, in fact colossal, axons in the fish spinal cord (**Figure 1(b)**). He was at the time an associate in the laboratory of Ernst Brucke, who, together with Carl Ludwig, Emil Du Bois-Reymond, and Hermann Helmholtz, constituted an influential group of scientists that provided the grounds for the modern understanding of the mechanisms underlying physiological processes. In opposition to the then prevalent dogma of vitalism (the life force which gave vitality to all living organisms), they adopted the view that all physiological processes were potentially understandable in terms of ordinary physical and chemical principles (the doctrine of mechanism).

Honoring perhaps the context of its discovery, Mauthner's seminal observation endured over the years by providing the opportunity to examine the physiological properties of a single vertebrate neuron and to correlate them with its structure, leading to seminal discoveries in

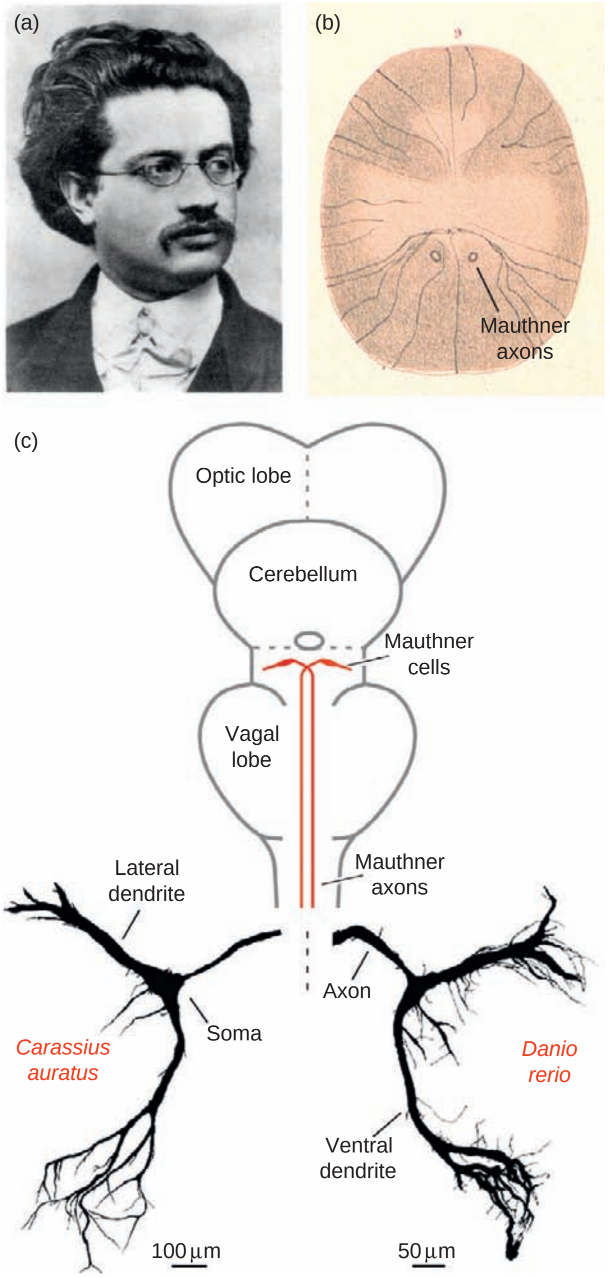

Figure 1 Description of the Mauthner cells. (a) Portrait of Ludwig Mauthner, the discoverer of these giant reticulospinal neurons, which have taken his name. (b) Koestler's 1898 hand-drawn cross section of pike (*Esox lucius*) spinal cord, based on microscopic observations, and illustrating the prominent Mauthner axons. (c) Schematic of a dorsal view of the teleost brain, with the paired Mauthner cells superimposed. Note that the axons cross the midline and descend to the spinal cord on the contralateral side. With this perspective, only the lateral dendrites are represented. Below are camera lucida drawings of goldfish (left) and zebrafish (right) Mauthner cells, projected onto the saggital plane and highlighting the two dominant dendrites. Modified from Lee RK, Eaton RC, and Zottoli SJ (1993) Segmental arrangement of reticulospinal neurons in the goldfish hindbrain. *Journal of Comparative Neurology* 329: 539–556; and Lee RK and Eaton RC (1991) Identifiable reticulospinal neurons of the adult zebrafish, *Brachydanio rerio*. *Journal of Comparative Neurology* 304: 34–52.

the understanding of the complexities of mechanisms underlying synaptic transmission. Today, this model vertebrate neuron provides a catalog of cellular and synaptic specializations that are repeatedly found to be relevant to neurons and their networks in general and for a wide range of species, including mammals.

The added attraction of this neuron is that it also has a well-defined function, as its physiological properties are critical to the appropriate expression of a signal behavior, the tail flip or escape response. Yet, the full extent of the functional role of this enigmatic colossal neuron remains undetermined. The physiological properties of the Mauthner cell, emphasizing its use as a model system to investigate cellular and synaptic properties, are reviewed in this article. The physiological role of the Mauthner cell in organizing reflex and voluntary behaviors and the cellular properties of the Mauthner cell in the context of its functional role are discussed elsewhere in this encyclopedia.

The Mauthner Cell

While Ludwig Mauthner later became a prominent ophthalmologist, his observation led to the identification by others of the origin of these large axons: a pair of large cells in the medulla of teleost and other fish (**Figure 1(c)**). Due to their uncommon size and shape, these cells are anatomically identifiable. The cell bodies are large (~100 µm in diameter) and characteristically exhibit, along with a number of much smaller dendritic processes, two large main dendrites: the lateral and the ventral dendrites (**Figure 1(c)**). Their prominent myelinated axons cross the midline to descend the length of the spinal cord, issuing axon collaterals that massively activate cranial and spinal motor systems. Such an anatomical arrangement allows a single action potential in this cell to initiate an escape response by producing a tail flip and coordinated movements of the jaw and eyes (see below). These anatomical features seem to be fairly constant among various species of fish, allowing the unequivocal identification of these cells.

We know now that the Mauthner cells are two bilaterally paired, cholinergic, reticulospinal neurons located in rhombomere 4. As with most reticulospinal neurons, the Mauthner cells receive multiple sensory inputs (**Figure 2**). Some of these inputs are clearly segregated: while the lateral dendrite receives information from the octavolateralis system (vestibular, lateral line, and, prominently, auditory modalities), the ventral dendrite receives visual and somesthetic information (**Figure 2**). Interestingly, a group of reticulospinal neurons in mammals is thought to mediate a comparable function, the startle response. The presence of a single, albeit larger,

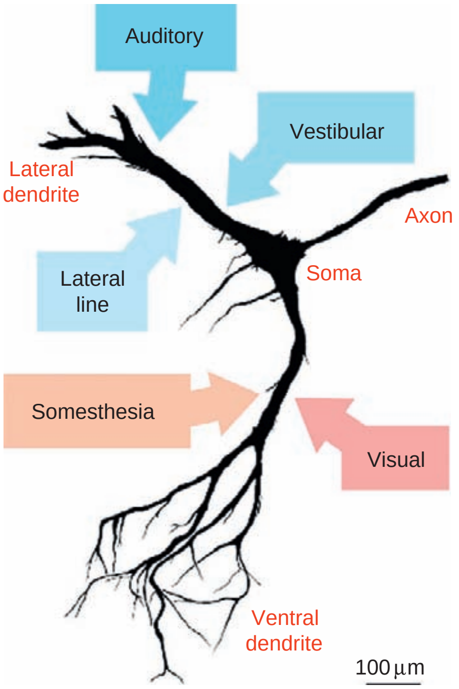

Figure 2 The projections of sensory afferents to the Mauthner cell dendrites are highly specified, as revealed by electrophysiological mapping experiments. The lateral dendrite processes stato-acoustic information, with the terminal fields of the auditory, vestibular, and lateral line systems localized to different dendritic regions. In contrast, the ventral dendrite is sensitive to visual and somatosensory stimuli. Goldfish Mauthner cell modified from Lee RK, Eaton RC, and Zottoli SJ (1993) Segmental arrangement of reticulospinal neurons in the goldfish hindbrain. *Journal of Comparative Neurology* 329: 539–556.

cell in rhombomere 4 seems to be functionally beneficial for the escape responses of fish, enabling a more efficient combination of speed and acceleration under water. This notion of a functional advantage, dependent in part on anatomical specializations, is emphasized by the finding that the amphibian Mauthner cells are identifiable only at the tadpole stage, and are either lost or significantly reduced in size during metamorphosis, when they become terrestrial.

The Mauthner Cell As Model Vertebrate Neuron

These uncommonly large cells are not only anatomically but also physiologically identifiable (see below) and have historically constituted a valuable experimental preparation. The large size of the Mauthner cell, the characteristic morphology of its soma and main dendrites, and its physiological identifiability and accessibility for intracellular microelectrode recordings combined to provide one of the first possibilities of exploring cellular and synaptic properties in a vertebrate neuron. While slice techniques now allow direct exploration of cellular properties in nearly every vertebrate brain structure, the Mauthner cells still provide the uncommon opportunity of correlating structure with function to study detailed cellular mechanisms. In particular, the use of the Mauthner cells and their identifiable synaptic inputs led to many insights into the mechanisms of synaptic transmission, including mechanisms of inhibition, transmitter release, and electrical transmission.

Inhibitory Mechanisms

As already noted, the Mauthner cell has served as a model for the discovery and elucidation of basic synaptic mechanisms. This advantage is derived from its *in vivo* identifiability, linked to a unique property of the axon cap, which is a sophisticated anatomical specialization restricted to the initial segment of the axon and amplifies the extracellular field produced by the action potential of the cell. In fact, this feature also underlies a unique form of inhibition that has made it possible to identify presynaptic inhibitory cells and to study their synapses in exquisite detail. Based on this property, Mauthner cells can be distinguished from thousands of other cells in the brain of fishes. This implies that from fish to fish, recordings can be obtained from the same neuron that was genetically determined to be the Mauthner cell, thereby providing a unique comparative advantage.

The special property of the axon cap is that it has a very high extracellular resistance, such that the Mauthner cell action potential, which can be antidromically evoked experimentally by a stimulating electrode on the spinal cord, is as large as 30 mV in the center of the cap (**Figure 3(a)**). The current associated with this field directly hyperpolarizes the membrane of a special class of interneurons, called ‘passive hyperpolarizing potential’ (PHP) cells; their impulses in turn electrically inhibit the Mauthner cell. These impulses are associated with a positive extracellular field, and both electrical inhibitions are mediated by field effects. That is, the electrical field produced by one neuron can modify the excitability of a nearby neuron without the existence of cellular contacts. In the case of the Mauthner cell, the positive extracellular electrical field produced by the synchronization of many PHP cells generates a mirror hyperpolarization in the initial segment, the region of the cell in which action potentials originate (**Figure 4(b)**). While field effects (also known as ephaptic interactions) have been observed to occur in some pathological conditions (i.e., hippocampus during seizures), the axon cap of the Mauthner cell truly represents a synaptic specialization, and thus this mechanism is considered the best example of electrical inhibition. Similar mechanisms are thought to operate in the cerebellum.

The electrical inhibition of the Mauthner cell was discovered first, by Furukawa and Furshpan, as

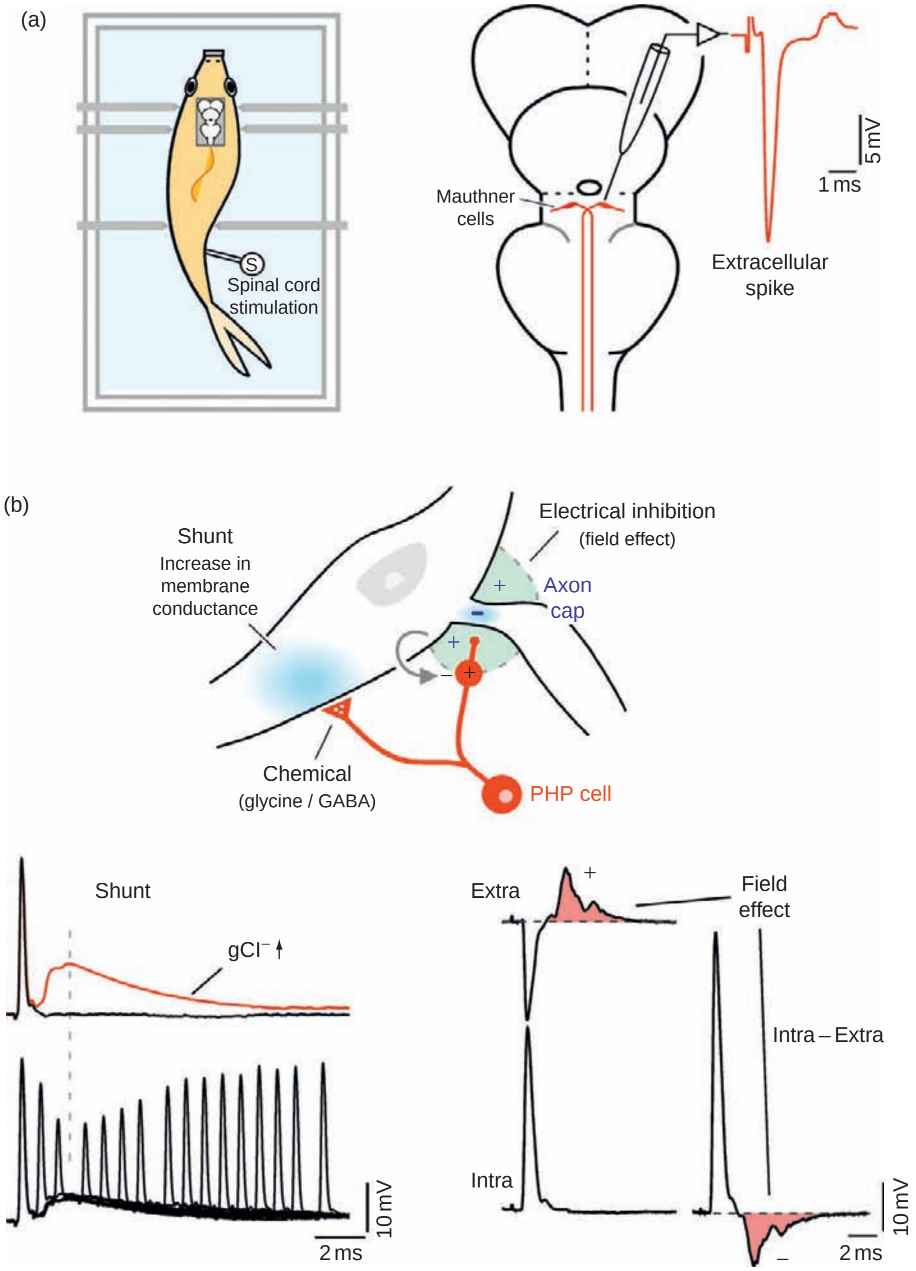

Figure 3 Hallmarks of Mauthner cell electrophysiology: inhibitory mechanisms. (a) Schematic of *in vivo* recording arrangement (left panel), with an immobilized and anesthetized fish in air. A bipolar electrode on the exposed vertebral column is used to antidromically activate the Mauthner axon while recording extra- or intracellularly from defined regions of the cell. Right panel shows the Mauthner cell electrophysiological signature that allows this localization, namely an antidromic action potential as large as -40 mV in the center of the axon cap that surrounds the cell's axon hillock and initial segment. This locus serves as a reference for all the other recording loci. (b) A special class of inhibitory interneurons, the PHP cells, mediates both electrical and chemical (glycinergic) inhibition of the Mauthner cell soma. Electrical inhibition is a consequence of failure of action potentials in PHP cells to actively propagate beyond the border of the axon cap and on the high electrical resistance of this region. It is signaled by an extracellular positivity in the center of the cap. Chemical inhibition, due to release of glycine, and possibly γ-aminobutyric acid activated (GABA) receptors, is the consequence of an increase in Cl^- conductance that shunts any currents generated in the Mauthner cell. Records below illustrate the electrical (right) and chemical (left) inhibitions evoked experimentally by antidromic stimulation of the Mauthner axon. The former is a frank hyperpolarization that follows the Mauthner spike and is revealed by computing the true transmembrane potential change, that is, the difference between the responses recorded intra- and extracellularly. The time course of the shunt produced by recurrent inhibition is manifested by the reduction in the amplitude of a second antidromic action potential, evoked at different intervals in the lower left panel. Note that the shunt mirrors the underlying increase in Cl^- conductance, which appear as a depolarization after Cl^- injections (red trace).

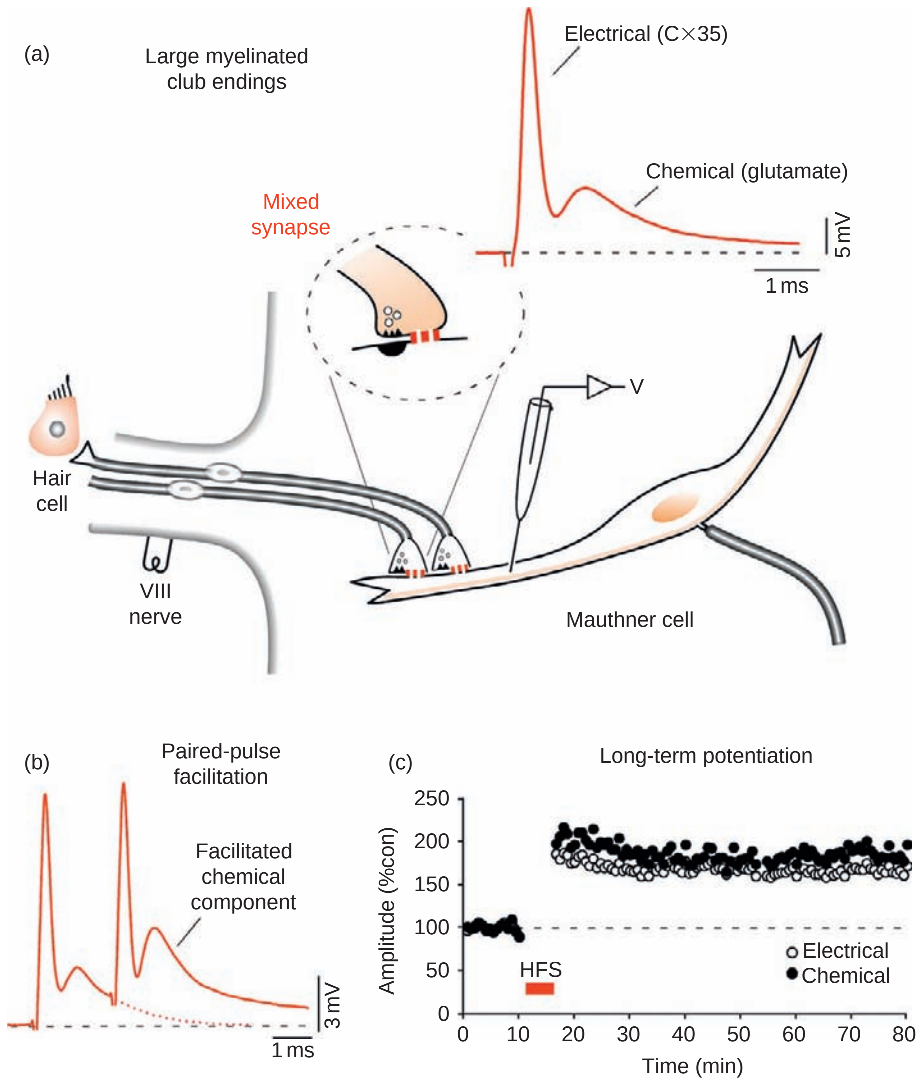

Figure 4 Club endings mediate mixed synaptic transmission. (a) Experimental arrangement showing VIII nerve auditory primary afferents (from saccular hair cells) terminating as club endings on the Mauthner cell lateral dendrite. (Inset) Both mechanisms of synaptic transmission, electrical (gap junction), and chemical (glutamatergic), coexist. VIII nerve stimulation evokes graded, mixed electrical and chemical synaptic potential. (b) Glutamatergic synapses at club endings exhibit paired-pulse facilitation. (c) High-frequency stimulation (HFS) of club endings (VIII nerve stimulation) leads to long-term potentiation of both the electrical and chemical components of the mixed synaptic response.

antidromic stimulation triggers a feedback activation of about 40 PHP cells, and their synchronous activity hyperpolarizes the Mauthner cell by about 10–15 mV. However, a major advance came when these cells were identified by the field effect from Mauthner cell activation, and it became apparent that their impulses also mediated glycinergic inhibition of the Mauthner cell. Thus, as shown in **Figure 3(b)**, action potentials in terminals of PHP cells produce a two-component inhibition of the Mauthner cell: a fast and brief electrical component followed by a slower and longer-lasting chemical component. The latter is due to the opening of Cl^- channels, and because the Cl^- equilibrium potential is close to the Mauthner cell resting potential, this inhibition does not itself produce a significant membrane potential change. Rather, the inhibition works by producing a shunting effect (i.e., synaptic conductance short-circuits the currents that are generated at adjacent excitatory synapses), which can be clearly appreciated by comparing the time course of the synaptic potential with that of the underlying conductance change (**Figure 3(b)**), evidenced in this case by a reduction in the amplitude of consecutive antidromic spikes obtained at different intervals. The Mauthner cell action potential, generated in the initial segment, is a convenient indicator of the cell's conductance. Because it propagates passively through the somatodendritic membrane, changes in the conductance of the cell alter its amplitude. As a footnote, the two electrical inhibitions are associated with fields of opposing polarities. This observation has driven home the point that the sign of a field effect can only be determined by computing the true transmembrane potential change, which is the difference between the potentials recorded intracellularly and extracellularly (**Figure 3**(**b**)).

Mechanisms of Transmitter Release

There followed a decade of research in which the properties of central inhibitory synapses were studied with paired presynaptic and postsynaptic intracellular recordings, as well as dye injections to expose fundamental properties of synaptic transmission and their morphological correlates. This breakthrough was achieved by combining physiological and ultrastructural data that were possible to collect due to the anatomical and physiological identifiability of the Mauthner cell and the afferent synapses of the PHP cells. Some basic properties discovered in this system include: (1) the quantal and probabilistic nature of transmitter release in the CNS, with the realization that at most one or two synaptic vesicles undergo exocytosis at a single synaptic site; (2) the first support for the concept that there is crosstalk between neighboring central synapses due to the lateral diffusion of transmitter; and (3) the evidence for activity-dependent plasticity of inhibition.

Mixed Electrical and Chemical Synapses at Primary Auditory Afferents

Because of their large size, characteristic myelinization, and dendritic localization, a group of auditory afferents constitutes the most recognizable synaptic input to the Mauthner cells. Such anatomical characteristics support high-speed impulse conduction and suggest that they likely provide the Mauthner cells with critical auditory information for the initiation of escape responses. First described by Bartelmez in 1915 in the catfish (*Ameiurus*), (**Figure 4**(**a**)), this population of ~90 large afferents (8–15 μm in diameter) originates in the rostral portion of the saccular macula (the main auditory component of fish ear) and runs in the posterior branch of the VIII nerve. Although each afferent issues a few substantially thinner branches, likely targeting other neurons in the hindbrain, the primary axon characteristically terminates as a large single terminal (about the same diameter as that of the parent axon) on the lateral dendrite of the Mauthner cell. These endings are known as large myelinated club endings or simply club endings.

A wealth of anatomical and electrophysiological data shows that club endings support both chemical and electrical modalities of transmission (**Figure 4**(**a**)). In fact, these contacts provided one of the first demonstrations of gap junction plaques and electrical transmission in the vertebrate central nervous system and, because of their accessibility, constitute a valuable model for exploring the properties of this modality of transmission. These gap junctions are formed by connexin 35, the fish ortholog of the widely expressed mammalian connexin 36, which is responsible for electrical coupling between many cell types, including neocortical inhibitory interneurons and inferior olivary cells.

From the electrophysiological point of view, a presynaptic impulse generates a mixed excitatory response in the Mauthner cell. The stimulation of the posterior branch of the VIII nerve, where these fibers run, evokes a gap junction-mediated electrical synaptic potential followed by a chemically mediated excitatory postsynaptic potential (**Figure 4**(**a**)). Due to the fast time constant of the Mauthner cell (~400 μs), the two components can be easily distinguished.

Chemical transmission is mediated by the release of glutamate, which activates both *N*-methyl-D-aspartate (NMDA)-activated glutamate receptors and non-NMDA receptors. Even at its relatively hyperpolarized resting potential (~−80 mV), the chemical component of the mixed synaptic response of the club endings on the Mauthner cell is normally mediated by the activation of both NMDA and non-NMDA receptors and, surprisingly, the NMDA component is almost as fast as the non-NMDA component. In contrast to most primary auditory afferent synapses, which are known to depress in response to multiple stimuli, glutamatergic synapses at club endings characteristically exhibit frequency-dependent facilitation (**Figure 4**(**b**)), suggesting the existence of unusual synaptic specializations in these teleost afferents.

While mixed synapses are often found in lower vertebrates, the combination of these two forms of transmission matches the functional role of club ending afferents in the Mauthner cell system. Electrical transmission provides speed and reliability of transmission (i.e., absence of synaptic delay and associated probabilistic mechanisms), and the presence of chemical transmission, with a relatively longer duration, allows temporal summation during repetitive responses in a cell in which the membrane time constant is unusually brief (**Figure 4**(**b**)). In fact, electrical component of the response predominates when naturalistic acoustic stimuli are used, suggesting chemical transmission might also have another functional role. Indeed, the advantage gained by combining electrical and chemical synapses is emphasized by the existence of important functional interactions between these two modalities of transmission. The most remarkable of these interactions is the induction by glutamatergic synapses of long-term activity-dependent changes in the efficacy of both chemical and electrical synaptic transmission. That is, not only the glutamatergic component but also the gap junction-mediated component of the mixed synaptic response undergo activity-dependent potentiation of their synaptic strengths in response to high-frequency stimulation of the VIII nerve (**Figure 4(c)**). This phenomenon provided the first example of activity-dependent plasticity of electrical synapses and the opportunity to explore its mechanisms in an accessible experimental model. The induction of long-term activity-dependent synaptic plasticity requires stimulation with brief trains, a protocol inspired by the natural bursting properties of these afferents. Induction also requires activation of NMDA receptors, leading in turn to a localized increase in the intracellular concentration of Ca^{2+} that activates the kinase Ca^{2+}-calmodulin-dependent kinase II (CaM-KII), which is necessary for the potentiations. Interestingly, another activity-dependent protocol has also been shown to lead to potentiation of the mixed synaptic response, suggesting that multiple mechanisms converge for the regulation of the strength of these important synapses. In this second case, the mechanism involves the production of endocannabinoids by the Mauthner cell and is indirectly mediated via the release of dopamine from nearby varicosities that in turn leads to potentiation of the synaptic response via a cyclic adenosine monophosphate (cAMP)-dependent protein kinase-mediated (PKA) postsynaptic mechanism. The increased synaptic gain of these auditory nerve synapses should sensitize a vital escape response, lowering its threshold to acoustic stimuli, and it likely represents a mechanism for modulating sensory-motor processing.

Summary

Because of their experimental accessibility, the Mauthner cells have provided important insights into basic mechanisms of cellular excitability and synaptic transmission. Despite the availability of modern techniques, which now allow direct exploration of cellular properties in slices of brain tissue, these cells will still provide the uncommon opportunity of directly correlating structure with function to study detailed cellular mechanisms. Moreover, the rich and singular physiological properties of the Mauthner cells will continue to provide a unique, fascinating window for the discovery of basic mechanisms of brain function.

Glossary

Command neuron A single neuron whose activation evokes an endogenous, naturally occurring behavior. Because they often receive a convergence of integrative and sensory inputs and are connected to specific efferent systems, command neurons have the property of acting as decision-making cells.

Directional hearing Ability to identify the location or origin of sound in space.

Electrical resonance Ability of neurons to respond selectively to inputs at preferred frequencies, supporting subthreshold oscillatory behaviors. Oscillatory properties of neurons can serve as substrates for coordinating network activity around a particular frequency and are generated by a variety of ionic mechanisms.

Escape response A sudden acceleration maneuver (i.e., a fast start) as a response to a threatening stimulus.

Excitatory input Synaptic input that increases the probability of initiating an action potential in the postsynaptic neuron.

GABAergic Synapse that uses GABA as its neurotransmitter, the major inhibitory neurotransmitter across the central nervous system.

Glycinergic Synapse that uses glycine as its neurotransmitter, one of the major inhibitory neurotransmitters in the spinal cord and the brainstem.

Inhibitory input Synaptic input that decreases the probability of initiating an action potential in the postsynaptic neuron.

Sensory–motor processing Aspects of vertebrate behavior indicate that both motor actions and sensory processing are inextricably linked. Alterations in sensory–motor processing are thought to underlie various cognitive dysfunctions.

Time constant Index that expresses how fast the membrane potential of a neuron changes in response to changes in an applied transmembrane current. The time constant (τ) can be calculated as the product between membrane resistance and membrane capacitance. As with other RC circuits, it expresses the time needed to charge the capacitor through the resistor to ~63% of full charge, or to discharge it ~37% of its initial voltage (values derived from the mathematical constant *e*). Thus, due to the presence of the membrane capacitance, the voltage across the membrane usually lags behind current injections. Time constants are usually fast in neurons that require high temporal precision.

Introduction

Together with its use as an experimentally accessible model neuron for the study of cellular mechanisms (**see also Brain and Nervous System**: Physiology of the Mauthner Cell: Discovery and Properties), the Mauthner cell also constitutes a model for the study of cellular determinants of vertebrate behavior. While activity of the Mauthner cell has been correlated with a number of behaviors, its role as the principal neuron in the organization of escape responses has been documented in detail (**see also Buoyancy, Locomotion, and Movement in Fishes**: Fast Start). The evidence supporting the participation of the Mauthner cell in escape and voluntary responses will be reviewed here, and the shared aspects of the neural network that make these behaviors possible will be described.

Functions of the Mauthner Cell

Escape Responses

Initial speculations about the behavioral function of the Mauthner cell centered around the likelihood that it controlled or coordinated swimming activities, in part because its axon extended the length of the spinal cord. However, Zottoli provided strong evidence in 1977, subsequently reinforced by Eaton and his colleagues, for its central role in the auditory-evoked escape, by recording the Mauthner cell action potential extracellularly from the axon cap in free-swimming goldfish (*Carassius auratus*): the recorded Mauthner cell never fired during swimming, but always fired when a loud and abrupt sound was rapidly followed by a fast body turn to the side, contralateral to that cell. This escape response is referred

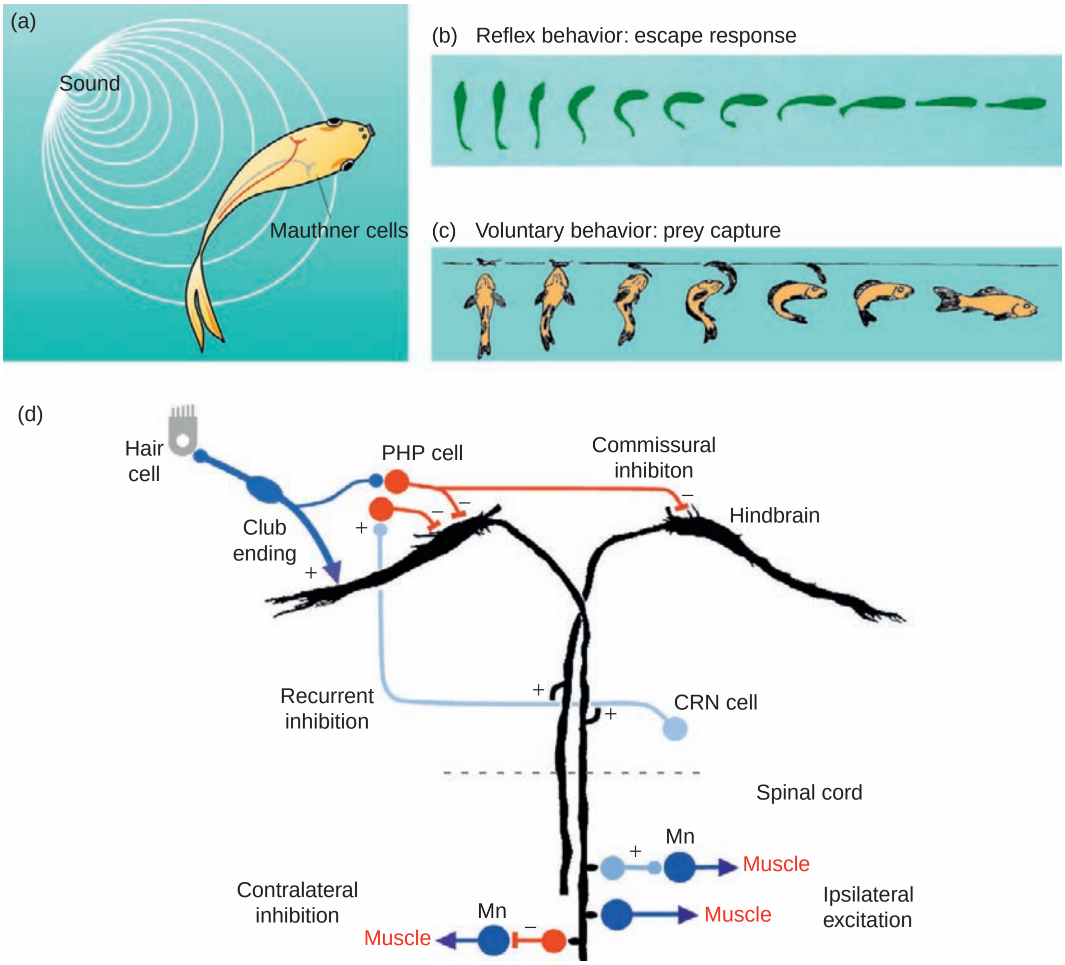

Figure 1 Functional role of unilateral Mauthner cell activation. (a) Acoustic startle response is directional, due to excitation of the ipsilateral Mauthner cell (left). (b) The resulting escape response takes the form of a C-bend and propels the fish away from the threatening stimulus (silhouettes captured at 5 ms intervals). (c) The same output circuits can be used for prey capture, or feeding (middle five drawings at 16.6 ms intervals. (d) Backbone of the input and output networks brought into play by a sound from the left. Excitation of hair cells in the left inner ear activates feedforward excitation and inhibition of the ipsilateral Mauthner cell, as well as feedforward inhibition of the contralateral cell. At the spinal level, the resulting pattern of contralateral activation and ipsilateral deactivation of motoneurons (Mn) causes contraction of contralateral trunk musculature and relaxation of the ipsilateral musculature (goldfish Mauthner cells). (b) Modified from Eaton RC, Bombardieri RA, and Meyer DL (1977) The Mauthner-initiated startle response in teleost fish. *Journal of Experimental Biology* 66: 65–81. (c) Modified from Canfield JG and Rose GJ (1993) Activation of Mauthner neurons during prey capture. *Journal of Comparative Physiology A* 172: 611–618. (d) Modified from Lee RK, Eaton RC, and Zottoli SJ (1993) Segmental arrangement of reticulospinal neurons in the goldfish hindbrain. *Journal of Comparative Neurology* 329: 539–556.

to as a‘C-start’, as the body of the fish takes the form of that letter (**Figures 1**(**a**) and **1**(**b**)), and it can be easily examined in any household by simply tapping on the wall of a fish tank. However, it was found that the recorded cell did not fire when the C-start was in the ipsilateral direction. These correlations are consistent with the trajectory of the Mauthner axon, which crosses the midline before descending in the spinal cord. Hence, the conclusion was reached that only one Mauthner cell fires once before an escape, and which cell fires determines the initial direction of the behavior. As described in the following section, the auditory-evoked escape is typically directional, that is, directed away from the location of the aversive stimulus.

By combining extracellular Mauthner cell recordings with electromyography and high-speed video, it has been possible to apportion the timing of the auditory-evoked escape to the successive steps in the Mauthner cell circuits. Here we stress its speed by noting that at room temperature the total time from sound onset to the first detectable movement of body musculature is ∼15 ms, and this timing has been important in addressing a question fundamental to neuroscience. Specifically, it has long been postulated that there exist command neurons, cells that are both necessary and sufficient for a behavior. The Mauthner cell comes closest to fitting that definition: a single action potential in one Mauthner cell can trigger a C-start with initial kinetics comparable to that evoked with natural stimuli. That observation might support the requirement for sufficiency, but in fact, later components of the escape evoked by directly activating one Mauthner cell are less complex than those produced by the natural stimulus. Also, the results of testing for necessity are open to debate, as deleting one Mauthner cell does not block the C-start but does delay the response and decreases the maximal angular velocity, both of which could have catastrophic consequences for the survival value of an escape response. The appropriate perspective might be that there is a parallel (perhaps multiple) system(s) that can both compensate for the Mauthner cell, if absent, and also have a role in the execution of the Mauthner-initiated escapes.

The considerations above have led to the notion of a brainstem escape network that is more extensive than the Mauthner cell and its associated circuitry. Indeed, experiments in zebrafish (genus species) embryos, where it is possible to record noninvasively from individual identified neurons and to selectively laser ablate them, have focused on the role of the Mauthner cell and of its identifiable homologs in adjacent rhombomeres, the MiD2cm, and MiD3cm neurons. These studies have shown that specific homologs are differentially active depending on whether the aversive stimulus is directed toward the head or tail of the fish. While stimuli coming from the head activate all three neurons, those coming from the tail only activate the Mauthner cell, supporting the notion of their organization into functional groups. These findings provided a basis for understanding some variable aspects of the escape behavior that are expressed after the initial C-start. For example, the final direction taken by the fish depends upon the initial angle between the stimulus source and body orientation. Also, escapes evoked by stimuli originating from behind the fish include a mid-course direction change, so that the fish can escape by forward propulsion rather than continue to turn toward the predator.

In addition to its role in auditory-evoked behaviors, the Mauthner cell is also central to other types of escapes, a feature that is consistent with its identification as a reticulospinal neuron responsive to multiple modalities of sensory information. For example, the ventral dendrite is responsive to visual inputs relayed to it from the retina via the pretectum and optic tectum. While there is minimal support for the notion of short latency visual-evoked escapes in fish, looming stimuli that mimic the shadows cast by the approach of diving birds, natural stimuli, are very effective in triggering Mauthner-mediated C-starts. Looming auditory stimuli, which would be associated with predation from other fish, are also effective. In contrast to C-starts evoked by abrupt acoustic stimuli, the latency of the behavior triggered by the looming stimuli is of the order of hundreds of milliseconds. Yet, it has the same kinematics once it is initiated. It can be postulated that noxious tactile and olfactory inputs may also trigger the escapes. Finally, it should be emphasized that although specific sensory modalities predominate in evoking certain types of escape behaviors, most escape-triggering stimuli are likely to be multisensory in nature and include the participation of other modalities.

Prey Capture and Voluntary Behavior

As mentioned above, the Mauthner cells are known to initiate the characteristic C-start escape response of many fish. There exists, on the other hand, an increasing amount of evidence indicating that in species that exhibit C-start escapes, the Mauthner cell might play a role in other behaviors.

When the activity of the Mauthner cell was monitored using chronically implanted electrodes while fish were surface feeding on live crickets, it was observed that this cell became active when the fish performed a C-shaped flexion in association with the terminal phase of prey capture (**Figure 1**(**c**)). Mauthner-initiated flexions during feeding rapidly served to remove the prey from the water's surface, also minimizing the fish's own susceptibility to surface predation. Other behaviors that might involve the contribution of the Mauthner cells include hatching, social interactions, feeding, intercepting, and capturing targets shot down from above, airborne behaviors in flying fish, and upstream swimming in salmon. None of these behaviors, however, have yet been directly correlated with the activation of this cell. Interestingly, goldfish were observed to strike an object while executing voluntary C-bends that are similar to their C-start escape responses, suggesting that the Mauthner cells can be activated voluntarily, even in the absence of predator or feeding-associated stimuli. Thus, the Mauthner cell is known to be active in the context of at least two general types of behaviors, involuntary and voluntary (predatory escape and prey capture), which have a significant amount of circuitry in common.

The Mauthner Cell Network and Its Functional Properties

The escape behaviors that have been studied most extensively are those evoked by abrupt sounds in goldfish or vibratory tactile stimuli in zebrafish and, therefore, our knowledge of the functional structure of the underlying network is primarily based on these modalities. The organization of the escape circuit supports the notion of two parallel competing systems, represented by the right and left Mauthner cell and their respective inputs, capable of triggering escapes in opposite directions. As previously mentioned, large primary auditory afferents, known as Club endings, provide each Mauthner cell with essential excitatory information for the initiation of auditory-evoked escape responses (**Figure 1**(**d**)). These afferents activate a feedforward inhibitory network of passive hyperpolarizing potential (PHP) interneurons. PHP cells (**see also Brain and Nervous System**: Physiology of the Mauthner Cell: Discovery and Properties) represent a population of neurons that regulate the excitability of the Mauthner cell. There are two classes of PHP cells. One class, the 'commissural' PHP neurons, provides the substrate for a feedforward inhibitory network. The interplay between excitatory and inhibitory inputs to the Mauthner cell is thought to influence both the threshold and direction of the escape responses, where feedforward inhibition plays a determinant functional role. Only powerful excitatory inputs that overcome feedforward inhibition are thought to be capable of firing the Mauthner cell. In the case of directionality, the characteristic bilateral distribution of feedforward inhibition, with its contralateral commissural projections, allows these neurons to influence the excitability of both cells (**Figure 1**(**d**)). The activation of this feedforward inhibitory network by other sensory inputs remains unexplored.

In contrast to sensory inputs of the Mauthner cell, which have a high degree of variability in terms of connectivity (di- vs. multisynaptic), the output network of the Mauthner cell is likely to be common to all C-shape behaviors. At the cranial level, activation of cranial relay neurons (CRNs) activates contralateral inhibitory neurons called 'collateral' PHP cells, the second class of PHP cells, providing the substrate for feedback inhibition. These cells form feedback networks with each Mauthner cell, as well as the reciprocal inhibitory networks. Thus, when one Mauthner cell is activated, the other is inhibited by the PHP feedback network (**Figure 1**(**d**)), which also inhibits the active cell to prevent further discharges. In addition, CRN cells activate circuits that lead to bilateral closure of the opercula, rendering the fish more hydrodynamic during the execution of the escape. At the spinal level, because the crossed Mauthner axon reliably activates its follower neurons, the activation of the Mauthner cell results in a massive unilateral excitation of interneurons and motoneurons on the opposite side of the body, which, combined with a simultaneous inhibition of ipsilateral motorneurons, leads to a tail flip of the fish, representing the initial stage of the so-called C-start (**Figure 1**(**a**)).

The properties of escape behaviors suggest that this neural network does not support simple reflexes. For example, in the goldfish auditory evokes response, both Mauthner cells are brought close to threshold in only a few milliseconds, yet the response typically is appropriately directional in 75–85% of the trials, if the fish is in an open field. That is, the initial direction of movement is to the side opposite the sound source. However, directional hearing in fish is poorly understood, in that fish are transparent to sound pressure. More specifically, because the fish body and water have the same acoustic density, bilateral external ears would not detect changes in pressure. The receptor organs are thus encased within the head of the animal and accessible to sounds from all directions. Furthermore, the presence of a single pressure-detecting organ that connects to both inner ears, such as the swimbladder in hearing specialists, also does not seem to support directional hearing (**see also Hearing and Lateral Line**: Auditory System Morphology and Biomechanics of the Inner Ear in Fishes). The apparent lack of directionality in the acoustic information prevents the existence of interaural time differences, such as those underlying directional hearing in mammals (**see also Hearing and Lateral Line**: Sound Source Localization and Directional Hearing in Fishes). Thus, the question arises of how the Mauthner cells detect stimulus direction. The two models that might explain this puzzle, at least in the context of the C-start, both invoke a critical role for the feedforward inhibitory pathway. In one, the PHP cells are part of logic gates that compare sound pressure and acceleration signals from the left and right inner ears, and in the second, phase locking of PHP cell activity accomplishes the necessary discrimination.

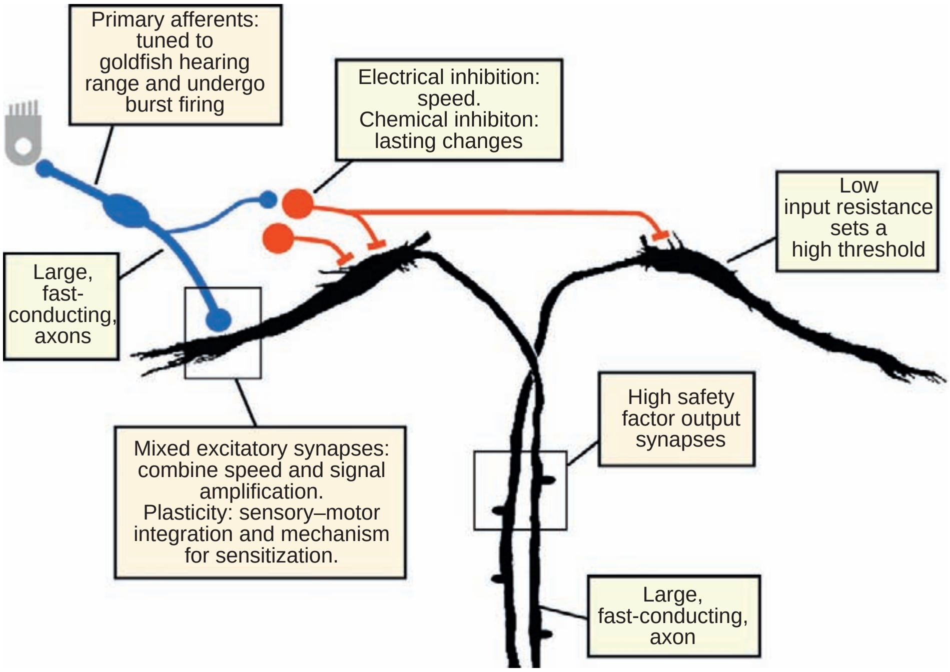
Another remarkable and perhaps underappreciated feature of the escape behavior is the degree of uncertainty in the decisions reached by the Mauthner cell networks, in that the response is not always appropriately directional and there is no guarantee that even a strong threatening stimulus will always evoke a C-start. Interestingly, these uncertainties are presumably adaptive, as predictability would allow predators to anticipate the fish's response to a threat and to then reliably correct their attack trajectories. This adaptive property is best illustrated by the scaling function that is computed by the Mauthner cell for visual looming stimuli and determines the timing of the C-start. This function peaks and then declines while the stimulus is still approaching, providing the basis for a significant number of trials when the fish does not respond. This feature, coupled with evidence for bilateral Mauthner cell excitation for all naturalistic stimuli studied so far, stresses the complexity of this supposedly simple system and further supports the notion of two parallel and competing Mauthner cell systems, right and left.

Cellular Properties as Functional Specializations

The best-known function of the Mauthner system is its role in organizing sensory-evoked escape responses, most notoriously those triggered by sound. The morphological characteristics of the Mauthner cell as well as the circuit in which it is embedded (i.e., sensory inputs and motor outputs) seems highly appropriate to this function. Together with these network factors, a number of relevant cellular properties constitute important determinants of this behavioral response. These properties, often called 'specializations', denote the adaptation of neurons to the requirements of their particular functions. In this case, the synaptic and membrane properties of the cells involved in the Mauthner cell network match the functional requirements not only of the sound-evoked escape response but also of escapes evoked by visual looming stimuli, as well as for prey capture behaviors, particularly speed, reliability combined with an element of uncertainty, and a high behavioral threshold (**Figure 2**).

As a first example, the escape response has a characteristic high threshold, presumably because of its dramatic behavioral consequences, and this feature is supported by the cellular properties of the Mauthner cells. Specifically, the low input resistance, short-time constant, and hyperpolarized membrane potential (~–83 mV) of the Mauthner cell act in concert to prevent the spontaneous occurrence of this behavior as a consequence of weak, environmental noise. That is, they guarantee a high behavioral threshold. This property also derives from the strong afferent or feed-forward inhibition of the Mauthner cell that is evoked by the same sensory stimuli that drive excitation of this neuron.

Another functional adaptation is that Mauthner cells are unable to fire repetitively, an otherwise inconvenient feature for a cell in which a single action potential initiates an escape response that lasts several hundreds of milliseconds. In other words, a second C-start would be likely to defeat the purpose of the initial behavioral reaction. It has been proposed that this intrinsic membrane property relies on the presence of K^+ channels of the K_v1 family, known to antagonize repetitive firing. Again, specialized membrane properties are complemented by a powerful feedback synaptic inhibition that also blocks the firing of the other Mauthner cell after the escape is triggered. Further, the large diameter and heavily myelinated Mauthner axons, which span the length of the spinal cord, guarantee fast conduction of action potentials and are connected to their output targets via high-safety factor synapses, that is, synapses with a high probability of generating a postsynaptic action potential in response to a presynaptic one. Interestingly, these strong output synapses are mediated by acetylcholine, which acts on a combination of post-synaptic cholinergic receptors.



Primary afferents: tuned to goldfish hearing range and undergo burst firing
Electrical inhibition: speed. Chemical inhibiton: lasting changes
Low input resistance sets a high threshold
Large, fast-conducting, axons
Mixed excitatory synapses: combine speed and signal amplification. Plasticity: sensory–motor integration and mechanism for sensitization.
High safety factor output synapses
Large, fast-conducting, axon

Figure 2 Schematic of Mauthner cell connections, annotated to indicate some of the synaptic and membrane properties that match the functional requirements of both the sound-evoked escape and the prey capture behaviors, particularly speed, reliability, and a high but modifiable behavioral threshold (goldfish Mauthner cells). Modified from Lee *et al*. (1993).

The most important inputs to the Mauthner cell, such as those carrying auditory information for the initiation of the escape response, also have special cellular specializations (**Figure 2**). The existence of a single terminal in the large diameter and heavy myelinated auditory afferents (the Club endings) constitutes by itself a functional specialization. The lack of terminal branching provides safe impulse conduction, eliminating the possibility of branch point failures and of slower conduction through thinner processes, thus guaranteeing faster transmission and higher temporal fidelity. Consistent with these anatomical features, the dendritic arborization of these afferents at the saccular macula is also significantly simpler and with thicker processes than those of other afferent types. Thus, the relatively simpler anatomical features of Club ending afferents are likely to represent a functional specialization advantageous to their vital behavioral role.

In addition to these anatomical features, both intrinsic synaptic and membrane properties contribute to shaping the function of this relevant input. As previously mentioned, the combination of electrical and chemical synapses is particularly beneficial, as electrical transmission provides speed and reliability of information transfer while the relatively longer-lasting chemical component allows temporal summation during repetitive responses and provide the means for induction of long-term activity-dependent potentiation in both forms of transmission. Such plastic properties are unusual for synapses of a primary auditory afferent, and they likely represent a mechanism for modulating sensory–motor processing and therefore a clear cellular specialization of these contacts, whose function is to provide a decision-making neuron such as the Mauthner cell with critical sensory information.

Finally, the intrinsic membrane properties of these afferents seem also adapted to their function. Specifically, Club ending afferents are endowed with electrophysiological properties that favor the generation of high frequency (200–600 Hz) bursts in response to strong depolarization. Because the Mauthner cells are not capable of repetitive firing (see above), rather than relaying timing information via one-to-one spiking correlations, the ability to generate high-frequency bursts most likely represents a functional specialization of these afferents that provides the Mauthner cell with adequate (phase-locked) patterns of synaptic activation for the initiation of an escape response. Bursts, which are often generated by the interaction of synaptic inputs with intrinsic membrane properties, are thought to represent reliable neural codes during information processing, and they play special roles in the induction of synaptic plasticity. The generation of bursts in response to abrupt strong acoustic stimuli seems particularly advantageous to the Mauthner cell system since, in contrast to a single action potential, they produce a prolonged synaptic response that can efficiently depolarize the large and unusually low input resistance Mauthner cell. In addition, bursts are required for the induction of activity-dependent potentiation of the synaptic strength of these endings.

The bursting properties critically rely on the interplay between a persistent Na^+ current and an A-type K^+ current. Furthermore, the interaction between these conductances with the membrane's passive properties supports the presence of electrical resonance, whose frequency preference is consistent with both the effective range of hearing in goldfish and the firing frequencies required for synaptic facilitation, the latter being obligatory for the induction of activity-dependent changes. Thus, membrane properties allow these afferents to translate behaviorally relevant, naturally occurring auditory signals into patterns of activity that match the requirements of their fast and highly modifiable synapses.

Inhibitory inputs also present remarkable specializations that are adapted to their function. Inhibitory interneurons are capable of exerting powerful inhibition of the Mauthner cell via a combination of mechanisms (**Figure 2**). The unusual electrical inhibition, based on field effects, produces fast and short-lasting inhibition of the Mauthner cell by targeting the initial segment of this cell, where action potentials are initiated, providing speed and adequate temporal resolution. In addition, glycinergic and GABAergic synapse contacts produce longer-lasting inhibitory action by producing a more profound reduction in the excitability of the cell, via an increase in conductance of chemically gated Cl^- channels. The probability of release from the glycinergic terminals is relatively high, maximizing the initial strength of both the feedforward and feedback inhibitions, thereby supporting the high behavioral threshold and helping to prevent repetitive Mauthner cell firing, respectively. In addition, feedforward inhibition depresses in the same frequency range that afferent excitation facilitates, properties that aid in reaching threshold and evoking the escape.

Summary

Our current knowledge indicates that the Mauthner cells are involved in escape behaviors that are essential for the survival of fish. These escape responses can be triggered by a variety of sensory inputs, most prominently auditory. Based on the connectivity of the Mauthner cell axon at cranial and spinal cord levels, the activation of this cell produces a tail flip (C-start), which constitutes the initial phase of the escape response. The properties of the escape network are supported by singular cellular and synaptic properties that endow the system with speed and functional flexibility. However, a full understanding of their functional role remains undetermined. A growing body of evidence suggests that the Mauthner cells are involved in a number of voluntary behaviors. Furthermore, the fact that fish often execute motor behaviors that are reminiscent of the C-start raises the possibility that these cells could be involved in a wide range of functions. The use of zebrafish, where it is possible to combine physiology with sophisticated methods of behavioral analysis and genetic manipulations, promises to bring our understanding of the function of the Mauthner cells and its use as cellular model to new, exciting, levels.

Glossary

Adrenergic A general term pertaining to processes or structures related to catecholamines. For example, neurons that release noradrenaline as transmitter; catecholamines binding to adrenergic receptors (adrenoceptors), and adrenergically activated (catecholamine-activated) physiological processes.

Autonomic nervous system A collection of motor neurons (ganglia) ordered segmentally from cranial to caudal levels. The system controls the inner organs (viscera) through reflexes without conscious control.

Catecholamine Any of a class of amines derived from a catechol that acts as chemical messangers (a hormone or neurotransmitter). The main catecholamines are dopamine, adrenaline, and noradrenaline and these are secreted by neurons of the autonomic nervous system or specific chromaffin cells of the head kidney.

Cholinergic A general term pertaining to processes or structures related to acetylcholine. For example, neurons that release acetylcholine as transmitter. Nicotinic and muscarinic receptors are cholinergic receptors because they bind acetylcholine. Cholinergic synapses are found in both the central and peripheral nervous systems.

Cranial autonomic nerve Autonomic nerve starting in the cranial (head) region of the CNS.

Enteric nervous system The part of the autonomic nervous system contained within the gastrointestinal wall.

Ganglion A collection of nerve cell bodies of similar function. A ganglion is a type of nucleus but often refers to structures in the peripheral nervous system. An exception is the basal ganglia that are nuclei of the telencephalic subpallium.

Parasympathetic nervous system Autonomic pathways in the cranial and sacral nerves.

Peptidergic Neurons that release a peptide as transmitter.

Spinal autonomic nerve Autonomic nerve initiating from the spinal cord region of the CNS.

Sympathetic chains Paired strings of ganglia, more or less connected longitudinally, that run parallel to the spinal column.

Sympathetic nervous system Autonomic pathways from the thoracic and lumbar segments of the (mammalian) spinal cord.

Introduction

The term autonomic nervous system (ANS) was proposed by John Newport Langley near the end of the nineteenth century, and the suggested terminology has well withstood the ravages of time – at least for mammals. Langley subdivided the ANS into three parts: (1) the sympathetic nervous system, where the pathways leave the thoracic and lumbar segments of the spinal cord, (2) the parasympathetic nervous system, where the pathways leave in cranial nerves III, VII, IX and X, and also in the sacral nerves, and (3) the enteric nervous system (ENS), which is the local nervous system within the wall of the gut. (**see also Integrated Function and Control of the Gut**: Nervous System of the Gut).

In his original subdivision, Langley noted that for the sympathetic and parasympathetic systems, each autonomic pathway consists of two neurons known as preganglionic and postganglionic. At the connection between the two neurons of each pathway, the nerve terminals of the preganglionic neuron release a transmitter substance that excites the soma (cell body) of the postganglionic neuron. The postganglionic somata normally form clusters; much like bunches of grapes, called ganglia – hence the terminology that simply means before the ganglion and after the ganglion.

Langley also noted that the axons of the preganglionic neurons in the sympathetic system were short, while the axons of the postganglionic neurons were long. The reverse is true for the parasympathetic pathways, where the ganglia lie close to, or within the walls of the target organs. This is true for both the cranial and the sacral pathways, which is the reason why the pathways from the most anterior and the most posterior part of the CNS are lumped together as parasympathetic.

In the nonmammalian vertebrates, however, the original subdivision made by Langley is imperfect, because it is generally impossible to separate a lumbar from a sacral region along the spinal cord. This is certainly true for the fish from different groups. Therefore, it is better to refer to cranial autonomic pathways, which are identical to the cranial part of the parasympathetic system in Langley's terminology, and spinal autonomic pathways for all pathways leaving the spinal cord – that is, the sympathetic system, and the sacral parasympathetic system in Langley's terms.

The most advanced – or tetrapod-like – features of the ANSs of the different groups of fish are found in the (few) teleost species that have been examined. The descriptions of the basic anatomy of the ANS in cyclostomes, elasmobranchs, teleosts, and dipnoans are supplemented by brief presentations of autonomic nerve function in the control of two systems only: the heart and the iris of the eye (see later). For detailed accounts of the anatomy and functions of the autonomic control systems in fish, the reader is referred to the 'Further reading' section at the end of this article.

The ANS and Chromaffin Tissue

Closely related to the ANS is the chromaffin tissue, which consists of catecholamine-storing cells with many of the characteristics of adrenergic neurons of the ANS. Just like the adrenergic neurons of the ANS, these cells can synthesize, store, and release noradrenaline and/or adrenaline. The release is not from specialized nerve endings directly on top of the target cells as with the autonomic neurons, but instead into the bloodstream. This makes the chromaffin cells formally endocrine in function.

The similarity between the chromaffin cells and the adrenergic neurons runs further. In both cases the cells are controlled by preganglionic neurons that release acetylcholine as transmitter substance (**Figure 1**). In some cases, it is also possible to discern a third type of adrenergic cell: chromaffin cells intermingled with cells of the target tissue, for example, heart muscle cells (see later). These chromaffin cells release their amines to the neighboring tissue, and are therefore neither truly neurocrine (i.e., neurons) nor endocrine, but are often referred to as paracrine.

The ANS of Different Fish Groups

There are great similarities in the anatomical arrangement of the ANS in all vertebrates except, possibly, the cyclostomes where the structure and function of the system need further elucidation. The ANS of teleosts is

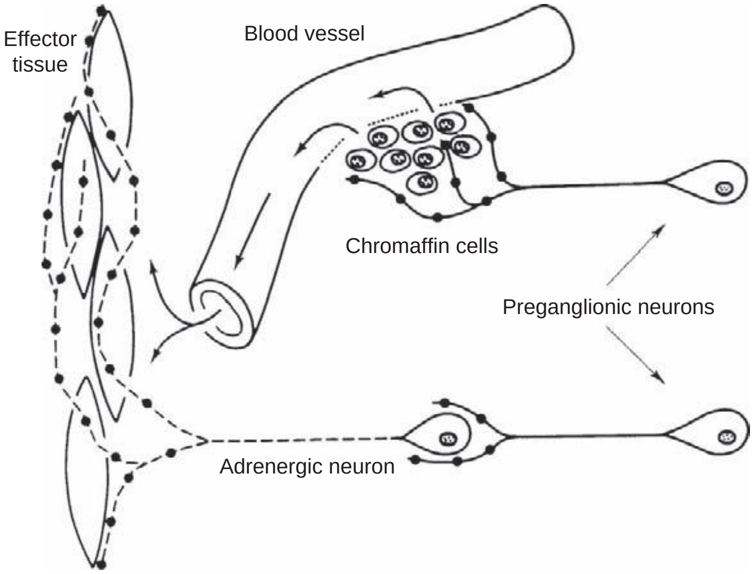

Figure 1 An adrenergic control of tissues and organs by the ANS can occur either by an innervation of catecholamine-containing chromaffin cells, or by a traditional autonomic nervous pathway, where the postganglionic neurons are adrenergic. The chromaffin cells and the adrenergic neurons share many features in catecholamine synthesis, storage, and release. Reproduced from Fig. 1 in Nilsson S (1984) Adrenergic control systems in fish. *Marine Biology Letters* 5: 127–146, with permission from Elsevier Science Publishers BV.

very similar to that in the tetrapods, while elasmobranchs show some less advanced features. The ANS of other fish, such as ganoids, is not well known, and it is worth remembering that the general view of the structure and function of the ANS in the different fish groups rests on more or less intense studies of only a handful of species. The much generalized patterns presented here, therefore, should be best enjoyed with a pinch of salt. Of the three divisions of the ANS, the ENS of fishes is well described in **Integrated Function and Control of the Gut**: Nervous System of the Gut, and will not be discussed further here.

Cyclostomes

As already mentioned, the ANS of the two cyclostome groups, hagfish (myxinoids) and lampreys (lampetroids), is not well known. At least one main reason for this is probably that the organization is less coherent than in the other fish groups. The normal pattern in the vertebrates is that autonomic pathways from the spinal cord leave via the ventral roots of the spinal nerves, but in the cyclostomes there is also a dorsal root outflow.

In hagfish, there is no extrinsic innervation of the heart, although cardiac control via intrinsic chromaffin cells has been well documented (see later). In fact, the best and clearest evidence for any control via the ANS in hagfish is a well-developed cholinergic, vagal control of the gallbladder! (**see also Hagfishes and Lamprey**: Hagfishes).

Lampetroids possess an autonomic innervation of the heart via the vagus but, interestingly, the effect of vagal stimulation is a stimulation of the heart – quite the opposite to vagal effects on the heart of all other vertebrates (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development, Lampreys: Environmental Physiology).

Elasmobranchs

An ANS that more or less follows the plan of the other vertebrates is found in the elasmobranchs. The seminal work of John Z Young in the early 1930s included both anatomical and functional studies in teleosts and elasmobranchs. In this work, Young made use of pharmacological tools – drugs that were used to elucidate the nature of the autonomic transmitter substances involved and consequently the functional patterns of the innervation.

Cranial autonomic pathways in the cranial nerves III (oculomotor) and X (vagus). Although tear glands and salivary glands are absent in elasmobranchs, pathways in cranial nerve VII (facial) and IX (glossopharyngeal) have been postulated and may control the pharynx. Oculomotor pathways synapse in the ciliary ganglion and postganglionic fibers control the iris (more about this later), and the vagal pathways control the heart and the gut. The spinal autonomic system (the sympathetic) shows paired segmental ganglia that are not always longitudinally connected to form sympathetic chains, as is the case in teleosts and most tetrapods. Preganglionic fibers from the spinal cord synapse with postganglionic neurons in the segmental ganglia, and several sets of splanchnic nerves (anterior, mid-, and posterior) run to the viscera. The most anterior sympathetic ganglia are relatively large, and comprise both cell bodies of postganglionic autonomic neurons and clusters of chromaffin cells. These anterior ganglia are known as axillary bodies, originally described as Axillar-Herz. They lie within the dorsal venous sinuses, and catecholamines released from the chromaffin cells will rapidly reach the heart, and subsequently the gills.

The general design of the ANS in elasmobranchs is shown in **Figure 2**.

Teleosts

The teleost ANS follows relatively closely the general vertebrate plan, as shown in most textbooks on mammalian and, especially, human anatomy/physiology (see also **Figure 2**). One of the most striking deviations from this plan is the lack of autonomic pathways in the facial (VII) and glossopharyngeal (IX) cranial nerves – a deficiency most likely related to the lack of tear glands and salivary glands. Autonomic fibers do, however, run in the oculomotor (III) nerve to the ciliary ganglion and the eye and in the vagus nerve (X) to the gills, heart, gut, and swimbladder (in fish that possess a swimbladder).

A second discrepancy from the plan is the cephalic portion of the sympathetic chains. These run forward into the head region, with sympathetic chain ganglia in close contact with the cranial nerves. The autonomic pathways in the cranial nerves are thus mixed, with both cranial autonomic (parasympathetic) and spinal autonomic (sympathetic) pathways running together. For this reason, the vagus nerve (X) is sometimes referred to as a vagosympathetic trunk.

An innervation of chromaffin tissue in the walls of the posterior cardinal veins by preganglionic spinal autonomic fibers has been demonstrated. Electrical stimulation of these nerve fibers does, indeed, produce a release of adrenaline from the chromaffin stores in the Atlantic cod (*Gadus morhua*). Similar to the situation in the elasmobranchs, the catecholamines released would immediately reach the heart via the blood stream, and shortly after the gills.

It was argued earlier that the distinction between the classical sympathetic and sacral parasympathetic portions makes little sense, and the mix of the two portions in the posterior parts of the teleost sympathetic chains can be illustrated in **Figure 3**. Relatively small cell bodies occur in the chain ganglia, while a bit more peripherally in the posterior splanchnic nerve along the ureter, a vesicular ganglion with somewhat larger nerve cell bodies can be found. The small cells in the chain ganglia contain

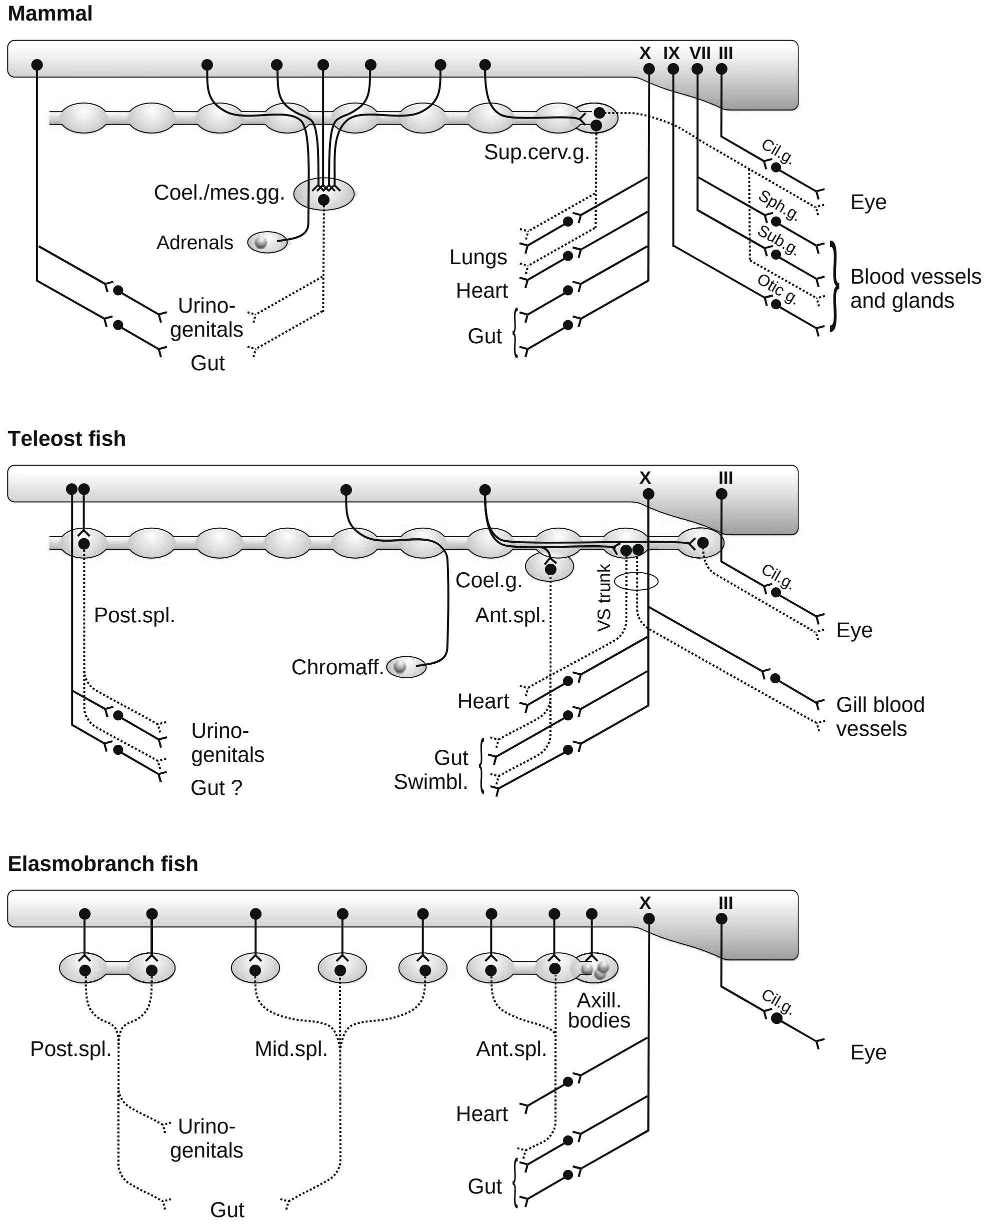

Figure 2 Simplified summary of the anatomy of the ANS in elasmobranch and teleost fish, compared to the mammalian system. catecholamines, while those in the vesicular ganglion do not. It is very tempting to regard the neurons of the chain ganglia as classically sympathetic/adrenergic, and those of the vesicular ganglion as parasympathetic (possibly cholinergic). However, a mix up of anatomical and functional terminology is not useful.

The full wiring diagram of the teleost ANS, albeit simplified, is presented in **Figure 2**.

Dipnoans

The ANS and its function in the lungfish have received comparatively scant attention. Sympathetic chains were described by E Giacomini in 1906, who was pleased (one assumes) to quote verbatim texts in German and English by workers who failed to find the chains. In fact, the sympathetic chains are flimsy and indeed hard to spot.

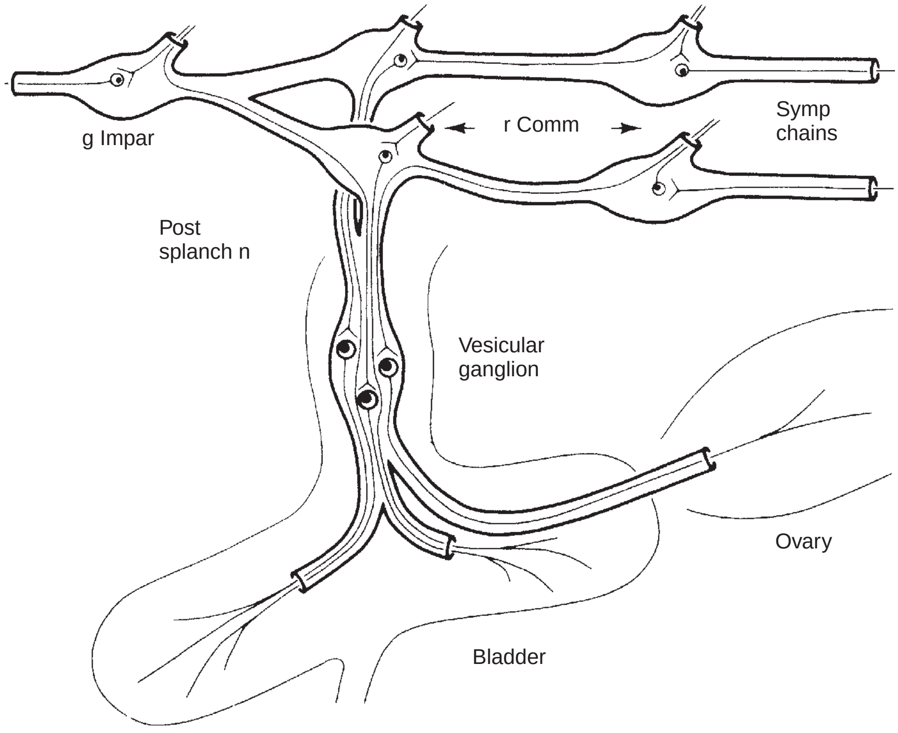

Figure 3 Arrangement of the ANS in the posterior part of the sympathetic chains in the Atlantic cod, *G. morhua*. Nerve fibers from the spinal cord enter the chain ganglia as white (i.e., myelinated) rami communicantes (r comm) and synapse either on smaller ganglion cells within the sympathetic ganglia, or on larger ganglion cells in the vesicular ganglion along the ureter. A double antagonistic innervation of the urinary bladder has been demonstrated, and it is possible that the smaller, catecholamine-containing cells in the ganglia represent the sympathetic/adrenergic control, while the larger nonadrenergic cells in the vesicular ganglion represent postganglionic parasympathetic/cholinergic control. Reproduced from Fig. 2 in Holmgren S and Nilsson S (1982) Neuropharmacology of adrenergic neurons in teleost fish. *Comparative Biochemistry and Physiology* 72C: 289–302.

They run parallel to the spinal column, just as in other vertebrates, and form loops (annuli) around the intercostal arteries. Histochemical studies have so far failed to provide solid evidence for adrenergic nerve fibers in lungfishes, but there is an extensive system of chromaffin tissue that may, and perhaps does, service as an adrenergic control system.

This chromaffin system resides in three places: in the wall of the atrium of the heart, in the wall of the left cardinal (azygos) vein, and in the walls of the intercostals arteries where they exit from the dorsal aorta. The control of the chromaffin tissue in these sites is not well understood.

Cranial autonomic components occur in the vagus (X) nerve and, in the Australian lungfish (*Neoceratodus*), probably also in the oculomotor (III) nerve. A brief comment on the cardiac control in dipnoans is given later. Some information about control of the very intriguing shunting of blood between the lung and the gill is available.

Functional Aspects of the Fish ANS

The number of fish groups multiplied by the number of organs and organ systems that are controlled by the ANS makes for a formidable variation in wiring diagrams, transmitter systems, and physiological adaptations. All this cannot be covered here; the interested reader is referred to the 'Further reading' section.

There are two systems that could, maybe, serve to illustrate on the one hand some kind of phylogenetic development and, on the other hand, a much less organized albeit still functional control. The systems chosen here are the patterns of cardiac control – from cyclostomes to elasmobranchs, dipnoans, and teleosts, and the autonomic nervous control of the iris of the eye.

Control of the Fish Heart

The systemic heart of fish, like in all vertebrates, serves as a pump to propel blood through the body (**see also Design and Physiology of the Heart**: Cardiac Anatomy in Fishes). The ANS is an important system for controlling cardiac performance, to regulate blood flow and blood pressure. Cardiac control in tetrapods is performed by an inhibitory innervation by vagal, cholinergic nerve fibers that slow the heart rate, and decrease stroke volume. In addition, there is an excitatory innervation by adrenergic fibers from the sympathetic chains. This double antagonistic innervation is a common pattern in the ANS.

In the cyclostomes, there may be no autonomic cardiac innervation at all (hagfish), or the vagal innervation is excitatory (lampreys). Some influence from catecholamines released from intra-cardiac chromaffin cells can be surmised, since drugs that block β-adrenoceptors cause a slowing, and eventually a stop, of the heart in hagfish.

In the elasmobranchs there is no solid evidence for an adrenergic nervous control of the heart, although a cholinergic inhibitory vagal innervation (as in all other vertebrates) is present. A contribution to cardiac control by circulating catecholamines released from the axillary bodies is possible, although definite evidence is required. The main question being: Is the blood concentration of the amines high enough to affect the heart?

In the lungfish, not much is known about the cardiac control beyond the vagal inhibitory innervation, but the presence of chromaffin tissue in the atrium certainly suggests some kind of catecholaminergic contribution to the control of cardiac performance. As in the elasmobranchs, catecholamine release from chromaffin tissue in the large veins running to the heart is likely. The role of these circulating catecholamines in direct cardiac control does, however, need further attention.

In the teleosts, finally, cardiac control by the ANS resembles that in the tetrapods, with a cholinergic, vagal inhibitory control forming a double antagonistic innervation together with an adrenergic excitatory innervation from the spinal autonomic portion of the ANS. A stimulation of the heart performance in the Atlantic cod (*G. morhua*) has been shown in response to electrical stimulation of the preganglionic autonomic nerve supply to the chromaffin tissue of the posterior cardinal veins. The importance of the circulating catecholamines in cardiac control *in vivo* needs further elucidation similar to the situation in the other fish.

The cardiac control patterns in fish are summarized in **Figure 4**.

Figure 4 Cardiac control in four groups of fish, showing vagal nervous control (cholinergic – solid lines) and control by spinal autonomic pathways (adrenergic – dotted lines) via postganglionic neurons from the sympathetic chains, and endogenous or exogenous chromaffin cells. The vagal control of the heart is absent in hagfishes, excitatory in lampreys and inhibitory in the other fish groups (and also in tetrapods). It may be possible to discern a phylogenetic trend in the adrenergic control: from endogenous catecholamine-releasing cells with unclear control, via exogenous chromaffin cells releasing catecholamines (CATs) to the blood, to the direct innervation of the heart seen in teleosts (and, again, also in the tetrapods). Reproduced from Fig. 2 in Nilsson S (1997) The autonomic nervous system of the dog and the dogfish: A comparative approach. *Acta Physiologica Scandinavica* 161(supplementum 638): 39–46.

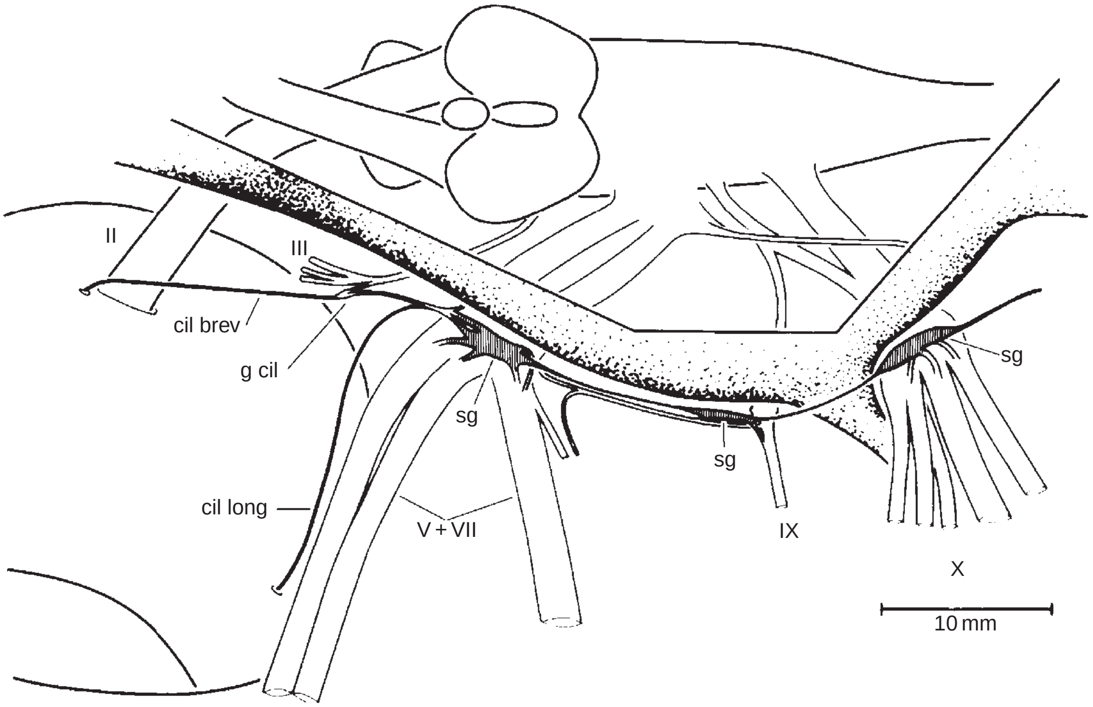

Figure 5 ANS anatomy in the head of the Atlantic cod, *Gadus morhua*, outlining the cephalic portion of the sympathetic chain and the ciliary nerves. Legend: cil brev, short ciliary nerve; cil long, long ciliary nerve; g cil, ciliary ganglion; sg, sympathetic ganglion; II, optic nerve; III, oculomotor nerve; V + VII, trigeminus-facialis nerve complex; IX, glossopharyngeal nerve; X, vagus nerve. Reproduced with kind permission from Fig. 1 in Nilsson S (1980) Sympathetic nervous control of the iris sphincter of the atlantic cod, *Gadus morhua. Journal of Comparative Physiology A*, 138: 149–155.

Control of the Iris

If it is possible to see some phylogenetic trend in the adrenergic control systems of the heart of fish and other vertebrates (cf. **Figure 4**), this is certainly not so for the ANS control of the iris in those few vertebrates that have been studied. There are two sets of muscle that act to alter the size of the pupil: the circular sphincter around the edge of the iris and the radial arrangement of muscle from the edge, much like the spokes of a bicycle wheel. Contraction of the sphincter causes miosis (narrowing of the pupil), while contraction of the radial muscle causes mydriasis (widening of the pupil). The smooth muscle cells of the iris are of ectodermal origin, originating from retinal cells. An indication of this can be found in the direct constrictor effect of light on the isolated iris muscle in some fish and amphibians (**see also Vision**: Vision in Fishes: An Introduction).

The pattern of ANS influence on the two sets of smooth muscle varies between the fish studied, and also further into the tetrapods. The structure of the cephalic sympathetic chains in teleost fish is somewhat aberrant from other vertebrate groups, in that chain ganglia are present in contact with the cranial nerves as they emerge from the cranium (**Figure 5**).

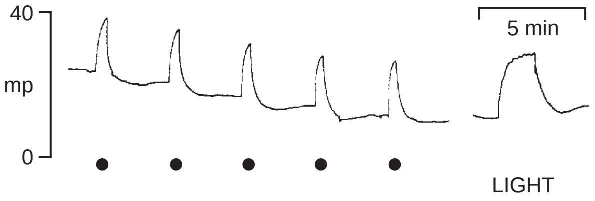

Figure 6 Contractions of the iris sphincter of the Atlantic cod, *Gadus morhua*, caused by electrical stimulation of the sympathetic chain posterior to cranial nerves V + VII with trains of pulses for 20 s every 4 min. The contraction on the right (LIGHT) is caused by 2 min of illumination of the iris by bright light. Reproduced with kind permission from Fig. 7 in Nilsson S (1980) Sympathetic nervous control of the iris sphincter of the atlantic cod, *Gadus morhua. Journal of Comparative Physiology A*, 138: 149–155.

A control via the oculomotor nerve (III) appears to be absent in *Gadus*, but present in other fish. This effect is cholinergic, and affects the radial muscle and not, as in for instance mammals, the sphincter. At least in the teleost *Uranoscopus*, an innervation of the sphincter by fibers from the spinal autonomic system has been described; these fibers are also cholinergic. Thus, in this species, a double antagonistic innervation of sorts is present – spinal

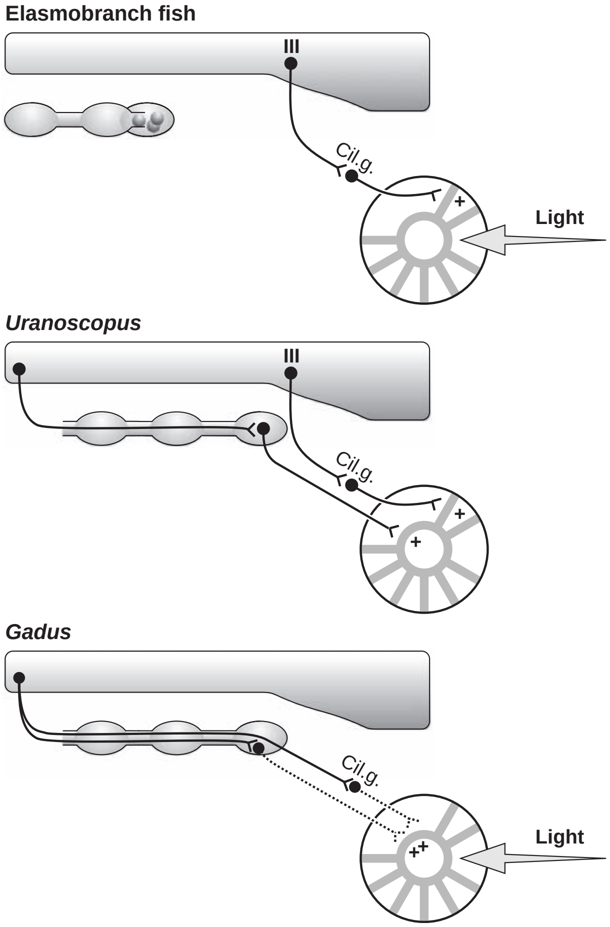

Figure 7 Control of the fish iris by autonomic innervation of the sphincter and the radially arranged dilator muscle. In addition, there is a direct pupillo-constrictor effect of light on the iris sphincter in both elasmobranchs and in *Gadus*. In the elasmobranchs, an excitatory oculomotor innervation of the radially arranged muscle antagonizes the direct pupillo-constrictor effect of light on the sphincter. In *Uranoscopus*, there are cholinergic fibers (solid lines) to both the sphincter (spinal autonomic in origin) and the dilator muscle (from the oculomotor nerve) that serve a double antagonistic control of the pupil. There may, however, be no direct effect of light on the sphincter. In *Gadus*, finally, a third pattern can be seen, in which there appears to be an innervation of the iris sphincter by excitatory nerve fibers from the spinal autonomic system that are adrenergic (dotted lines). These produce pupillo-constriction, as does direct light on the sphincter. Any double antagonistic control, therefore, appears to be lacking. Reproduced with kind permission from Fig. 3 in Nilsson S (1997) The autonomic nervous system of the dog and the dogfish: A comparative approach. *Acta Physiologica Scandinavica* 161(supplementum 638): 39–46.

autonomic pathways cause miosis, while the cranial autonomic fibers cause mydriasis.

In contrast to the elasmobranchs studied and *Uranoscopus*, the nervous control of the sphincter in the cod (*G. morhua*) is solely adrenergic, with postganglionic fibers running from the sympathetic chain ganglia or even from as far anterior as the ciliary ganglion. The adrenergic control is excitatory, acting via α-adrenoceptors. Again, this is a different arrangement from mammals (and the amphibian *Bufo marinus*) where spinal autonomic adrenergic innervation produces a relaxation of the sphincter muscle via β-adrenoceptors. As in many fish and amphibians, the iris sphincter of the cod responds directly to light with no need for an involvement of nerves (**Figure 6**).

To further complicate the view of pupillary control patterns in the vertebrates, the iris muscle of reptiles and birds is largely composed of striated muscle fibers. However, further discussion of this does not fit into the scope of the present text. However, it can be concluded (**Figure 7**) that already in the few fish that have been investigated, there are marked variations in the nervous control patterns of the iris.

Endogenous Opioid Peptides
Opioid Receptors
Further Reading

Glossary

G-protein-coupled receptors (GPCRs) Comprise a large protein family of transmembrane receptors that sense molecules outside the cell and activate inside signal transduction pathways. Also known as seven-transmembrane domain receptors (7TM receptors), heptahelical receptors, serpentine receptor, and G-protein-linked receptors (GPLRs).

Opioid peptides Short sequences of amino acids that activate opioid receptors.

Opioid receptors A group of G-protein-coupled receptors that are activated by opioids ligands.

Phylogenetic analysis The use of the structure of molecules to gain information about evolutionary relationship between different organisms, the result of which is expressed in a phylogenetic tree.

Endogenous Opioid Peptides

Endogenous opioid peptides are primarily synthesized by distinct neurons in the central nervous system. Some peptides are also synthesized in regions of the pituitary gland in both fishes and mammals. Typical endogenous opioid peptides are agonists of opioid receptors and behave like inhibitory neuropeptides. They are derived from four precursors: proenkephalin (PENK), prodynorphin (PDYN), proopiomelanocortin (POMC), and pronociceptin/orphanin FQ (PNOC). The most representative opioid peptides are the enkephalins (ENKs), which are derived from the precursors PENKs and PDYNs.

It is possible that the ancestral opioid gene evolved in a chordate, as opioid precursor genes have not been detected in bacterial or protostome genomes. Thus, the proenkephalin hypothesis suggests the successive duplication of a *PENK*-like gene of an ancestral chordate. The sequential duplication of this gene gave rise to *PENK, POMC, PNOC*, and, subsequently, to *PDYN*.

The genomic organization of opioid precursor genes has been conserved. In brief, one to two small exons encode a portion of the 5′untranslated region (UTR) of the messenger RNA (mRNA), and another small exon encodes the rest of the 5′UTR, the signal sequence, and a portion of the N-terminal region. One large exon encodes the remainder of the open reading frame and the 3′UTR of the transcript.

Opioid peptides influence a great variety of physiological processes when bound to opioid receptors, including analgesia, respiratory function, cardiovascular function, and thermoregulation.

Proenkephalin

In mammals, the *PENK* classically codes for seven ENKs: four Met (M)-ENKs, one Leu (L)-ENK, the octapeptide M-ENK-Arg-Gly-Leu (MERGL), and the heptapeptide M-ENK-Arg-Phe (MERF). In contrast, in fishes, the *PENK* codes for six ENKs (**Table 1**). The number and spatial distribution of opioid sequences in these precursors have been well conserved within the vertebrates. However, there are different groups of amino acids in the C-terminal domain of the MERGL and the MERF sequences of mammals, which are species specific. In addition, a heptapeptide M-ENK-Gly-Tyr (MEGY) sequence in PENKs has been characterized in zebrafish (*Danio rerio*), Neopterygian fishes, and lungfishes. In addition, other sequences, such as M-ENK-Arg-Ser-Val/Ile/Leu (MERS(V/I/L)), have been identified in PENKs from Neopterygian fishes and lungfishes, and two hexapeptide M-ENK-Ile/Asp sequences (MEI/MED) have been detected in zebrafish PENKs.

MEGY, a newly discovered endogenous peptide from fishes, as well as two of its analogs (D-Ala^2)-MEGY (Y-D-Ala-GFMGY) and (D-Ala^2, Val^5)-MEGY (Y-D-Ala-GFVGY), have been identified in zebrafish and other fishes (**Table 1**). These peptides, homologous to the mammalian MERF, bind differentially and with high affinity (a K_D in the nanomolar range) to the two duplicate

[a] Partial sequence.

δ opioid receptors (DORs) present in zebrafish (DOR1 and DOR2) and other opioid receptors in rat (*Rattus norvegicus*) brain.

Prodynorphin

PDYN and *PENK* precursor genes may have arisen from a common ancestral gene as paralog genes nearly 400 million years ago (Ma). In particular, the *PDYN* gene could have been present in the ancestral Gnathostomes.

Interestingly, in comparison with PDYNs from mammals, fish PDYNs contain opioid peptides different from mammalian M-ENK. The Sarcopterygian Australian lungfish (*Neoceratodus forsteri*) has an L-ENK, Actinopterygian fishes have an Ile (I)-ENK, and another Sarcopterygian fish, African lungfish, *Protopterus annectens* has a Phe (F)-ENK (**Table 2**). The presence of these types of opioid sequences (L-, I-, or F-ENK) is similar to the structure of PENKs from Actinopterygians.

The pharmacological profiles of two zebrafish dynorphins (DYN A and DYN B) and mammalian DYN A indicate similarities. Both mammalian DYN A and zebrafish DYN A bind to the four classical opioid receptors from zebrafish (μ or MOR, κ or KOR, DOR1, and DOR2), although with different affinities. The differences in receptor distribution, functional regulation, and the ratio of each receptor *in vivo* also may modify the pharmacological profile of zebrafish DYN A. The zebrafish DORs display a relative preference for the M-ENK found in zebrafish DYN A than for the L-ENK present in the mammalian DYN A, although, interestingly, zebrafish MOR shows higher affinity for the mammalian DYN A than for its own DYN A.

Pronociceptin

Nociceptin (NOC) is the endogenous ligand of the NOP receptor and it is derived from the cleavage of a larger precursor named PNOC. In fishes, PNOCs have been fully cloned in the white sturgeon (*Acipenser transmontanus*) and zebrafish. Two partial sequences exist for Japanese pufferfish (*Takifugu rubripes*) (PNOC1 and PNOC2) probably reflecting the genome duplication that took place in teleosts.

The amino acid sequences of fish PNOCs are slightly longer than the sequence of mammalian PNOCs. The mammalian precursor includes only one NOC, while the cleavage of fish *PNOCs* can produce two possible NOCs and a C-terminal peptide. Moreover, fish PNOCs do not contain the nocistatin peptide, an endogenous molecule with rather controversial functions in mammals. The fact that one NOC from zebrafish contains a Tyr residue (vs. Phe) as the first amino acid at the N-terminus domain, as occurs in DYN A, suggests that zebrafish NOC could bind to opioid receptors, especially to KOR, and as a consequence, it could have different roles than those observed for the mammalian NOC.

The expression of zebrafish *PNOC* gene in CNS was expected, but it is surprising to find PNOC in intestine, since in mammals, *NOC* is expressed in brain and in lower levels in kidney, spleen, ovary, and peripheral blood leukocytes, but not in the digestive tract. It is interesting to note that the expression in intestine is more similar to that displayed by opioid precursors, such as *PENK* and *PDYN* in mammals.

Proopiomelanocortin

POMC is the most complex precursor in the opioid gene family. This gene is the most common precursor of an endorphin opioid peptide (β-END), in addition to the α-neo-END encoded by *PDYNs*. *POMC* also encodes nonopioid peptides such as melanocortins and is involved in stress, pain, energy balance, and food intake. In addition, in fishes and amphibians, it is implicated in the adaptation to background color.

In fishes, *POMC* mRNA is expressed in two types of cells of the pituitary gland. In the corticotrophs in the *rostral pars distalis* (RPD), *POMC* is processed into ACTH (adrenocorticotropic hormone) and β-lipotropin. In the melanotrophs in the *pars intermedia* (PI), *POMC* gives rise to alpha-melanocyte-stimulating hormone (α-MSH) and β-END. Moreover, *POMC* transcripts can also be detected in a subset of neurons in the CNS such as in the *nucleus lateralis tuberis* (in the ventral hypothalamus) and in the *preoptic nucleus area*; both regions are considered to be the topological and functional equivalent to the *arcuate nucleus* and the *paraventricular* and *supraoptic nuclei* of the mammalian *hypothalamus*, respectively.

The POMC-derived peptides have undergone specialization in different fishes (**Table 3**). For instance, cartilaginous fishes have an extra melanocortin, δ-MSH, and the teleosts that existed before the divergence of eels (*Anguilla japonica*, Japanese eel and *A. rostrata*, American eel) lack the segment that encodes γ-MSH.

Furthermore, the higher teleosts have two *POMC* paralog genes (*POMC*α and *POMC*β) that originated after the ancient teleost whole-genome duplication. This duplication apparently occurred in the teleost lineage after the branching of the longnose gar lineage (*Lepisosteus osseus*, Neopterygii) and before the branching of Elopomorpha Anguilliformes (Japanese and American eels) and, within the Clupeocephala, the separation of the superorders Ostariophyssi, Portacanthopterygii, and Acanthopterygii. In the Agnathan sea lamprey (*Petromyzon marinus*), two *POMC-related* genes (*POC*-procortin and *POM*-promelanocortin) have also been found. They are expressed in the pituitary and may be the result of a genome duplication.

Opioid Receptors

Opioid receptors are members of the Rhodopsin family, formed by four closely related protein subfamilies, which belongs to the large superfamily of G-protein-coupled receptors (GPCRs). Opioid receptors are the targets for endogenous opioid peptides and opiate drugs (morphine and its synthetic derivatives). Using pharmacological criteria, these receptors have been classified into four types: MOR, DOR, KOR, and an orphanin FQ receptor or nociceptin opioid receptor (NOP). The vertebrate opioid system has always been a complex system, even before the radiation of jawed vertebrates (≈450 Ma). Different comparative studies have suggested that the opioid receptor gene family arose early in vertebrate evolution by tetraploidization and has been highly conserved over time. Evolutionary analysis of vertebrate opioid receptors suggests that early in animal evolution, there was a single opioid receptor gene, which was present in the first jawed vertebrates. The first round (1R) of genome duplication early in chordate evolution produced the ancestral *DOR/MOR* and *NOP/KOR* genes. A second round (2R) of genome duplication led to the specification of the four opioid receptors present in all extant vertebrates today. In addition, there is evidence of a third round (3R) of genome-wide duplication in fishes that took place early in ray-finned fish evolution and it led to the lineage of bony fishes (teleosts).

Opioid receptors from fishes have been implicated in a broad range of physiological roles, including nociception and cognition, as well as affective, endocrine, cardiovascular, gastrointestinal, immune, metabolic, and respiratory functions, stress, and autonomic regulation. The first studies on the analgesic effects of opioids in fish models, carried out in goldfish (*Carassius auratus*), Derjugin codfish (*Gadus morhuamarisalbi*), rainbow trout (*Oncorhynchus mykiss*), and common carp (*Cyprinus carpio*), demonstrated that these species showed a dose-dependent anti-nociceptive effect when treated with morphine-like compounds (β-casomorphine or dermorphin) or the opioid analgesic tramadol. The effects produced by some of these compounds are partially antagonized by naloxone, as observed in mammals.

All opioid receptors from vertebrates, studied to date, show high constitutive expression in the nervous system. In fishes, opioid receptors are found in the nucleus preopticus of the hypothalamus and pituitary gland. A much lower constitutive expression of opioid receptors occurs in peripheral tissues such as kidney and head kidney (the anatomical equivalent of the mammalian adrenal gland), and all systemic immune organs, including thymus and spleen. Furthermore, pharmacological analysis of opioid-binding sites in brain homogenates from fishes indicate three types of classical opioid-binding sites (μ, δ, and κ), similar to those characterized in mammalian tissues, but with significant differences in the binding of selective opioid ligands.

μ Opioid Receptor

MOR is the opioid receptor that shows higher affinity for morphine, the most used analgesic. Several *MOR* genes have been cloned from teleost species (zebrafish, common carp, and white sucker (*Catostomus commersoni*)). Moreover, partial sequences of *MORs* have been identified in other two fish species (Euteleostean teleost: *Morone saxatilis,* striped bass, and the cartilaginous fish, chondricthyes, *Alopias vulpinus,* thresher shark) and one jawless fish (Agnatha: *Eptatretus stoutii,* Pacific hagfish). Recently, the genomes of many animals have been completely or nearly completely sequenced, which facilitates the identification of *MOR* genes in different vertebrate species. In this sense, *in silico* determinations have identified the putative MORs of four teleost species (*Tetraodon nigroviridis,* black pufferfish; Japanese pufferfish; *Oryzias latipes,* Japanese medaka; and *Gasterosteus aculeatus,* three-spine stickleback).

The genomic organization of all vertebrate *MOR* genes, including fishes, presents interesting homologies. In all vertebrates, only one copy of the *MOR* gene has been detected, but at least three different genomic organizations have been identified. Most *MOR* genes are composed of three main coding exons. In fishes, the *MOR* genes from Euteleostei teleosts (black pufferfish, Japanese pufferfish, three-spine stickleback, and Japanese medaka) display a different genomic organization. They have five exons; the equivalent of the third mammalian exon is subdivided into three exons. Mammalian *MOR* genes could have lost two introns between exons 3–4 and 4–5 during evolution, although it is also possible that these two introns were acquired by the Euteleost lineage. Different studies have also identified several variants that encode truncated proteins of mammalian MORs, and although the functional significance of these truncated receptors is not clear, other research on different receptor systems have reported that truncated proteins modulate the activity of other receptors.

The amphibian and fish MORs express fewer GCPR and MOR-specific motifs than the tetrapod species, despite their position in the MOR clade in phylogenetic analysis. Analysis of functional mapping indicates that MORs from teleosts (and several amphibians) may not function as classical MORs, suggesting that opioid ligands may be less selective in nonmammalian species. In particular, the functional characterization of zebrafish MOR, by competition, saturation, [^{35}S]-GTPγS binding experiments, and intracellular cyclic adenosine monophosphate (cAMP)-level determinations using both peptidergic and nonpeptidergic opioid ligands, shows a pharmacological profile similar to that of the mammalian MOR. Besides, the internalization process of MOR from zebrafish after opiate agonist treatment (morphine, [D-Ala^2, N-Me-Phe^4, Gly5-ol]-enkephalin (DAMGO), etorphine) resembles the pattern observed in its mammalian counterpart.

δ Opioid Receptor

Analysis of *DOR* genes from fishes has been fully cloned and characterized in only one teleost, the zebrafish, although recently a new *DOR* from other cyprinid, the common carp, has been identified. *DOR1* and *DOR2* in zebrafish are also named ZFOR1 and ZFOR4.

As mentioned above, the degree of homology is not uniform along the opioid receptor sequences. Hence, in DORs of fishes identified up to now, the most divergent area is the second extracellular loop, which has more positive and negative charges than tetrapods. This may explain why the highly selective δ ligands from mammals show lower or no affinity for some DORs from fishes, such as zebrafish DOR2. In addition, zebrafish DORs have some divergences in their amino-acid sequences that may explain their pharmacological differences. *DOR1* and *DOR2* are co-expressed in the same brain areas and, like the mammalian *DOR,* are detected in olfactory bulb regions. However, *DOR1* is uniquely detected in the supracommisural part of the ventral area of the zebrafish telencephalon, which is considered to be homologous to the mammalian amygdaloid complex. The expression of two *DORs* from zebrafish in neuroendocrine regions, including the preoptic area and the hypothalamus, is likely involved in control of gonadotrophin-releasing hormone (GnRH) release. Moreover, zebrafish DORs may be involved in analgesic mechanisms because both mRNAs are present in the rostrocaudal extension of the reticular formation. Finally, the moderate expression of *DOR2* in other brain areas from zebrafish, such as the pretectum and posterior tuberculum, suggests that this receptor might be influenced by adaptive mechanisms also related to behavioral responses basic for survival.

On the other hand, pharmacological analysis of zebrafish DORs shows specific and saturable binding with nonspecific antagonist [^{3}H]diprenorphine, displaying one binding site with an affinity constant in the same range (nM) to that previously observed for mammalian DORs. However, the δ-selective radioligand [^{3}H] [D-Pen^2, D-Pen^5]-enkephalin (DPDPE) does not bind to DOR2 and has low affinity for DOR1. The selectivity of this ligand is gradually lost when moving down in the evolutionary scale, which suggests that it may not be suitable for understanding the δ-binding profile in nonmammalian vertebrates.

κ Opioid Receptor

The analysis of *KOR* genes from fishes has been characterized in zebrafish and common carp. The distribution of zebrafish KOR is throughout the dorsal telencephalic areas, epithalamus, hypothalamic recess nuclei, periventricular layer of the optic tectum, granular layer of the cerebellum, reticular formation, facial lobe, and with lower intensity in other regions such as the olfactory bulb, vagal lobe, octavolateral areas, and spinal cord.

Pharmacological analysis of KOR from zebrafish shows specific and saturable binding using the nonspecific antagonist [^{3}H]diprenorphine, displaying one binding site. The selectivity of this κ ligand is also gradually lost when moving down in the evolutionary scale, which suggests that it may not be suitable for determining the κ-binding profile in nonmammalian vertebrates. Although the κ-selective agonist U69,593 ([5α,7α,8β)-(+)-*N*-methyl-*N*-[7(1-pyrrolidinyl)-1-oxaspiro[4.5]dec-8-yl]-benzeneacetamide]) failed to show effective displacement, the antagonist naloxone, the nonspecific antagonist bremazocine, morphine, and DYN-related peptides displaced the specifically bound [^{3}H]diprenorphine, but with different affinities.

Nociceptin Opioid Receptor

NOP exhibits a significant degree of sequence identity with the three classical opioid receptors. Nevertheless, the pharmacological implications of these receptors are different, since NOP does not recognize the classical opioid ligands such as morphine or naloxone. Analysis of *NOP* genes from fishes has been exclusively characterized in one teleost (zebrafish), with two *NOP* cDNAs that could be the result of the extra genome duplication that took place in teleosts.

Glossary

Benthic Organisms living on, or near, the sea floor; lowest level of a body of water.

Bioluminescence Light produced by living organisms by physiological processes and without heat.

Chromophore Part or moiety of a molecule responsible for its color. In visual pigments the chromophore is retinal, the aldehyde of vitamin A, combined with the protein, opsin.

Circadian rhythm An internal rhythm, free running under constant conditions with a period slightly differing from the environmental 24 h cycle.

Cone The sensory cell type in the eye (photoreceptor) involved in color vision and bright light conditions.

Diverticulum An out-pocketing, or blind-ending sac, branching out from a hollow anatomical structure, here used to refer to ventrolaterally facing 'accessory eye' of some mesopelagic fish with dorsally directed tubular eyes.

Electroretinogram (ERG) A recording of the retina's electrical activity in response to light, usually recorded either on the cornea or on the retinal surface.

Endosymbiont An organism that lives symbiotically within the body of another.

G-protein A large class of intracellular, membrane-associated, proteins that act as second messengers for a wide range of receptors (including visual pigments) and transduce receptor signals by activating a chain of cellular events resulting in amplification and cell signaling.

Hadal Biogeographic region of the ocean bottom below the abyssal zone, typically ocean trenches deeper than about 6500 m depth.

Irradiance The amount of light or electromagnetic radiation at a surface. Spectral irradiance is used here to describe the light incident on the reef available for vision.

Melatonin Neurohormone synthesized and released in the dark by photoreceptor cells (or their derivatives, pinealocytes) in the retina and the pineal gland (epiphysis cerebri).

Mesopelagic A biogeographic region of open oceans between 200 and 1000 m depth and not near the ocean floor.

Microspectrophotometry A technique in which a narrow beam of light is passed through an isolated rod or cone outer segment in order to measure the absorbance of the visual pigment.

Myctophidae A family of teleosts known as lantern fish whose name originates from their conspicuous bioluminescent photophores. They account for up to 65% of the deep-sea fish biomass and are among the most widely distributed and populous of all vertebrates.

Opsin Protein component of the rhodopsin photopigment.

Optical aberration The deviation of light originating from a point in space from a single point in the image. There are monochromatic and chromatic aberrations that affect image quality and there is no perfect optical system that is entirely free of aberrations. Longitudinal spherical aberration and longitudinal chromatic aberration are the major aberrations in fish eyes.

Photic environment The distribution of light, in terms of brightness and spectral composition, within the environment.

Photopigment Labile molecules that change conformation upon absorbing light, thereby triggering various secondary reaction cascades, with transducin and arrestin as intermediate enzymes. In photoreceptive cells photopigments are composed of a protein moiety (generally called opsin) and a nonprotein chromophore part called retinal. Retinal-based opsins are called rhodopsins. The wavelength of the absorption maximum can be tuned by modifications of the amino acid sequence of the opsin molecule, and/or substituting retinal by dehydroretinal.

Pineal gland Part of the diencephalic epithalamus with cells specialized in the production of melatonin. In fish, it is composed of a stalk and a hollow vesicle located underneath a transparent window in the skull. The cellular components include photoreceptor and nerve cells.

Porphyropsin All visual pigments based on vitamin A_2.

Radiance A radiometry term to describe the amount of light, emitted from a particular area and from a defined solid angle or direction.

Receptive field The area of retina within which stimulation effects a response from a given neuron.

Refractive index The speed of light in vacuum divided by the speed of light in the medium in question. Because the speed of light is highest in vacuum, the refractive index of any other medium is always greater than 1. Light changes its direction of propagation according to Snell’s law if it passes across the interface between two media of different refractive indices.

Retinal ganglion cells The output neurons of the retina. Their axons, called ‘optic fibers’, terminate in the tectum and nuclei of the preoptic–thalamic–pretectal (PTP) area.

Retinomotor movements The myoids (parts of the inner segments) of rod and cone photoreceptors contract and elongate in response to changes in light levels and circadian endogenous signals. In the retinal pigment epithelium, melanosomes disperse and aggregate, which may be accompanied by changes in cell shape. Retinomotor movements occur in fishes, amphibia, reptiles, and birds.

Retinotopic map, organization, or projection Found in brain areas, such as tectum, that receive a spatially ordered set of input fibers from the retina, thereby forming a representation of the retina, and the visual field of the eye. A particular case of ‘topographic map’. The retinotectal map is an instance.

Rhodopsin All visual pigments based on vitamin A_1, but commonly used to refer only to rod visual pigments.

Rod A rod-shaped photoreceptor type in the eyes of vertebrates that functions in dim light conditions so may allow night vision. The photoreceptor molecule within rods generally absorbs light in the middle of the spectrum giving it a spectral sensitivity around 500 nm.

Spectral reflectance Objects reflect and absorb wavelengths of light differentially according to their spectral reflection and defined by the pigmentary or physical structure of their surface. The color of the object is also a product of the visual system’s spectral sensitivity and this varies among animals substantially.

Spectral sensitivity At least two cones, each with a different spectral sensitivity, are required for color vision.

Tetrachromatic color vision Color vision based on four spectrally distinct cone classes, normally maximally sensitive in the red, green, blue, and violet or ultraviolet.

Transmitter A chemical released by one neuron that causes a change in the polarization of target neurons with which it makes a synapse.

The visual system of fish has fascinated scientists for many different reasons. It has been used as a model system not only in visual science, but also in neuroscience and cell biology in general, behavioral sciences, embryology, and even for evolutionary ecology, as shown in the following few examples. Sticklebacks (*Gasterosteus aculeatus*) and cichlids were used to demonstrate the importance and specificity of visual stimuli as triggers of defined patterns of innate behavior. Cichlids and their visual system play an important role for the observation of the unexpected dynamics of evolution by ongoing speciation and occupation of new ecological niches in the African rift lakes. The marked morphological and physiological changes associated with light and dark adaptation in the fish retina have contributed to knowledge in synaptic plasticity and cell motility (retinomotor movements). Most of these cold-blooded animals are available in large numbers and their retina is easy to experiment on physiologically – these are good reasons for the great popularity of the teleost visual system. The first intracellular recordings from retinal neurons were obtained by Svaetichin as early as 1953; subsequently, the retinal circuitry for color vision was established. Many of these experiments were based on cyprinids such as the goldfish which were often regarded as the standard model species comparable to the lab rat. More recently, the zebrafish visual system has replaced that of the goldfish in a similar way the mouse has largely replaced the rat for genetic and molecular work (**see also Deep-Sea Fishes**).

However, as important as the insight from these studies undoubtedly is, in the author's view, they miss the most important point about fish as a model system, because, essentially, there is no such thing as the fish visual system. Rather, there is a tremendous diversity of fish and their adaptive radiation, a term used for vertebrate eyes, in general, in the title of G Wall's 1942 seminal book. According to recent numbers in FishBase, there are 31 500 different fish species and these live in habitats as diverse as coral reefs illuminated by the brightest tropical sun; the abyssal depths of the deep sea to which no sunlight penetrates; clear freshwater lakes; murky rivers; and dark caves. Obviously, the entire organism reflects the special constraints imposed by these divergent environments, but the visual system plays a key role. Size and orientation of the visual field are reflected in the design and motility of the eye; the average intensity is reflected by the complement of photoreceptor types; the spectral environments and even their seasonal changes may be reflected by the diversity of visual pigments; and the lifestyle as a predator or vegetarian is reflected by the topography of photoreceptors and retinal ganglion cells. J Lythgoe has characterized this aspect as visual ecology.

The present section on the fish visual system takes a double approach in an attempt to account for these issues.

In the first part, we follow the path of light into the eye onto the retina, investigate its effect on the visual pigments, and watch the processing of the neural signals within the retina and the brain, that is, the optic tectum. R Kroger (**see also Vision**: Physiological Optics in Fishes) outlines the rules of optics to explain the constraints underlying the shape of the teleost eye and lens. More specifically, he deals with the mechanisms that limit, or even overcome, the effects of longitudinal and chromatic aberration. When light enters the photoreceptor outer segments, it may be absorbed by as many as four different cone visual pigments in addition to a rod rhodopsin. Thus, some teleosts are capable of seeing a wider range of color than humans. J Bowmaker (**see also Vision**: Photoreceptors and Visual Pigments and Adaptations of Photoreceptors and Visual Pigments) explains the evolution of these pigments and demonstrates how an exchange of a very limited number of amino acids in the opsin protein and/or the presence of a vitamin A_1 or A_2-based chromophore lead to a discrete shift in absorbance that allows fish to perfectly adapt to their spectral environment. With their spectral identities established and attributed, the morphological diversity of photoreceptor types helps to trace the synaptic connectivity of the chromatic channels with the bipolar and horizontal cells. M Levine (**see also Vision**: Inner Retina and Ganglion Cells) unravels the intraretinal network and shows how the photoreceptor signals are transformed into the various types of receptive field at the ganglion cell level. These constitute the codes that are transmitted via the optic nerves to the targets in the brain, foremost among them is the optic tectum. In this complex neural processor, the visual input is integrated with signals from other sensory systems, and D Northmore (**see also Vision**: Optic Tectum) outlines how the tectum arrives at discrimination and decision making preceding motor responses.

The blueprint of the visual system in teleosts outlined in this first group of articles is subject to, sometimes, extreme changes during the adaptation to the diverse habitats fish have conquered. Starting with the very shape of the eye, deep-sea fish arguably show the profoundest deviations from the common plan. Tubular eyes, occasionally associated with highly complex diverticula, are found in many deep-sea fishes. R Douglas and J Partridge (**see also Vision**: Visual Adaptations to the Deep Sea) take the reader on a guided tour of this vast habitat and demonstrate that in spite of the absence of sunlight, vision plays an important role for the majority of fish. Tuning of the spectral sensitivity to the prevailing wavelengths as a general phenomenon and dual-band, not color, vision as an amazing strategy by stomiids to make them invisible to (most) other fish are additional fascinating examples from the deep sea. S Schuster (**see also Vision**: Behavioral Assessment of the Visual Capabilities of Fish) examines freshwater fish and studies mechanisms by which archer fish (*Toxotes jaculatrix*) achieve the high degree of spatial precision in visuo-motor coordination. On the other hand, he also shows that vision plays an important role even in the weakly electric elephant fish. The widest potential of the visual system is undoubtedly encountered in coral reefs fish. J Marshall and K Cheney (**see also Vision**: Color Vision and Color Communication in Reef Fish) focus on the role of color in this habitat and give vivid examples how color is used both for camouflage and for advertising behavior. Importantly, the multicolored pictures of reefs and their inhabitants that are so familiar and appealing to the human eye may appear significantly different when imaged through the visual system (i.e., optical filters and spectral channels) of most reef fish.

Glossary

Aphakic aperture Part of the pupillary aperture through which light can enter the eye without passing through the crystalline lens; such light is not focused on the retina and degrades image contrast.

Basement membrane Extracellular component attached to the epithelial layer, consisting of connective tissue made up of a complex of short filamentous proteins, e.g., collagens. Epithelial cells adhere to the extracellular matrix by expressing cell adhesion molecules on their basal surface.

Chaperone A protein that assists the biochemical noncovalent folding and unfolding, as well as the assembly and disassembly of macromolecular structures such as other proteins.

Constructive interference Waves of the same wavelength and phase add up in amplitude; such light waves can occur by partial reflections at interfaces between media of different refractive indices. If several such interfaces are stacked at wavelength intervals, the partial reflections at the interfaces add up by constructive interference, such that light incident on the stack is reflected. The wavelength being reflected and the efficiency of the interference mirror depend on the distances between the interfaces, their number, and the angle of incidence.

Diffraction Every point on a wave front of light can be considered as a point source of light from which a secondary radial wave emanates. The radial waves originating from a wave front passing through an opening spread in all directions and, depending on the angle and distance to the opening, add up if they are in phase (constructive interference) or take out each other if they are in counterphase (destructive interference). This leads to a typical pattern with a central light patch and radially alternating dark and light rings. The smaller the opening (aperture) is, the larger and more diffuse is the central light patch. The spreading of light behind an aperture, such as the pupil of an eye, may thus limit the sharpness of the image.

Optical aberration The deviation of light originating from a point in space from a single point in the image. There are monochromatic and chromatic aberrations that affect image quality, and there is no perfect optical system that is entirely free of aberrations. Longitudinal spherical aberration and longitudinal chromatic aberration are the major aberrations in fish eyes.

Ora retinalis The edge of the retina in the ciliary region, which is also called ora ciliaris retinae. In the human eye, the ora retinalis is serrated in appearance and therefore called 'ora serrata'.

Refractive index The speed of light in vacuum divided by the speed of light in the medium in question. Because the speed of light is highest in vacuum, the refractive index of any other medium is always larger than 1. Light changes its direction of propagation according to Snell's law, if it passes across the interface between two media of different refractive indices.

Retinomotor movements The myoids (parts of the inner segments) of rod and cone photoreceptors contract and elongate in response to changes in light levels and endogenous circadian signals. In the retinal pigment epithelium, melanosomes disperse and aggregate, which may be accompanied by changes in cell shape. Retinomotor movements occur in fishes, amphibians, reptiles, and birds, but not in mammals.

Introduction

One of the earliest known vertebrates, *Haikouichthys ercaicunensis*, was a lamprey-like creature that lived about 540 million years ago, that is, during the early Cambrian period. *Haikouichthys* had already a well-developed eye, most likely with an optical apparatus. From such early eyes, vertebrate vision has evolved into highly sophisticated sensory systems (**see also Vision**: Adaptations of Photoreceptors and Visual Pigments). The evolution of man-made optical systems began at least 3000 years ago. The Nimrud lens, a crudely ground quartz lens found in the ruins of Niniveh, is the oldest known optical instrument. Today, we are surrounded by countless optical devices. However, although the basic physical phenomena are the same, biological and manufactured optical solutions took different routes right from their beginnings, mainly because different materials are used.

Optical Principles

The simplest optical system capable of creating an image is the camera obscura or pinhole camera. Light is allowed to pass through a small opening into an otherwise light-tight chamber. Because light propagates along straight lines, each point in space is imaged at a corresponding location on the back surface of the chamber, creating an image of the surroundings that is rotated 180° (**Figure 1**(**a**)). The detail and the brightness of the image are directly and inversely, respectively, proportional to the size of the pinhole, unless the pinhole is so small that diffraction because of the wave-like nature of light limits resolution.

The light-gathering area can be increased by using a lens that collects light from an angle in space and focuses it on the back of the chamber (**Figure 1**(**b**)). Even in this case, the image is rotated 180°. The brightness of the image is proportional to the size of the light-gathering aperture, while the detail is limited by the quality of the lens, except for small apertures where diffraction plays a role.

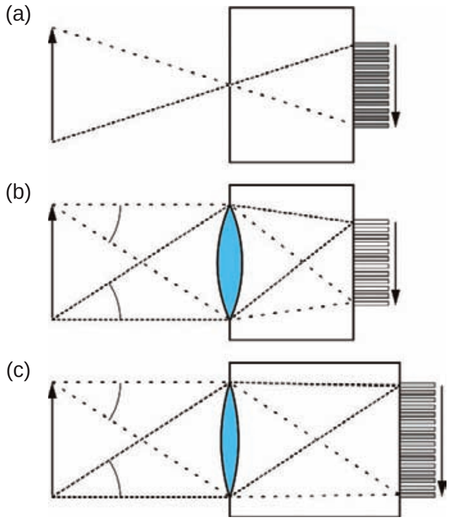

Figure 1 Schematic illustration of basic optical principles. (a) In a pinhole camera, light enters an otherwise light-tight chamber through a small aperture to the rear wall of the chamber. Photoreceptors located at that position (gray bars) would be stimulated with an image of an object that is rotated 180°. Each photoreceptor would receive little light from each corresponding point in space. (b) The amount of light reaching each photoreceptor is increased by a lens that collects light from an angle in space. (c) Image magnification and brightness are directly and inversely, respectively, proportional to the focal length of the lens.

The brightness of the image also depends on the focal length of the lens. If focal length is long, image size is large such that the light passing through the entrance aperture is distributed over a large area (compare the sizes of the images of the arrow in **Figures 1**(**b**) and **1**(**c**)).

In an eye, the image is sampled and translated into neural signals by photoreceptors in the retina (**see also Vision**: Photoreceptors and Visual Pigments and Inner Retina and Ganglion Cells). This means that the sampling density in the retina is limited and that leads to a notable exception from the general rule that image brightness is a function of the focal length of the optical system. The brightness of an imaged point source of light depends only on the size of the light-gathering aperture if all light originating from the point source and passing through the aperture is focused on a single photoreceptor. In this case, optical sensitivity is independent of the focal length and depends only on the size of the aperture. This also applies to groups of photoreceptors if their signals are summed by optical or neural mechanisms.

Constraints on the Evolution of Fish Eyes

Compared with air, water is a dense and viscous medium. An animal therefore has to have a streamlined body if it wants to move swiftly through the water column. This has had an effect on eye evolution because large protruding eyes would hamper a fish's locomotion. Evolution has therefore favored small eyes with a maximum of information capacity in many species. Furthermore, most underwater environments are relatively dark and large pupils are necessary for gathering light.

Small eye size calls for maximizing the refractive power of the optical system. The refractive power of a lens depends on the shape of the lens and the refractive indices (RIs) of the lens material and the surrounding medium. The crystalline lenses of many fishes are spherical (ball-shaped) and such lenses have the shortest possible focal lengths relative to the aperture that collects light. The basic building blocks of the optical elements in fish eyes are water and proteins, and the RI of pure, dried protein is about 1.54. The surrounding intraocular fluids are basically water with an RI of about 1.34. This is the span of RIs with which natural evolution could work, in contrast to glass lenses (RI: 1.46–1.81) in air (RI: 1.0) used in manufactured optical systems.

The information content of an image is limited by diffraction and/or the quality of the optical system. Of many possible optical imperfections, the so-called aberrations, two are most important with regard to fish vision:

- *Longitudinal spherical aberration (LSA).* A spherical lens made of homogeneous material focuses light that passes through its periphery closer to the lens than light that

Figure 2 Main optical aberrations in fish eyes and the principle of operation of a multifocal fish lens. (a) Longitudinal spherical aberration (LSA) of a spherical lens of homogenous refractive index. Rays of monochromatic light passing through the periphery of the lens are focused closer to the lens than rays passing through the lens close to the optical axis (axis of symmetry). (b) Gradient-index lenses may be corrected for LSA, but suffer from longitudinal chromatic aberration (LCA). Light of short wavelength (blue) is focused closer to the lens than light of intermediate (green) and long (red) wavelengths. On the retina, only a narrow range of wavelengths is in focus, while the image is defocused for other wavelengths. (c) Multifocal fish lenses are gradient-index lenses with carefully tuned residual LSA. Note that the lens has several focal lengths for monochromatic light (left half of illustration). Because of LCA, different zones (I–III) focus different spectral ranges on the retina (right half of illustration). The central zone (IV) has a small effective aperture and thus long depth of focus, such that all wavelengths are sufficiently well focused on the retina. Note that multifocal lenses create well-focused color images on a background of defocused light that has passed through zones of inappropriate focal lengths, such as the green light that has passed through zones I and III (left half of the illustration).

takes a more central path (**Figure 2**(**a**)). LSA leads to blur and the loss of light that either cannot be captured by the photoreceptors because of exceedingly large angles of incidence or is not directed on any photoreceptor at all.

- *Longitudinal chromatic aberration (LCA).* The RI and thus the refractive power of a lens is a function of the wavelength of light. Lens power decreases from short wavelengths (blue end of spectrum) to long wavelengths (red end of spectrum). LCA leads to chromatic defocus (**Figure 2**(**b**)) that is relevant for color vision.

The biological solution to LSA and LCA are multifocal gradient-index lenses, while optical systems consisting of several lenses are the most common solution in manufactured devices.

Optical Elements of Fish Eyes

Light on its way from the environment to the light-sensitive outer segments of the photoreceptors in the retina passes through several transparent elements that may alter its path (**Figure 3**; **see also Vision**: Photoreceptors and Visual Pigments, Inner Retina and Ganglion Cells, and Adaptations of Photoreceptors and Visual Pigments). The cornea, the crystalline lens, and also the retina may contribute to image formation because they are higher in RI than the surrounding media, which are water (outside the eye), the liquid aqueous humor (between cornea and lens), and the gelatinous vitreous humor or body (between lens and retina; **Figure 3**). The vitreous humor may be highly viscous, almost solid in some species. However, its extracellular matrix has extremely high water-binding capacity such that the RI of the vitreous is only slightly higher than that of water.

The amount of light reaching the retina is limited by the iris that acts as a stop in the optical system. Some fishes have skin flaps that can be extended to cover parts of the pupil. These structures have similar functions as the iris. The spectrum of wavelengths that are allowed to reach the photoreceptor outer segments may be limited by filter pigments that may reside in the cornea, lens, and/or inner segments of the photoreceptors. Long-pass cutoff filters that block short wavelengths are common in the cornea and/or lens and protect the retina from potentially dangerous ultraviolet (UV) light. There are, however, numerous fish species that are sensitive to near-UV light. In the mesopelagic zone that is barely reached by downwelling sunlight, short-wave absorbing pigments may enhance the visibility of bioluminescent signals that contain more long-wave radiation than the

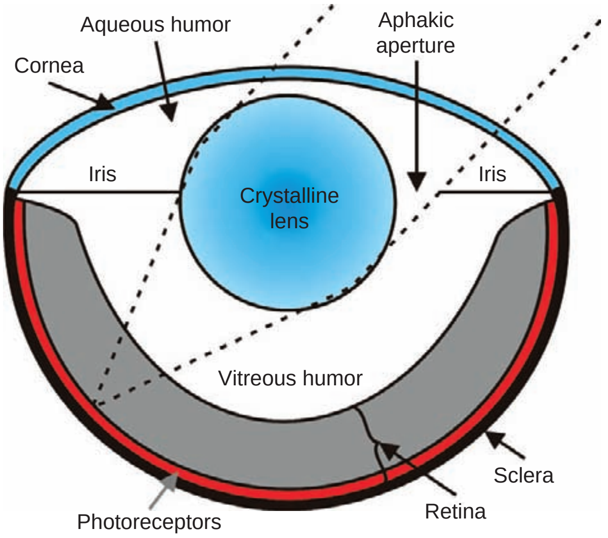

Figure 3 Sketch of a typical fish eye illustrating relevant structures. Note that the aphakic aperture allows for use of the full width of the lens for light that is incident at an angle (dashed lines) and focused on an off-axis area of highest retinal resolution. In small eyes of fish larvae, the neural retina (gray) may fill the entire volume posterior to the iris and lens.

residual sunlight (**see also The Skin**: Bioluminescence in Fishes and **Vision**: Visual Adaptations to the Deep Sea).

Cornea

The cornea is a multilayered sheet of cells and dense extracellular matrix that comes about by the fusion of a transparent patch of skin over the eye (the dermal cornea or primary spectacle) and the primary cornea that is derived, like the sclera, from the dura mater. The separation between dermal and primary corneas is conserved in some groups of fish. In a typical fish eye (**Figure 3**), the cornea's contribution to the total refractive power of the eye is negligible. The cornea is thin and its anterior and posterior surfaces are parallel to each other. Furthermore, the cornea is surrounded by media (water and aqueous humor) that are very similar in RI. In consequence, any refraction of light that occurs at the anterior surface of the cornea is canceled out by a refraction of the same magnitude, but of opposite sign at the posterior surface.

Iridescent layers reflect light by constructive interference and occur mainly in the corneas of shallow-water marine teleosts. If the fish is illuminated from above, the iridescent cornea reflects the light laterally away from the animal. This reduces intraocular glare by preventing strong downwelling light from entering the eye and camouflages the otherwise conspicuously dark pupillary opening for an observer viewing the animal from the side. Light incident on the eye axially or from below is unobstructed because of the orientation of the reflective structures in the iridescent layer.

Iris

The iris is a thin sheet of tissue that is usually richly vascularized on its posterior surface. It stretches from the ora retinalis toward the lens and acts as a stop that limits the amount of light passing through the lens. The anterior surface of the iris is usually pigmented to match the coloration of the body or to be part of a disruptive pattern, while the posterior surface is black such that light astray within the eye is absorbed. In species with contractile pupils, the inner rim of the iris glides on the anterior surface of the lens (**see also The Skin**: Coloration and Chromatophores in Fishes).

In many teleost species, the iris is unresponsive to changing light levels and the pupillary opening may be somewhat larger than the lens, such that there is an aphakic aperture through which light can enter the eye without being focused by the lens. This seems to be an adaptation that allows a maximum of light to be focused on a temporal or dorso-temporal region of highest retinal resolution that exists in a number of fish species (**Figure 3**).

A drop-shaped pupil with an aphakic aperture in the nasal or ventro-nasal region is typical for shallow-water teleosts, but there is a large variety of other pupil shapes among fishes. Irises and extendable skin flaps of complicated shapes, such as in flatheads (Platycephalidae), may camouflage the eye by disrupting the shape of the dark pupillary opening. Shading dorsal flaps are present in a number of fishes that are exposed to large differences in brightness between the dorsal and ventral visual fields. In the Loricariidae among the catfishes (Siluriformes), the pupil is almost circular when dark-adapted. In bright light, an operculum extends from the dorsal rim of the iris and fills the center of the pupil, such that a narrow crescent-like and almost circular slit remains open. Similar ring-shaped apertures are used in astronomical telescopes to increase the contrast of small objects at the expense of some reduction in contrast for large objects.

Lens Structure and Optical Properties

The crystalline lens is derived from an inverted epithelium that develops by invagination of the ectoderm during early embryogenesis. The lens is surrounded by a particularly strong basement membrane, the lens capsule. Directly interior to the lens capsule there is a monolayer of cells, the lens epithelium. These cells are the metabolically most active cells in the lens, but of little optical relevance. The lens epithelium covers the anterior surface of the lens and ends somewhat posterior to the lens's equator, where there is a proliferation zone that remains active throughout life in all vertebrates with well-developed eyes. Here, new cells arise continuously and enter the developmental path toward mature lens fiber cells. The cells stretch over existing cell layers and, when their ends have reached the anterior and posterior poles of the lens, they connect with other cells in the new layer. The areas of interconnecting lens fiber cells are called 'lens sutures' and may be visible in fresh lenses as they scatter some light. The final step of lens fiber cell differentiation is the degradation of all organelles including the nucleus, which leads to the exceptional transparency of the tissue, but also permanently removes the cells from the cell cycle. A mature lens fiber cell has to last for the entire remaining lifetime of the animal.

The main proteins present in lens fiber cells are called 'crystallins' that are synthesized by peripheral cells with full complements of organelles. The crystallins are a heterogeneous group of water-soluble proteins and, during the evolution of vertebrates (and other animals), a variety of different proteins has been recruited for the purpose of refracting light. Many of these proteins have in common that they are exceptionally stable and some of them have enzymatic or chaperone activities.

James C. Maxwell was the first to notice that fish lenses, despite being spherical, are almost free of LSA. Maxwell postulated that these lenses must be gradient-index lenses, with highest RI in the center and lowest RI at the surface (**Figure 2**(**b**)). If such a radial or concentric gradient of RI has the correct shape, a spherical lens can be free of LSA. Today it is clear that Maxwell was right, although the search for the exact RI profiles of fish lenses is still ongoing.

A complication arises from the fact that many fishes have color vision. Surprisingly at first sight, the single crystalline lenses of fishes have the capacity to create well-focused color images despite LCA. In manufactured optical applications, chromatic aberration is accounted for by composite optical systems consisting of several lenses made of different materials. This method leads to sharp color images, and also to bulky optical systems with limited visual fields. The biological solution is based on multifocal lenses that are small and may not only have the same optical properties for all angles of incidence of light, but also have a counterintuitive mode of operation. Well-focused color images are overlaid by defocused light (**Figure 2**(**c**)) that should reduce the information transfer capacity of the lens.

Multifocal lenses are nevertheless common in all vertebrate groups studied to date, ranging from lampreys to primates. This illustrates the power and general applicability of the multifocal principle. There is, however, no single multifocal solution that suits all animals. At least in fishes, the optical properties of the lens are specifically tuned to the needs of the animals.

Furthermore, the optical properties of fish lenses show circadian and developmental plasticity. In many shallow-water fishes, dark adaptation leads to profound changes in retinal function. In a process called 'retinomotor movements', the cone photoreceptors, of which there are up to four different spectral types, are moved out of the presumptive focal plane of the optical system, while the rods, of which there is only one type, are brought into this plane. The switch from polychromatic color vision to monochromatic grayscale vision may be reflected in the optical properties of the lens. The lens of *Aequidens pulcher*, a South American cichlid with trichromatic cone-based color vision, is clearly multifocal during daytime, but significantly less so during nighttime. This means that the optical properties of *A. pulcher* lenses adapt to the changing demands of the retina on a short-term basis. Because retinomotor movements are common in fishes that are regularly exposed to widely changing light levels, adapting lenses may be common as well.

Long-term optical plasticity has been induced experimentally by rearing fishes in various spectral environments, dim light, and continuous darkness. Differences in the optical properties of the lenses have also been observed in a teleost species that has undergone a Lessepsian migration (i.e., migration through the Suez Canal) from the Red Sea to the Mediterranean Sea. In comparison to the Red Sea at comparable depth, the visual environment in the Mediterranean Sea is darker and red-shifted due to a higher load of organic material. Correspondingly, the lenses of *Siganus rivulatus*, a diurnal herbivorous rabbitfish (Siganidae), have shorter focal lengths in the Mediterranean than in the Red Sea.

Computational models of the optical performance and structure of fish lenses have shown that the RI gradient is stringently controlled, because even tiny deviations from the optimal gradient lead to profound reductions in optical quality. The regulatory mechanisms are still unknown, but it is clear that they involve mature lens fiber cells that are devoid of organelles. As the lens grows throughout life by addition of new fiber cell layers in the periphery, the RIs in older, more central cell layers increase such that the correct RI gradient within the lens is maintained. This occurs in parallel with post-translation modifications of the crystallins in lens fiber cells devoid of organelles.

Lens Suspension and Accommodation

A lens of high optical quality is an essential precondition for detailed vision, but not the only one. The lens has also to be exactly positioned, in particular in fishes as their lenses have short depth of focus because of short focal length in relation to the aperture diameter. In agile species, the lens has to be held in place firmly during rapid movements of the animal. It has long been believed that lens suspension in teleosts was rather simple, consisting only of a dorsal ligament and a ventral retractor lentis muscle. A recent analysis revealed, however, a system of several ligaments in addition to the previously described dorsal ligament. The retractor lentis muscle moves the lens toward the temporal (caudal) retina for accommodative adjustment of focus for distance vision.

Lens suspension in chondrichthyes consists of a dorsal ligament and a ventral papilla. In this papilla, there seems to be a muscle that protracts the lens for accommodation to near vision. Interestingly, in sturgeons that are usually regarded as ray-finned fishes, lens suspension is much more chondrichthyes-like than teleost-like. In lampreys, the most basal group of vertebrates, the lens is held in place by a thin fibrous membrane that stretches from the equator of the lens to the region of the ora retinalis. Intraocular muscles seem to be absent and it has been speculated that an extraocular muscle might pull on the dermal cornea to deform the entire eye for accommodation. Electrical stimulation of this muscle, however, failed to induce accommodative changes of focus. Surprisingly, African lungfishes (*Protopterus* spp.) have the same type of lens suspension as lampreys. It is an open question whether or not lungfishes are capable of accommodative adjustments of focus. The tetrapod mode of accommodation by deformation of the lens is unknown in fishes.

Retina

As a result of the invaginating type of eye formation in vertebrates, the neural retina is placed between the incoming light and the photoreceptors' outer segments, that is, the photosensitive layer (**Figure 3**; **see also Vision**: Photoreceptors and Visual Pigments, Inner Retina and Ganglion Cells, and Adaptations of Photoreceptors and Visual Pigments). The retinal nerve cells scatter some light, which leads to loss of light and blur. The inverse retina has therefore long been considered as mainly disadvantageous. There is, however, an optical rationale that identifies a potential advantage of the inverse retina.

The shortest reliably reported focal lengths of fish lenses are $2.2R$ (R = lens radius) or slightly longer. This seems to be the shortest possible focal length for a spherically well-corrected lens consisting mainly of proteins and water, and functioning in an aqueous environment. Consequently, there has to be some space between the lens and the light-sensitive outer segments of the photoreceptors in order to create well-focused images. Some distance between the optical center of the eye and the retina is also necessary for image magnification (**Figure 1**). In fish eyes, some or all of the space between the lens and the photoreceptors is occupied by the neural retina (**Figure 3**). The inverse retinas of fishes, in fact, of all vertebrates, thus allow for using the space between the lens and the outer segments for retinal neurons at no extra cost in terms of weight and volume. In consequence, even small animals can have relatively large eyes.

The inner segments of the photoreceptors have RI gradients that may contribute to the capture and containment of light. The photopigment-containing outer segments of photoreceptors are usually light guides that confine captured light within their volume. Distal to the photoreceptors there may be a reflecting sheet (tapetum lucidum) that reflects unabsorbed light back into the outer segments for a second passage and thus a second chance for absorption by the photopigment.

Fish cone photoreceptors occur often in partially fused pairs. These double cones may consist of morphologically identical partners expressing the same photopigment (twin cones) or partners that differ in one or both of these parameters. An optical reason for the occurrence of double cones may be that the cell membranes between the partners can make the cells sensitive to the polarization of light by polarization-selective reflection and transmission of light.

Some Special Optical Adaptations

Fish vision has evolved to meet very different needs because fish eyes are used in widely varying visual environments, for instance, brightly lit and colorful coral reefs in contrast to the almost completely dark deep sea (**see also Vision**: Visual Adaptations to the Deep Sea and **The Skin**: Bioluminescence in Fishes). Accordingly, there are numerous interesting deviations from the typical fish eye as shown in **Figure 3**.

Lens Focal Length in Relation to Body Size and Feeding Habits

Image magnification is a function of the focal length of the optical system. Large fishes can, in general, support large eyes and have lenses with long absolute focal lengths to see larger, more detailed images. However, many large fishes such as billfishes (Istiophoridae and Xiphiidae) have eyes that are small in relation to body size. Such species tend to have long normalized focal lengths of the lens (i.e., focal length expressed in units of lens radius), probably because even if the eye is large in relation to the lens, it is still small in relation to the body. Another correlation exists between long normalized focal length of the lens and feeding habits. The long and slender coral-reef-associated cornetfish (*Fistularia commersonii*) attacks in short bursts of fast swimming and captures prey with elongated mandibles (**see also Vision**: Color Vision and Color Communication in Reef Fish). Suitably for the long working distance of the eye, its lens has long normalized focal length.

Telescopic Vision

The sandlance (*Limnichthytes fasciatus*) is a small teleost species that lives in shallow, brightly lit waters with sandy bottoms. It buries in the sand with only the eyes exposed and dashes out to capture planktonic prey. The eye has a thick cornea with considerable positive refractive power (converging lens) and an optically weak, flattened crystalline lens (**Figure 4**(**a**)). The optical center of this two-lens optical system is more anterior than the center of the crystalline lens, such that image magnification is higher than in a typical fish eye.

The inner surface of the fish retina is usually smooth and largely perpendicular to incoming light, such that there is little refraction. The sandlance, however, has a so-called deep fovea with a steeply curved inner surface of the retina (**Figure 4**(**a**)). Similar deep foveas are present in some birds of prey and are assumed to increase image magnification locally in the foveal region. The thick cornea and deep fovea of the sandlance lead to telescopic vision that may be necessary to detect small planktonic prey items when they come into the striking distance of the animal.

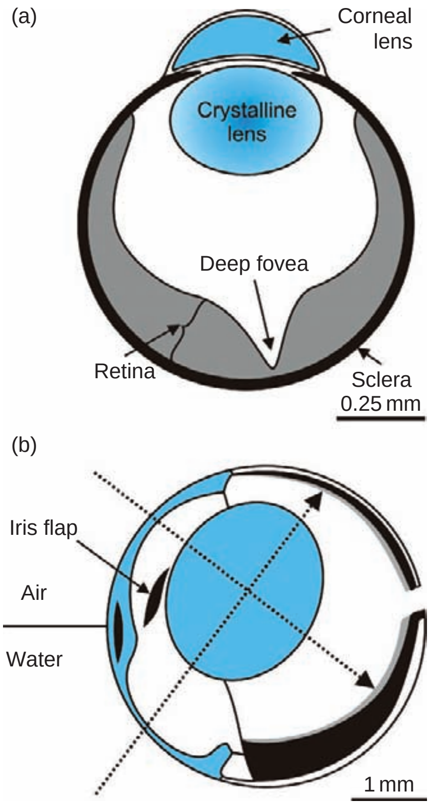

Figure 4 Examples of special optical adaptations in fishes. (a) In the sandlance (*Limnichthytes fasciatus*), the cornea is thick and has considerable positive refractive power, while the crystalline lens is flattened axially and optically weak. This moves the optical center of the eye anteriorly, in comparison to a typical fish eye as illustrated in **Figure 3**, and thus increases image magnification. Further magnification may be achieved locally by the curved inner surface of the retina in the deep fovea. (b) The eye and lens of the four-eyed fish (*Anableps anableps*) are highly asymmetric and there are separate optical paths (dotted lines) for well-focused aerial and aquatic vision. (a) Modified from Pettigrew JD and Collin SP (1995) Terrestrial optics in an aquatic eye: The sandlance, *Limnichthytes fasciatus* (Creediidae, Teleostei). *Journal of Comparative Physiology* 177: 397–408. (b) Modified from Sivak JG (1976) Optics of the eye of the "four-eyed fish" (*Anableps anableps*). *Vision Research* 16: 531–534.

Amphibious Vision

The typical fish cornea is curved (**Figure 3**) and has thus positive refractive power in air, which renders the eye myopic (short-sighted) for aerial vision. However, some fish use their eyes also in air. Atlantic flying fish (*Cypselurus heterurus*) use aerial vision for landing in windrows of Sargassum weed. The cornea is pyramid shaped with three flat zones. The intertidal fishes, foureye rockskipper (*Dialommus macrocephalus*) and Galapagos four-eyed blenny (*Dialommus fuscus*), move considerable distances out of the water and have prism-shaped corneas with two flat zones. In these species, the flat corneal zones do not contribute to the refractive power of the eye in neither water nor air. In both media, the lens is the only focusing optical element. The four-eyed fish (*Anableps anableps*) of South America swims at the water surface with the upper half of the eye exposed to air and the lower half to water. The crystalline lens and the entire eye are highly asymmetric and each half of the eye creates a well-focused image in its respective medium (**Figure 4**(**b**)).

Monofocal Lenses in Deep-Diving Species

Because of the wavelength-selective absorption and scattering of light by water, the available spectrum narrows with increasing depth (**see also Vision**: Visual Adaptations to the Deep Sea and **The Skin**: Bioluminescence in Fishes). Wavelengths around 485 nm penetrate the deepest in clear-blue ocean water. Some fishes make extended foraging excursions from warm and well-lit surface waters to cold and dim depths. At least some of these species have color vision. Within the narrow spectrum at depth, however, LCA leads to little chromatic blur. In accordance with this, a number of deep-diving fish species have monofocal lenses. Some of these lenses are perfectly corrected for LSA within the accuracy of measurement.

Vision in the Deep Sea

Vision in deep-sea fishes may be adapted to the detection of shadows against faint downwelling light or bioluminescence emitted by other organisms (**see also Vision**: Visual Adaptations to the Deep Sea and **The Skin:** Bioluminescence in Fishes). Various astonishing optical adaptations, such as tubular eyes and imaging systems based on mirrors, have evolved and are treated elsewhere in the encyclopedia (**see also Vision**: Visual Adaptations to the Deep Sea).

Glossary

Agnaths (agnathostomes) Primitive jawless (a=without; gnathos=jaw) fish dominant in the early Paleozoic, and represented today by hagfish and lamprey.

Chromophore Part or moiety of a molecule responsible for its color. In visual pigments the chromophore is retinal, the aldehyde of vitamin A, combined with the protein, opsin.

Ionone ring A cyclic ring configuration of carbon atoms linked by single and double bonds.

Microspectrophotometry A technique in which a narrow beam of light is passed through an isolated rod or cone outer segment in order to measure the absorbance of the visual pigment.

Opsin The membrane-bound G-protein-coupled receptor protein found in photoreceptors in the retina, which, when combined to the chromophore retinal, forms a visual pigment.

Orthologous genes Genes in different species that are similar to each other because they originated from a common ancestor.

Photic environment The distribution of light, in terms of brightness and spectral composition, within the environment.

Porphyropsin All visual pigments based on vitamin A_2.

Rhodopsin All visual pigments based on vitamin A_1, but commonly used to refer only to rod visual pigments.

Schiff base A functional group that consists of a carbon–nitrogen double bond. In visual pigments, a nitrogen atom of amino acid lysine 296 in opsin is connected to the terminal alkyl group (CH_3) of the chromophore, retinal.

Teleosts A bony fish of the subclass Teleostei, having rayed fins and a swimbladder.

Tetrachromatic color vision Color vision based on four spectrally distinct cone classes, normally maximally sensitive in the red, green, blue, and violet or ultraviolet.

The aquatic environment, both marine and freshwater, provides a wide array of photic environments, ranging from surface waters exposed to almost full daylight, with a broad spectrum available for vision extending from the ultraviolet (UV) to the far red, to deep waters where brightness is severely attenuated and the spectrum is reduced to a narrow band centered in the blue, around a wavelength of 460–480 nm. Different regions of the aquatic environment may show almost any variation between these two extremes, from the clearest oceans to coastal waters, lakes and rivers which may carry high levels of suspended particles and/or be heavily stained with organic run-off from the land and/or with dissolved minerals. These photic environments provide a major evolutionary driving force for the visual systems of fish, and indeed any aquatic animal, leading to dramatic modifications in the basic structure of the vertebrate eye. This article considers specifically the retinal photoreceptors and photosensitive visual pigments concerned with visual imaging.

Visual Pigment Structure

Vertebrates evolved about 550 million years ago (mya) and are clearly recognizable in the primitive jawless fish, agnaths, of the early Paleozoic. These fish swam in shallow seas with the luxury of the full daylight spectrum and rapidly evolved a set of photoreceptors and visual pigments to maximize their visual input. Vertebrate retinas contain two types of photoreceptor cells, cones used in bright light conditions and which form the basis of color vision, and more specialized, highly sensitive rods that function at low light levels and provide only monochromatic vision. Both rods and cones contain visual pigments that are tuned to be most sensitive to a particular spectral region. The pigments are composed of a protein, opsin, combined with a chromophore, the aldehyde of vitamin A, retinal. Opsins, like most proteins, absorb light in the far UV around 280 nm, whereas retinal absorbs in the near UV at about 370 nm. When combined to form a visual pigment, there is an opsin shift, mostly to longer wavelengths, so that visual pigments have maximum absorbances ($\lambda_{\max}$) anywhere from the near UV, around 350 nm, to the red, over 600 nm. The size of the opsin shift and the specific $\lambda_{\max}$ depends on the structure of the opsin, determined by the precise sequence of its constituent amino acids.

Vertebrate opsins are membrane-bound G-protein-coupled receptors composed of about 350 amino acids that form seven transmembrane α-helices connected by straight chain loops (**Figure 1**). The helices form a palisade surrounding the chromophore retinal, which is bound via a Schiff base link to a lysine residue in the seventh helix. Retinal consists of an ionone ring with a conjugated carbon chain and it is the interaction of amino acids lying close to either the ionone ring or the Schiff base which are primarily involved in tuning the pigment to a specific wavelength. In addition to opsin tuning, pigments may also shift their $\lambda_{\max}$ by exchanging their chromophore. Vitamin A exists in two forms, A_1 and A_2, giving rise to two forms of retinal, retinal, based on vitamin A_1 and 3-dehydroretinal, derived from vitamin A_2. Visual pigments based on retinal are termed rhodopsins (*rhodon*, Greek for rose), whereas those based on 3-dehydroretinal are termed porphyropsins (*porphyra*, Greek for purple). Somewhat confusingly, rhodopsin is often used as a term for visual pigments contained only in rods, and not for those in cones. Porphyropsins have an additional double bond in their ionone ring (**Figure 1**) and this causes a long wave shift in the absorbance spectrum of the pigment when compared to the equivalent rhodopsin. The long wave shift is wavelength dependent, being much greater at longer wavelengths, so that a rhodopsin with $\lambda_{\max}$ at 560 nm has a paired porphyropsin with $\lambda_{\max}$ at about 620 nm. The spectral shift reduces at shorter wavelengths and is only a few nanometers for pigments with maxima in the blue.

As a general rule, but with notable exceptions, marine fish, living in a relatively blue environment, possess rhodopsins, whereas freshwater fish, living in a more long-wave green environment, have more longer-wave porphyropsins.

Evolution of Visual Pigments

Ancestrally, there are four spectral classes of cone visual pigments, but only a single class of rod pigment. From studies of mutation rates of genes and of the opsins present in extant species of agnaths, lampreys, it is apparent that the four classes of cone pigment evolved very early in vertebrate evolution, about 450–500 mya (**Figure 2**). The four classes include long-wave-sensitive (LWS) (red/green), with $\lambda_{\max}$ ranging from about 495 to 570 nm; RH2; middle-wave-sensitive (green/blue), with $\lambda_{\max}$ from about 460 to 530 nm; and short-wave-sensitive 2 (SWS2) (blue/violet) with $\lambda_{\max}$ from about 415 to 480 nm and SWS1 (violet/UV) with $\lambda_{\max}$ from about 355 to 450 nm ($\lambda_{\max}$ values for rhodopsins). There is some overlap between these spectral ranges, so that knowing the $\lambda_{\max}$ of a pigment does not necessarily define its opsin class. Rods, RH1, the last class to appear, evolved from the RH2 cone class, and have a spectral range from about 460 to 530 nm, almost identical to that of the RH2 cones.

From an evolutionary position, modern extant species of agnaths, lampreys, have the potential to offer a glimpse of the visual system of early agnaths from the late Cambrian. In the Southern Hemisphere lamprey, *Geotria australis*, there are multiple spectral classes of cone and rods. Microspectrophotometry (MSP), a technique that measures the absorbance spectrum of individual photoreceptor outer segments, has identified two spectrally distinct classes of cone containing porphyropsins with $\lambda_{\max}$ at about 610 and 515 nm, along with rods with $\lambda_{\max}$ at about 505 nm. In addition, a study of the genetic complement of visual pigment opsins in *Geotria* has identified five opsin genes. Three of these are orthologous to the LWS, SWS2, and SWS1 opsin genes of jawed vertebrates (gnathostomes), but the remaining two, RHA and RHB, appear to be equally distantly related to the gnathostome RH1 and RH2 gene families. Four of the *Geotria* pigments, SWS1, SWS2, RHB, and RHA, have been regenerated with retinal, yielding pigments (rhodopsins) with $\lambda_{\max}$ at 358, 439, 492 and 497 nm, respectively, and although the LWS gene has not been regenerated, it represents the 610-nm porphyropsin measured by MSP. The RHA opsin would appear to be that expressed in the rods, whereas the RHB is presumably expressed in middle-wave-sensitive (MWS) cones. From these data, it is clear that the cone opsin genes originated before the major evolutionary event of the appearance of jaws, perhaps as early as 540 mya. The implication is that primitive jawless fish of the shallow late Cambrian and Ordovician seas, exposed to the full daylight spectrum, possessed four spectrally distinct cones classes, including sensitivity to UV and thus had the potential for a sophisticated tetrachromatic color vision system.

With this complex of opsins and chromophores, fish have a number of mechanisms for varying their spectral sensitivity and color vision. The basic plan of four spectral classes of cone can be modified in a number of ways. There may be an evolutionary loss of one or more of the four opsin genes or, in contrast, a duplication of a gene within a class and subsequent gene mutations to separate spectrally the two expressed cone pigment subclasses, such as RH2A and RH2B (shorter wavelength) and SWS2A and SWS2B (shorter wavelength). In addition, gene mutations can occur that spectrally shift pigments within each class or subclass. Finally, spectral variation can be achieved, not by opsin mutations, but by either

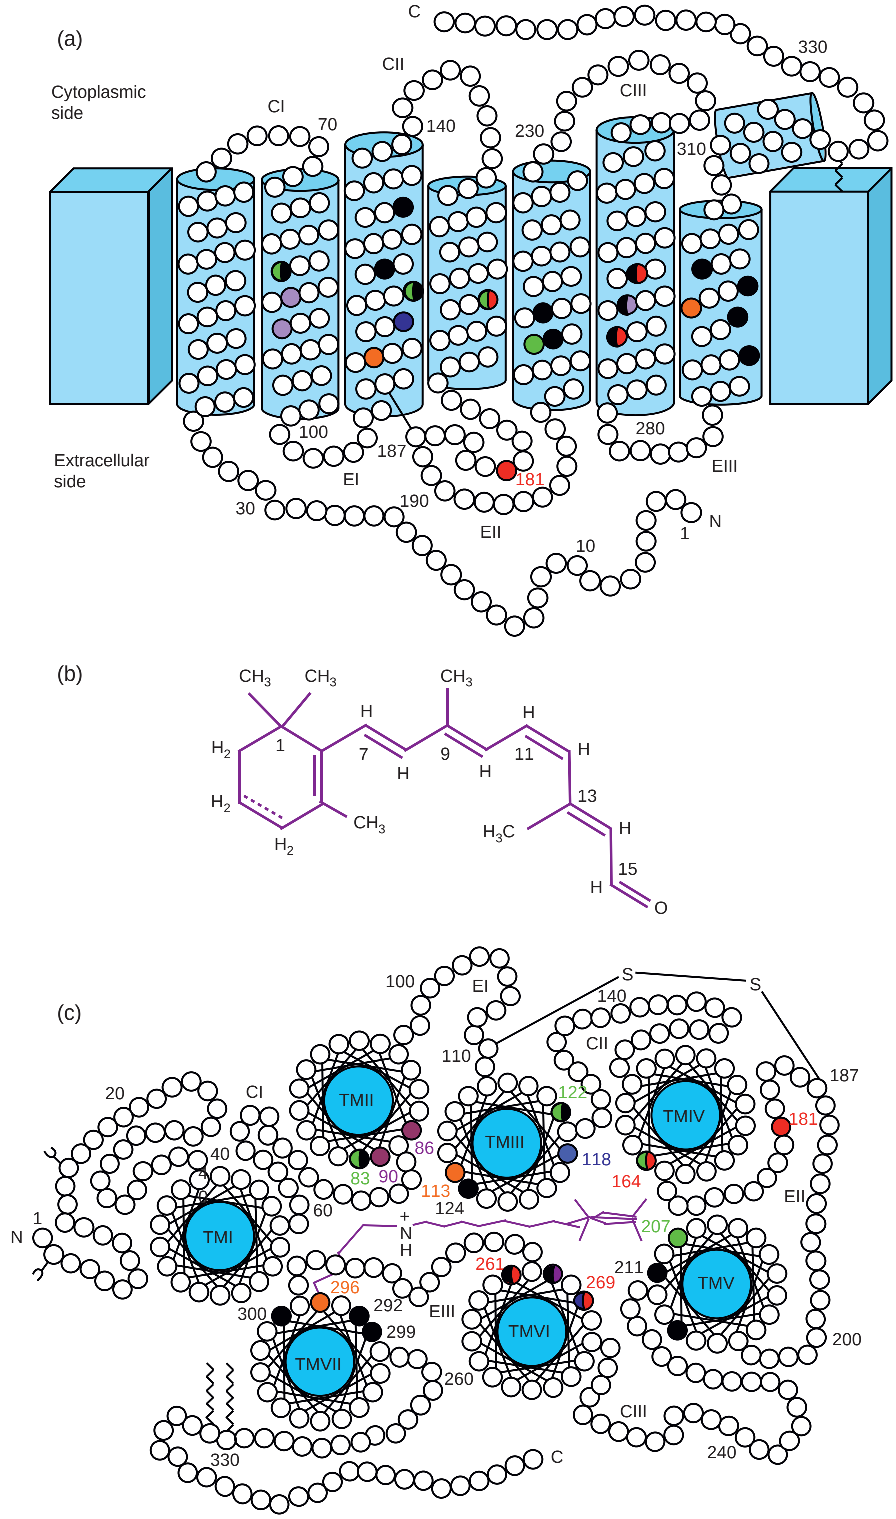

Figure 1 Schematic diagrams of a visual pigment molecule. (a) Two-dimensional diagram illustrating the seven transmembrane α-helices. (b) Molecular structure of retinal as an 11-*cis* isomer. The additional double bond (dashed line in the ionone ring) is found in 3-dehydroretional. (c) View showing the arrangement of the helices around the chromophore, retinal, shown in purple. Although the helices are of different lengths, for simplicity, each helix is shown with only the central 18 amino acids. The numbering is based on mammalian rhodopsin. Lysine 296 (orange) is the binding site of retinal and glutamate 113 (orange) provides the Schiff base counter-ion. Major sites involved in spectral tuning are coded with opsin class: LWS red, RH2 green, SWS2 blue, SWS1 violet, and RH1 black. Splits indicate sites involved in tuning in more than one opsin class. Note how sites tend to cluster around either the Schiff base linkage or the ionone ring of retinal. TMI to TMVII – the seven transmembrane helices of opsin; EI, EII, and EIII – extracellular straight chains of opsin; CI, CII, and CIII – cytoplasmic straight chains of opsin; C and N (carbon and nitrogen) – the terminals of the opsin molecule (common terminology for proteins), the numbering of amino acids starts from the N terminal; CN+, represents the protonated Schiff base. Modified from Bowmaker JK and Hunt DM (2006) Evolution of vertebrate visual pigments. *Current Biology* 16(13): R484–R489.

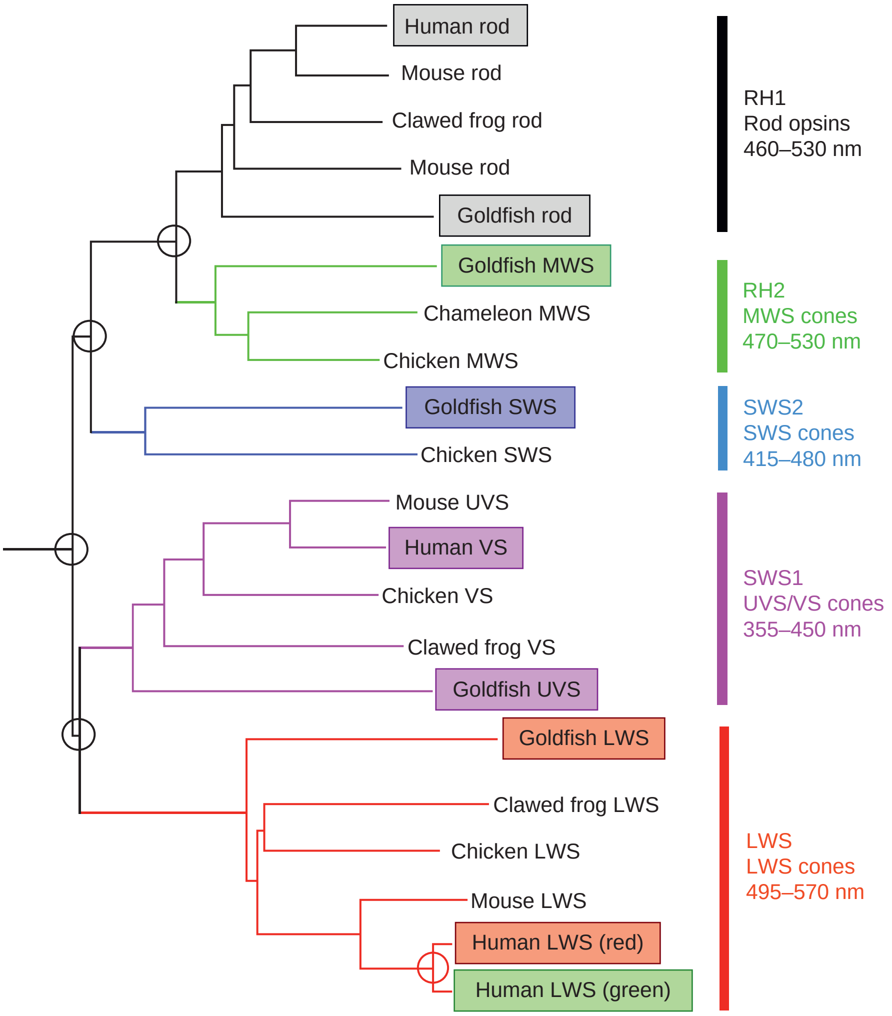

Figure 2 Simplified schematic phylogenetic tree of vertebrate visual pigment opsins with representative opsins from fish, amphibians, birds, and mammalians. Circles indicate gene duplications, four early in evolution about 500 mya, resulting in the four cone opsins and the rod opsins, and the recent duplication, about 35 mya, of the primate LWS opsin to produce the human L and M cone pigments. Note that mammals have lost the RH2 and SWS2 cone opsins.

switching the chromophore completely or varying the percentage of each chromophore incorporated into the opsin. None of these mechanisms are exclusive and the spectral sensitivity of a fish may vary during development, with selective temporal gene expression and by variations in chromophore, both developmentally and/or seasonally. For a more detailed discussion (**see also Vision**: Adaptations of Photoreceptors and Visual Pigments).

Cone Types and Retinal Mosaics

The different classes of cone visual pigments are expressed in a variety of morphologically distinct photoreceptors. Fish possess both single and double cones. In double cones the two halves may be adjacent, but not firmly attached, or they may be tightly bound with direct electrical connectivity. Generally, double cones tend to be relatively large and express the more LWS opsins, whereas single cones tend to be smaller and express more SWS pigments. Moreover, the nomenclature of double cones is confusing, but they can be divided into double cones in which the two halves are morphologically distinct, and twin cones in which the two halves are morphologically identical. Both of these types can be subdivided into identical and nonidentical forms. In nonidentical double or twin cones, the two halves contain spectrally different pigments, but in identical double or twin cones the two halves possess the same visual pigment (**Figure 3**). The precise function of double cones is not immediately apparent, but nonidentical double cones may offer good wavelength discrimination with high chromatic acuity, since the two halves occupy almost the same space within the visual field. By contrast, identical twin cones, probably

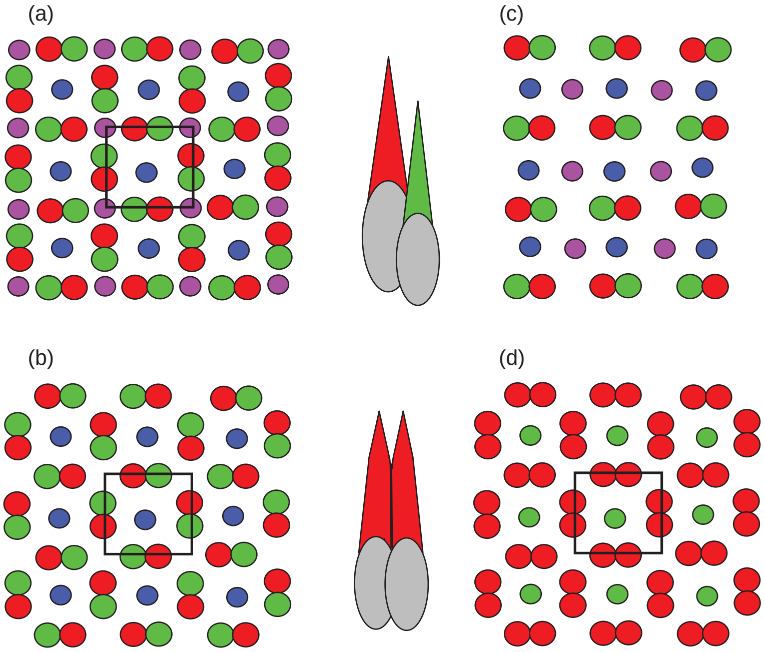

Figure 3 Schematic diagrams of retinal cone mosaics present in some teleost species. (a) The complete square mosaic found for example in some juvenile salmonids and cyprinids, with four longer-wave-sensitive double cones forming the sides of the square, with a central shorter-wave blue-sensitive single cone and UV-sensitive single corner cones. (b) A reduced mosaic with the absence of corner cones as found in some adult salmonids and cichlids. (c) A row mosaic as found in some cyprinids such as zebrafish (*Danio rerio*). (d) A square mosaic with LWS identical twin double cones and a central middle-wave-sensitive single cone, as found for example in pike (*Esox lucius*). The central diagrams illustrate a nonidentical double cone with a larger long-wave-sensitive member, and an identical twin cone.

electrically coupled, may act as large photon catchers designed to give photopic vision at relatively low light levels. In some species triple or even quadruple cones have been identified, in which the members may contain different visual pigments or all express the same pigment.

A striking feature of the retina of many fish is that the photoreceptors are not randomly distributed across the retina, but form a distinct array or mosaic. This normally involves either a row or square pattern with the double cones alternating with single cones (**Figure 3**). In the extreme form of a square mosaic, double cones form the sides of a square, with a central single cone, usually SWS, and four additional single cones occupying the corners of the square, often UV sensitive. In a number of species, the mosaic may not be complete, with some or all of the corner cones absent or the central single cone missing. These patterns can vary spatially across the retina and may also change temporally during development. The functional significance of these ordered arrays, not found outside of fish, is not immediately apparent. Suggestions have been made that they could improve movement detection, but there is only limited evidence to support such a theory.

The wide diversity and arrangement of photoreceptors and visual pigments found in fish can, perhaps somewhat simplistically, be related to differences in the photic environment of the various species and to distinct changes in environment and behavior experienced during development from larva to adult. There may be subtle influences that determine the differences in photoreceptor populations and spectral sensitivities across species. The bright colors and sexual dimorphism exhibited by many species are likely to be significant in species recognition and mate choice (**see also Vision**: Behavioral Assessment of the Visual Capabilities of Fish). Similarly, the feeding behavior of fish varies greatly and has certainly influenced anatomical features such as the mouth and jaws, and may be significant in determining retinal organization. The aquatic environment, unlike the terrestrial scene, is dominated by the direction of the downwelling light, daylight penetrating through the water column, so that the visual field above a fish is markedly different from the lateral view and from the visual field below the fish. These differences clearly will affect retinal organization so that variations in mosaic arrangements and cone complements may well differ between retinal regions that are viewing different visual fields. To understand the significance of all of these more detailed features of fish vision, extensive behavioral studies of individual species and fish communities are needed, which may then be related to the more easily obtained anatomy and physiology of the visual system.

Tetrachromatic color vision Color vision based on four spectrally distinct cone classes, normally maximally sensitive in the red, green, blue, and violet or ultraviolet.

Different types of photoreceptors and their visual pigments are discussed elsewhere in this encyclopedia. This article considers how the retinal photoreceptors and photosensitive visual pigments have adapted to different photic environments and how, in some fish, they may change during development.

The aquatic ecosystem provides a wide array of photic environments, ranging from surface waters exposed to almost full daylight, with a broad spectrum available for vision extending from the ultraviolet (UV) to the far red, to deep waters where brightness is severely attenuated and the spectrum is reduced to a narrow band centered in the blue around 460–480 nm. Different regions of the aquatic environment may show almost any variation between these two extremes, from the clearest oceans to coastal waters, lakes, and rivers which may carry high levels of suspended particles and/or be heavily stained with organic run off from the land and/or with dissolved minerals.

In the evolution of vertebrates, four spectral classes of cone photoreceptors evolved early and have representatives in all extant groups of fish, from lampreys to teleosts. The four classes can be defined as: LWS, long-wave-sensitive (red/green), with λ_{max} ranging from about 495 to 570 nm; RH2, middle-wave-sensitive (green/blue), with λ_{max} from about 460 to 530 nm; SWS2 (blue/violet), short-wave sensitive, with λ_{max} from about 415 to 480 nm; and SWS1 (violet/UV), with λ_{max} from about 355 to 450 nm (λ_{max} values for rhodopsins). There is some overlap between these spectral ranges, so that knowing the λ_{max} of a pigment does not necessarily define its opsin class. Rods, RH1, the last class to appear, evolved from the RH2 cone class, and have a spectral range from about 460 to 530 nm, almost identical to that of the RH2 cones (**Figure 1**).

Adaptations to the Photic Environment

Present-day bony fish, teleosts, arose about 150 million years ago (MYA) in the Cretaceous, and now comprise about 96% of all living fish species. They are found in all aquatic environments and show some of the greatest ranges in visual capacity, extending from pure rod vision in many deep-sea species to tetrachromacy in a number of shallow-living species. The filtering effect of the water column first attenuates longer wavelengths in the red, followed by the shorter UV and, as a consequence, epipelagic fish living in the top 100 m or so of the ocean tend to be trichromatic or dichromatic, no longer expressing

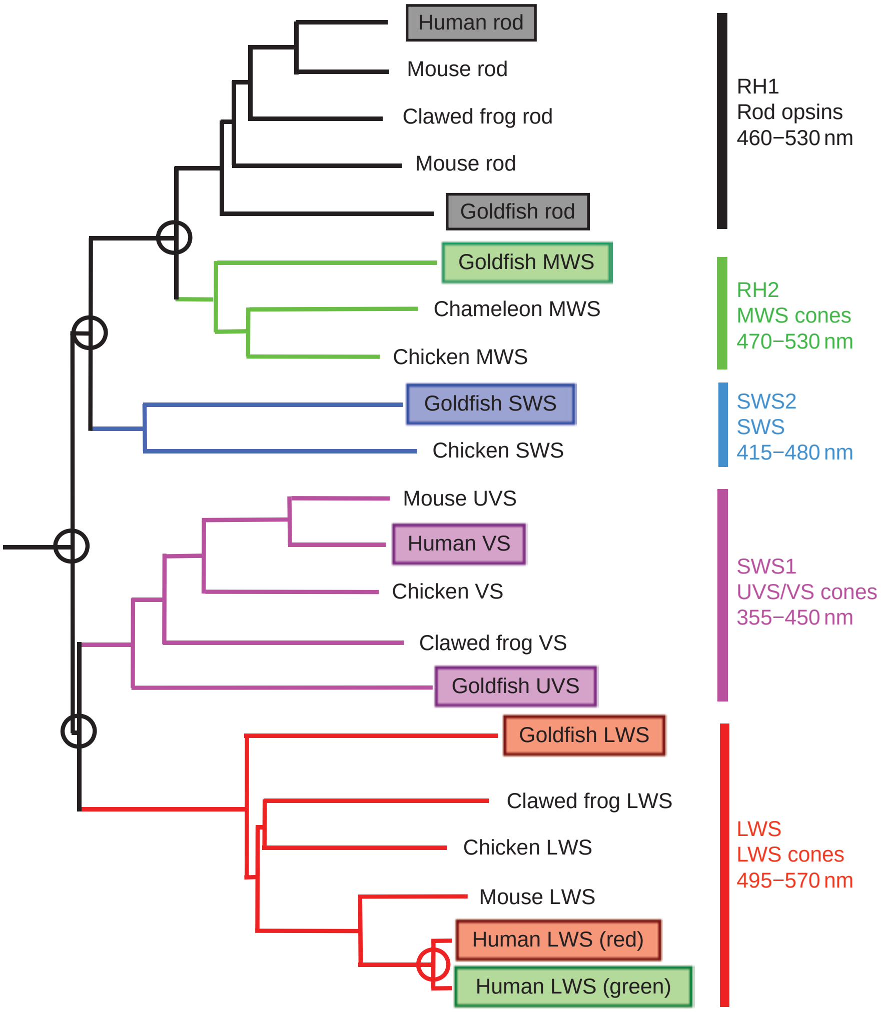

Figure 1 Simplified schematic phylogenetic tree of vertebrate visual pigment opsins with representative opsins from fish, amphibians, birds, and mammalians. Circles indicate gene duplications, four early in evolution about 500 MYA, resulting in the four cone opsins and the rod opsins, and the recent duplication, about 35 MYA, of the primate LWS opsin to produce the human L and M cone pigments. Note that mammals have lost the RH2 and SWS2 cone opsins.

either the LWS or the SWS1 opsins or both. In contrast, fish living in highly turbid or deeply stained waters, which strongly absorb and scatter short wavelengths, tend to lose or not express the shorter-wave opsins, but retain the LWS and RH2 opsin genes. In more extreme conditions at low-light levels, because of either increased depth or turbidity, fish may become cone monochromats expressing only the RH2 or LWS genes.

Adaptations to Increasing Water Depth

A striking illustration of the effects of the changing photic environment with depth on visual pigments and photoreceptors is provided by the distinctive environment of Lake Baikal. The lake, in central Siberia, is the deepest lake in the world at over 1600 m and is unique in that its waters are fully oxygenated even in the deepest regions. This has allowed a flock of over 20 species of sculpins, cottoid fish, to evolve endemic to the lake and which can be divided into groups that occupy progressively deeper habitats. Against the general rule for freshwaters, their visual pigments are all rhodopsins. Species living in the surface waters, exposed to the full daylight spectrum, have relatively cone-rich retinas with three spectral classes of cone, comprising red/green-sensitive double cones, green-sensitive identical twin cones, and single blue-sensitive cones (**Figure 2**). These cones are all relatively small and tightly packed presumably providing high visual acuity. Species occupying deeper waters, where daylight is restricted to a narrower spectral band centered in the blue/green region, have lost the LWS cones, retaining only the green-sensitive twin cones and blue-sensitive single cones. With increasing depth, the species show a series of short-wave shifts in the λ_{max} of

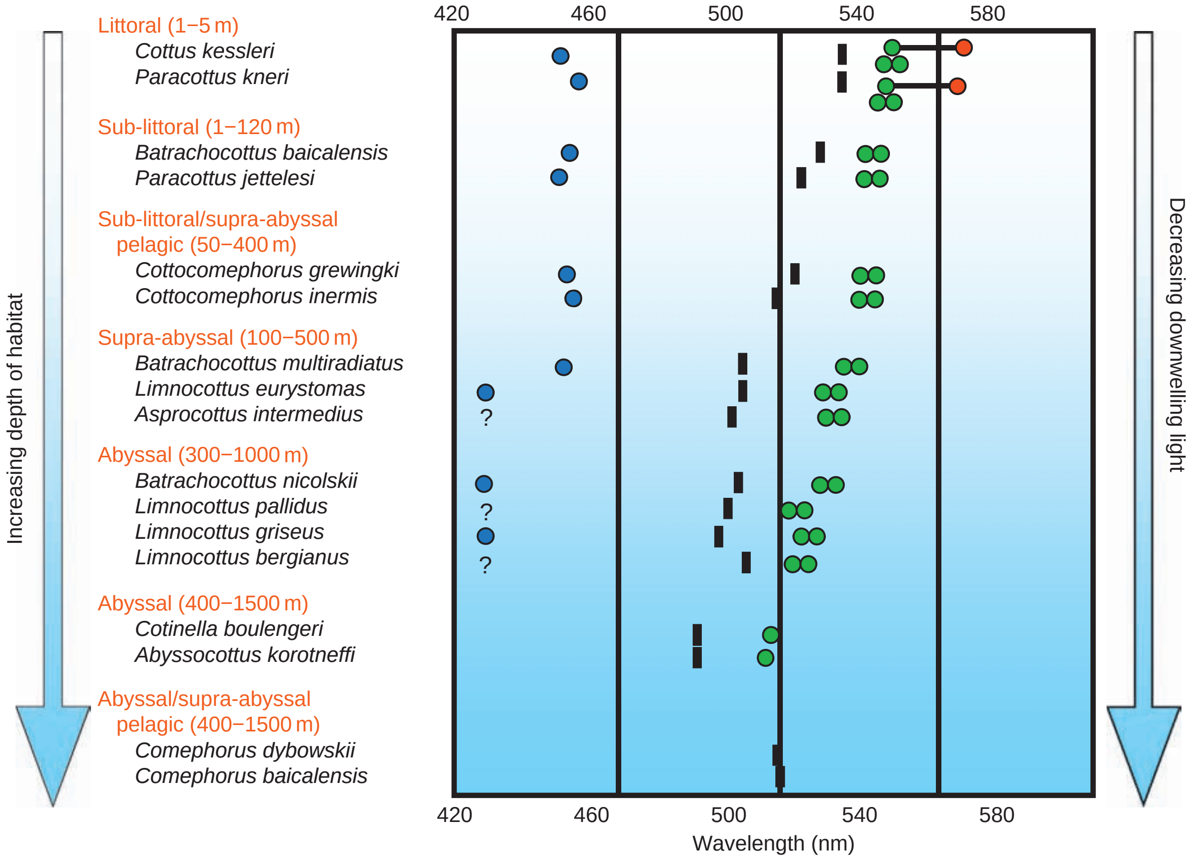

Figure 2 The distribution of visual pigments in the cottoid species flock of Lake Baikal. Spectral locations of the LWS, RH2, SWS2, and RH1 pigments from a range of species living at different depths in the lake. Red and green linked circles, LWS/RH2 double cones; twin green circles, RH2 double cones; blue circles, SWS2 single cones; black symbols, rods. Note the spectral shift to shorter wavelengths in all pigment classes with increasing depth of habitat. The LWS opsins are present only in surface-living species. Spectral tuning of the rod pigments is achieved through only three amino acid sites: 83, 261, and 292. From Bowmaker JK and Hunt DM (2006) Evolution of vertebrate visual pigments. *Current Biology* 16(13): R484–R489.

both the green-sensitive cones and the rods. The middle-wave cones (RH2) fall into four clusters with λ_{max} ranging from about 525 to 500 nm, and the rods similarly show distinct spectral steps, with λ_{max} shifting from about 516 nm in the more surface species down to 484 nm in abyssal species. In addition, with increasing depth, the twin cones become much larger, both in diameter and in length, becoming large photon-capturing devices maintaining photopic vision at depth, but with a concomitant loss in acuity. In abyssal species, where light levels are below the limits of photopic vision, cones have been lost completely, leaving pure rod retinas with maximum sensitivity around 480–500 nm (**Figure 2**).

Comparisons of the derived amino acid sequences of the opsin genes of the rod pigments from these sculpins have identified just four amino acid substitutions that account for the spectral shifts to shorter wavelengths (**Figure 2**). These same substitutions, along with a small number of additional substitutions, are also found in deep-sea fish rod pigments that show the same spectral shifts toward shorter wavelengths. Surveys of large numbers of deep-sea species suggest that the peak sensitivities of rod pigments cluster at specific spectral locations between about 450 and 500 nm the clusters being separated by 5–10 nm, with the vast majority of pigments centered at 477 and 483 nm. The effect of each amino acid substitution on the λ_{max} is approximately additive, and these mutations, which must have occurred independently within each group, are clear examples of parallel evolution. Sensitivity to these shorter wavelengths not only matches the wavelength of maximal spectral transmission of water at depth, but, in the case of oceanic fish, also matches the blue bioluminescence emitted by photophores present on many species of deep-sea fish. Bioluminescence is not present in Lake Baikal.

Gene Duplication in Shallow-Living Species

In contrast to the loss of opsin genes, many teleost families have duplicated their cone opsin genes to produce a range of functional opsins within each opsin gene class. The evolution of gene families is an active process, in which gene duplication is accompanied by the subsequent mutation of genes, leading either to the decay of some genes into pseudogenes and eventually junk DNA or to a divergent gene with a new function. In teleosts, such as cichlids, the dominant species in many tropical and subtropical lakes and rivers, and cyprinids, the equivalent to cichlids, but in more temperate regions, mutations in the duplicated genes have led to additional functional genes which are expressed as visual pigments spectrally displaced from one another.

Lake Malawi, one of the Great Lakes in central Africa, has more than 700 species of cichlids that have evolved from a common ancestor within the past million years, and the species flock provides a notable example of opsin gene duplication. Malawi cichlids are remarkable for their diversity, particularly in their color patterns, and most species are sexually dimorphic with visual communication crucial for mate choice. African cichlids typically possess three cone visual pigments, with nonidentical double cones maximally sensitive at longer wavelengths and shorter wavelength-sensitive single cones, with the precise λ_{max} of the cones seemingly related to the clarity of the water in their specific habitats. Species living in clear water above a rocky substrate tend to have double cones with maximum sensitivities at about 535 and 488 nm and UV- or violet-sensitive single cones with λ_{max} at about 370 or 420 nm, whereas species living in a more sandy environment may be less sensitive to shorter wavelengths, possessing double cones with maximum sensitivities at about 570 and 535 nm and blue-sensitive single cones with λ_{max} at about 450 nm (**Figure 3**).

In some species, however, rare additional spectrally distinct cones have been identified by microspectrophotometry, suggesting that at least seven spectral types of cone pigment are expressed in the retina. Analysis of the opsin gene complement of these cichlids has confirmed the presence of seven functional cone opsin genes, three

from the RH2 gene class, two from the SWS2 class, with single representatives of the LWS and SWS1 gene classes. The three green-sensitive cone pigments suggest that duplication in the RH2 gene has occurred on at least two occasions (**Figure 3**). It is most unlikely that all seven cone pigments are functional at one and the same time, but are selectively expressed during development. This has been demonstrated in at least one species, the Nile tilapia (*Oreochromis niloticus*), considered equivalent to the riverine ancestor of the lake cichlids, which expresses primarily four of the seven cone opsins in the larval form, including sensitivity to UV, but on maturity switches opsin gene expression by downregulating the shorter-wave opsin genes and upregulating the longer, giving the fish sensitivity to longer wavelengths, but with the loss of UV sensitivity (**Figure 4**).

Adaptations through Chromophore Exchange

A further group of teleosts that alter their spectral sensitivity by selective gene expression includes a number of migratory fish such as the anguilliform eels and the salmonids. In addition to switching opsin gene expression, these species also change chromophores during development and migration. The European eel, *Anguilla anguilla*, has a complex life history undergoing two distinct metamorphoses (**see also Fish Migrations**: Eel Migrations). As young yellow eels, the fish spend between 6 and 20 years maturing in the rivers of Western Europe and are somewhat typical of freshwater teleosts. Although rod dominated, the retina contains two spectrally distinct classes of single cone with λ_{max} at about 545 nm (RH2) and 440 nm (SWS2), with the rods having λ_{max} at 523 nm (**Figure 5**). All the pigments are porphyropsins, and, unusually for teleosts, double cones are not present. During autumnal downstream migration, the eel undergoes a metamorphosis, becoming a silver eel, showing dramatic changes in body structure and eye size. The eel becomes a truly oceanic mesopelagic fish, reaching sexual maturity, and is thought to breed at depths of up to 400 m in the Sargasso Sea.

As part of the metamorphosis, there is a substantial addition of new rods to the retina with probably a reduction in the number of cones. At the same time, the chromophore of the visual pigments switches, over a number of weeks, from 3-dehydroretinal to retinal, with a

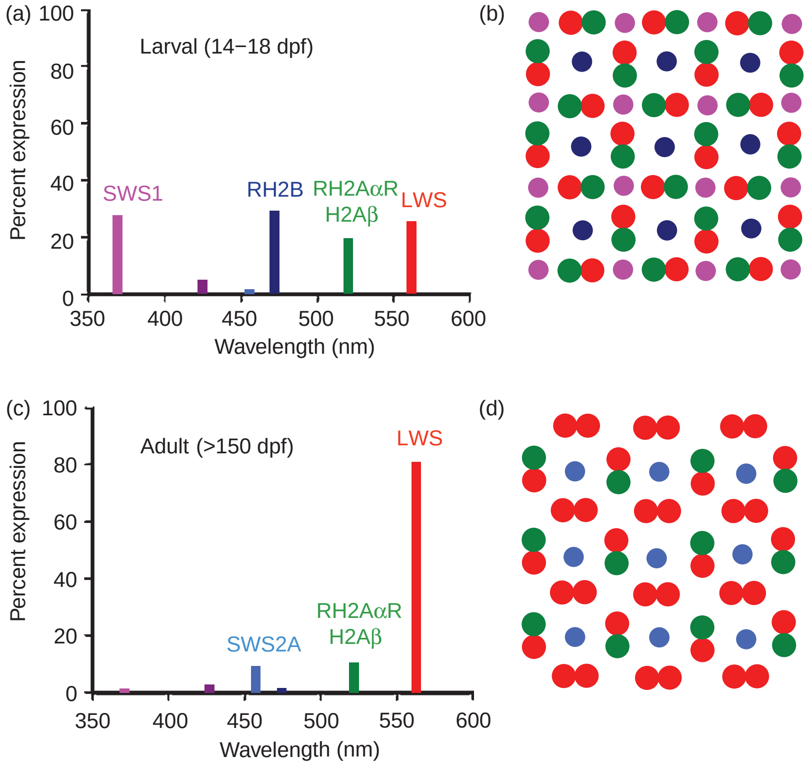

Figure 4 Differential expression of cone opsins during development in an African cichlid, the Nile tilapia. (a) Expression levels of the seven cone opsin genes in larval fish 14–18 days post fertilization (dpf). Relatively similar levels of expression of the LWS, RH2A, RH2B, and SWS1 opsins suggest the potential for tetrachromatic color vision. (b) Schematic of the possible cone array in these larval fish. (c) Expression levels of the cone opsins in adult tilapia. Expression is dominated by the LWS opsin with lower levels of expression of the RH2A and SWS2A suggesting the potential for trichromacy with the loss of UV sensitivity and the addition of identical LWS double cones, as shown in (d).

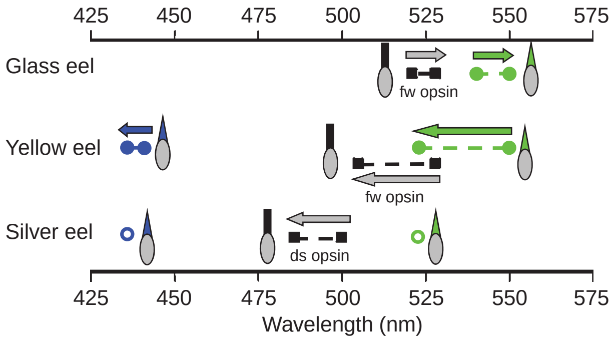

Figure 5 Variations in the peak sensitivities of the rods and cones of the European eel, *Anguilla anguilla,* at different stages during its life history. Circles indicate single cones and black squares indicate rods, as shown by the cartoons. Shifts in sensitivity are indicated by the arrows. At the juvenile glass eel stage, on entering freshwater, only rods and green-sensitive (RH2) cones are present and there is a shift from a rhodopsin-dominated system to porphyropsin-dominated pigments. At the yellow eel stage, both blue (SWS2)- and green sensitive cones are present and as metamorphosis progresses toward the silver eel stage there is a spectral shift toward shorter wavelengths with the reintroduction of rhodopsins. In addition, there is downregulation of the freshwater rod pigment (fw opsin) and upregulation of the deep-sea rod pigment (ds opsin). Cones may be lost at the silver eel stage (open circles).

displacement of the $\lambda_{\max}$ to shorter wavelengths: 525 and 435 nm in the cones and 501 nm in the rods. There is also a change in opsin expression in the rods, with a downregulation of a freshwater opsin and the upregulation of a new deep-sea opsin (**Figure 5**). The deep-sea opsin is expressed as a rhodopsin with $\lambda_{\max}$ at about 482, typical of deep-sea fish. During evolution of the anguilliforms, the rod opsin has been duplicated in order to achieve more short-wave sensitivity in an oceanic environment, enhanced by the change in chromophore to provide more short-wave rhodopsins. After breeding, the eel larvae, called 'leptocephali', return to Europe on the North Atlantic Drift over a period of a few years when they undergo a second metamorphosis changing into glass eels or elvers and entering into freshwater to develop into yellow eels. During the early stages of this transition, the glass eels initially express only the freshwater rod opsin and the RH2 cone opsin, with the SWS2 blue-sensitive opsin being expressed later (**Figure 5**).

A further group of teleosts, the salmonids, also illustrate a feature perhaps relatively common among fish and that is the loss of UV sensitivity during development. Salmonids, including migratory Pacific and Atlantic salmon (*Oncorhynchus* spp. and *Salmo salar*, respectively), as well as land-locked trout (e.g., *Salmo trutta*), exhibit at early juvenile stages the typical teleost square mosaic with red/green double cones forming the sides of the square, and single cones located in the center and at the corners of the array. Initially, it is likely that all the single cones express an UV-sensitive pigment (SWS1), but during development two distinct changes occur. First, the SWS1 opsin gene is downregulated and most of the UV-sensitive cones start to express a blue-sensitive SWS2 opsin. At the same time, the corner cones are gradually lost through apoptosis, so that after a few weeks or months (depending on species) the retinal mosaic changes from having central cones primarily expressing the SWS2 pigment and the corner cones primarily expressing the SWS1 pigment, to a simpler pattern with the loss of corner cones leaving only the central blue-sensitive single cone. The double cones and rods do not show changes in opsin expression. The developmental pattern in the single cones is further complicated by regional variations in expression and loss, with both progressing from ventral to dorsal across the retina.

The significance of these changes has traditionally been related to a number of environmental and behavioral aspects. UV sensitivity has been suggested as a means of improved detection of planktonic food, since plankton often absorb short wavelengths and UV sensitivity would increase visual contrast. In addition, it is thought that UV-sensitive cones are involved in the ability of fish to detect the plane of polarization of underwater light, thought to be involved in orientation. However, such theories have been questioned, since the transition from UV sensitivity to more blue sensitivity occurs at very different times during development across salmonid species – in some species occurring at the very early larval stages, but in others not until smoltification approaching 1 year of development. The early appearance of single cones, in many cases UV-sensitive, may be a more general feature important in retinal development, and may play a fundamental role in the establishment of the retinal photoreceptor mosaic, such a striking feature of many teleosts. Developmental opsin transitions have been reported not only in salmonids, but also in many other teleost groups, notably in cyprinids, such as goldfish (*Carassius auratus*) and zebrafish (*Danio rerio*).

In salmonids, as in eels, the chromophore also switches during migrations, with rhodopsins dominating in oceanic environments and porphyropsins becoming more prominent in freshwater. In land-locked species, there can also be chromophore variations that may be seasonal in temperate climates, and/or reflect the color and turbidity of the water. In dystrophic lakes where the water may be heavily stained yellow or brown with organic run off from the land, visual pigments have a higher percentage of porphyropsins than in clearer eutrophic lakes where more short-wave light can penetrate and rhodopsins predominate. In general, there may also be an increase in porphyropsins during the winter months, seen not only in salmonids, but also in some cyprinids, such as rudd (*Scardinius erythrophthalmus*), and again this is thought to relate to increases in turbidity and run off during the wetter winter season, but may also reflect seasonal changes in feeding behavior.

These examples of variations in visual capacity in a range of teleosts illustrate the great diversity of photoreceptors and visual pigments found in fish. Broadly, and perhaps somewhat simplistically, these can be related to differences in the photic environment of the various species and to distinct changes in environment and behavior experienced during development from larva to adult. However, there may be much more subtle influences that determine the differences in photoreceptor populations and spectral sensitivities across species. The bright colors and sexual dimorphism exhibited by many species are likely to be significant in species recognition and mate choice, but the degree to which this has governed spectral sensitivity and color vision is not well understood. Similarly, the feeding behavior of fish varies greatly and has certainly influenced anatomical features, such as the mouth and jaws, but how significant these behaviors are in determining retinal organization is again not well understood. The aquatic environment, unlike the terrestrial scene, is dominated by the direction of the downwelling light, so that the visual field above a fish is markedly different from the lateral view and from the visual field below the fish. These differences clearly affect retinal organization so that variations in mosaic arrangements and cone complements may well differ between retinal regions that are viewing different visual fields. To understand the significance of all of these more detailed features of fish vision, extensive behavioral studies of individual species and of fish communities are needed, which may then be related to the more easily obtained anatomy and physiology of the visual system.

Glossary

Axon The long extension of a nerve cell that carries spikes (action potentials, or neural impulses) to distant target cells away from the cell body where the nucleus lies (also called the nerve fiber).

Cross-correlation A measure of the relatedness of the firing of pairs of neurons. Typically, a cross-correlogram is created in which the number of occurrences of spikes in one neuron is tallied as a function of the time before or after each spike in the other neuron.

Counterphase A contrast alternating in time; dark areas become light and light areas become dark.

Distal The furthest from the central nervous system, or in the direction away from the central brain. Receptors are the most distal retinal neurons.

Electrotonic The passive spread of an electrical signal.

Gap junction A connection between two neurons that allows electrical signals to pass directly between them.

Maintained discharge The ongoing spiking activity of a neuron in the absence of changing stimulation.

Myelinated axon An axon that is coated with a fatty sheath that promotes faster conduction of spikes.

Nuclear layer The layer of the retina in which the cell bodies of neurons are found.

Plexiform layer The layer of the retina in which neurons synapse with other neurons.

Proximal Nearest to the central nervous system, or in the direction toward the central brain. Ganglion cells are the most proximal retinal neurons.

Receptive field The area of retina within which stimulation effects a response from a given neuron.

Sign-conserving A synapse in which depolarization of the presynaptic neuron leads to depolarization of the postsynaptic neuron; also called excitatory.

Sign-inverting A synapse in which depolarization of the presynaptic neuron leads to hyperpolarization of the postsynaptic neuron; also called inhibitory.

Spike (also called action potential or neural impulse) All-or-nothing brief depolarization that propagates along an axon, typically encoding a signal by the rate at which they occur.

Syncytium A large cell-like structure containing many nuclei derived from the fusion of many individual cells.

Transmitter A chemical released by one neuron that causes a change in polarization of target neurons with which it makes a synapse.

Introduction

Rods and cones of the retina respond to light and the optic nerve carries the information to the brain. However, there are nerve cells within the retina itself that analyze and integrate the signal. The cells involved in this pre-processing are arranged in layers at the back of the retina and are the focus of this article.

From the earliest days of electrophysiology, the fish retina has been an attractive preparation. It shares the major features and organization of all vertebrate retinas, with a level of complexity approximating that of the mammalian retina. This is in contrast to most amphibian and reptilian retinas, which apparently perform more complex processing that mammals relegate to the cerebral cortex.

The fish retina offers the simplicity of a cold-blooded preparation. The retina can be removed from the eyeball, providing a mechanically stable preparation devoid of feedback from higher centers. Lying on a glass slip, it is readily accessible for stimulation, recording, and pharmacological manipulation. The preparation is, of course, slowly dying, but it can be maintained in a relatively stable state for several hours.

As a result, several general principles of retinal processing were first described in fish retinas. These include the functional layering of the plexiform (synaptic) layers, many of the details of synaptic transmission, and even a new cell type (the interplexiform cell) later noted in mammalian retinas. Other important principles first described in anuran, reptilian, and mammalian retinas have been confirmed in fish. Thus, a description of the fish retina is, in many ways, a general review of the retinas of all vertebrate species.

The Major Cells of the Inner Retina

The cells of the retina present a variety of shapes and functions. This article considers the major types and most common categorizations. It does not include the glial cells (Müller cells), although they may also play a role in retinal processing. The anatomical configurations and arrangement of these neurons are illustrated schematically in **Figure 1**.

Horizontal Cells

Horizontal cells form the first layers of cells proximal to the receptors. As suggested by their name, horizontal cells are lateral elements that serve a relatively large area of retina. In fact, electrotonic connections (gap junctions) between horizontal cells allow each to share information over a larger area than its own anatomical extent. This electrically joined complex of cells is referred to as a 'syncytium'. Although the response of a horizontal cell is greatest directly under the receptors that are illuminated, a gradually diminishing response may be observed in horizontal cells over much of the retina. Some of this spread is through a long, tubular axon-like process that extends through the inner nuclear layer of the retina. The responses of horizontal cells were originally believed to be the responses of cones; when this was corrected, they were called S-potentials in honor of G. Svaetichin, who first recorded these responses.

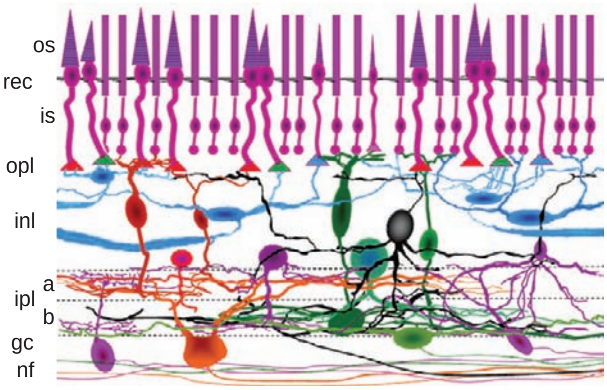

Figure 1 General schematic of the fish retina. Back of the eyeball is at the top; vitreous humor at the bottom (light enters from the bottom). Receptor layer (rec) at the top, with striped outer segments (os) above connecting inner segments (is; including somas, cone pedicles, and rod spherules) shown in purple. Cone pedicles are colored to indicate wavelength preferences. Horizontal (H) cells are blue. Small H1 is in the outer part of the outer plexiform layer (opl), with an exemplar at the left. An H2 is at the right, with a rod horizontal cell below it; an H3 is left of center. Bipolar cells span the inner nuclear layer (inl); hyperpolarizing bipolars shown in brown, and depolarizing bipolars in green. Various amacrine cells with their somas in the inl and processes branching in the inner plexiform layer (ipl) are colored according to type (orange for OFF-center, green for ON-center, and purple for ON–OFF). Ganglion cells (gc) are similarly color coded, as are their axons in the nerve fiber layer (nf). Interplexiform cells are shown in black, as are the centrifugal fibers. Glial cells are not shown.

Horizontal cells are presynaptic to both cones and bipolar cells. These are synergistic effects, antagonistic to the effects of light on individual cones and the bipolar cells that those cones influence directly. As horizontal cells collect information from a large area of retina, encompassing many receptors, the effect is to mitigate the effects of local illumination according to the general level of illumination. In effect, this is the first step in the process of extracting spatial contrast, rather than responding to the absolute level of illumination.

The synapses from receptors to horizontal cells are aminergic; glutamate is the transmitter released by cones, and aspartate by the rods. These transmitters produce what are commonly considered excitatory postsynaptic potentials; that is, the transmitter (released by depolarization of the receptor) causes depolarization of the postsynaptic membrane. It is often preferable to consider these as sign-conserving synapses, meaning the postsynaptic cell potentials mimic the presynaptic potentials.

Horizontal cells release the transmitter gamma amino butyric acid (GABA), which is generally inhibitory (hyperpolarizing the postsynaptic membrane; sign inverting). The release mechanisms seem to be through both a calcium-dependent vesicular release and a slower nonvesicular transporter release. The feedback to cones, however, seems not to be GABAergic.

Most fish have four layers of horizontal (H) cells. H1 cells form the outermost layer. The input to these cells is from cones, almost exclusively the long-wavelength-sensitive cones. H2 cells in the next layer contact the middle-wavelength-sensitive cones; they also receive indirect inhibition from the H1 cells. This inhibition is through feedback to the middle- and short-wavelength sensitive cones. As a result, H2 cells are biphasic with respect to wavelength; they are hyperpolarized by middle-wavelength lights and depolarized by long-wavelength lights. The feedback from H1 cells also enhances the temporal tuning of the cones.

The H3 cells at the next deeper level are postsynaptic to the short-wavelength-sensitive cones. They also receive indirect inhibition from horizontal cell feedback to the cones. As a result, they exhibit chromatically triphasic responses: hyperpolarizing for middle wavelengths, and depolarizing for long and short wavelengths.

H1, H2, and H3 are purely cone-driven horizontal cells; a deeper layer of horizontal cells that resemble H3 but lack an axon receive purely rod input. This is distinct from the mammalian horizontal cells, which have both rod and cone inputs. Note that this description refers to fish that live in shallow water and have color vision; deep-sea fish generally lack color vision, have rods but only one (or no) cone type, and may have only a single type of horizontal cell.

Bipolar cells

Bipolar cells convey the processing of the outer plexiform layer to the inner plexiform layer. There are at least two major types of bipolar cell: hyperpolarizing and depolarizing (also referred to colloquially as 'OFF' and 'ON', respectively). These two types represent the initiation of one set of parallel pathways carrying distinct or, in this case, complementary, information through the retina.

How is it possible for one bipolar cell to respond to light with hyperpolarization, while a neighboring bipolar cell, contacting the same photoreceptors, responds with depolarization? The answer is that the receptor molecules in the dendrites of hyperpolarizing bipolar cells respond by opening channels for sodium or closing channels for potassium and chloride; these are sign-conserving synapses in which the transmitter binds to a receptor molecule that opens or closes an ion channel (ionotropic or ligand-gated receptors). The receptors of depolarizing bipolar cells, on the other hand, act through a second messenger (metabotropic receptors) to open a chloride channel. This results in hyperpolarization when the transmitter is present, so it is a sign-inverting synapse.

In most species, the depolarizing bipolar cells have dendrites that form the central element of the invaginations in receptors, while the hyperpolarizing bipolar cells make more traditional synapses outside the invaginations. The depolarizing bipolar cells terminate in the deepest (innermost or proximal) portion of the inner plexiform layer, the sublamina b (also referred to as layers 4 and 5). The hyperpolarizing bipolar cells, on the other hand, terminate in the outer part of the inner plexiform layer, the sublamina a (layers 1–3). Thus, the parallel 'ON' and 'OFF' pathways are anatomically segregated in the inner plexiform layer.

Bipolar cells may display either transient or sustained responses. Transient bipolar cells, which respond maximally when a light is first presented and then relax to a level nearer their polarization in the dark, may have exclusively rod inputs, or mixed rod and cone inputs. The sustained type, which produces a nearly rectangular response to a step in illumination, may have exclusively cone inputs or mixed rod and cone inputs. The effect of rod inputs seems to be a change in sodium conductance, while cones affect both chloride and potassium conductances. Direct rod and cone inputs to the same bipolar cell are a feature of fish retinas that is not found in mammalian retinas.

About 25% of the bipolar cells in carp (*Cyprinus carpio*) have color-opponent cone inputs. That is, a cell might hyperpolarize in red light, but depolarize in green light. The opposite response is obtained from annular light in the receptive field surround. Other bipolar cells of this type have the complementary arrangement: depolarizing in red light in the center and hyperpolarizing in green, while hyperpolarizing in red light and depolarizing in green in the surround. This arrangement, called 'double opponent', is prevalent among ganglion cells of shallow-water fish.

As was noted for photoreceptors and horizontal cells, bipolar cells are electrically coupled with near neighbors of the same type. It might seem that this electrotonic spread would degrade images and undercut lateral inhibition, but it provides redundancy and noise reduction as well. It is also possible that correlation across the retina plays a role in joining parts of the images of single objects.

Amacrine Cells

Amacrine cells form a diverse group of neurons that often interconnect bipolar cells with ganglion cells. There are two major subgroups: transient amacrine cells that respond to changes in time, and sustained amacrine cells that have spatial and chromatic organization.

The transient amacrine cells typically have dendritic trees that either span the entire inner plexiform layer, or that have separate branches within sublamina a and sublamina b. The transient cells apparently receive depolarizing inputs from both hyperpolarizing and depolarizing bipolar cells, and respond with depolarization at both onset and offset of a stimulus (an ON–OFF response). Often, the response includes a series of brief depolarizations; some cells may actually produce a train of spikes, although others apparently produce a regenerated but scaled brief depolarization or pair of depolarizations riding on a slower depolarizing wave. In continuing illumination, the cell potential returns to its level in the dark.

The sustained amacrine cells show responses more like those of bipolar cells, although they may also produce graded brief depolarizations. These amacrine cells generally exhibit a center-surround organization, and may also have chromatic selectivity. Their dendrites are typically confined to a single sublamina of the inner plexiform layer. Among amacrine cells, there is usually electrotonic coupling.

Ganglion Cells

Ganglion cells are the major output cells of the retina. Their axons gather at the optic disk, where they become myelinated and form the optic nerve. As their message is conveyed over a significant distance, it is encoded as trains of spikes (also known as 'action potentials', or 'neural impulses').

Ganglion cell dendrites branch in the inner plexiform layer. Many arborize within one sublamina, depending on whether the cell is ON-center or OFF-center. Many are ON–OFF cells, which extend their dendrites through both levels of the inner plexiform layer. Some of these have diffuse dendrites, while some have distinct sets of dendrites arborizing in distinct sublaminae (see **Figure 1**).

In fish, most ganglion cells receive inputs from both bipolar and amacrine cells. There are also synapses and gap junctions between ganglion cells. The various response types and responses of ganglion cells are discussed later.

Feedback

One feature of visual processing is that higher centers influence the lower centers from which they obtain their information. This is also true within the retina of fish as well as those of mammals.

One example has already been discussed: horizontal cells are presynaptic to receptors, providing an area-wide adjustment of their membrane potentials. Similarly, many amacrine cells are presynaptic to the bipolar cells that convey information from the outer plexiform layer. There are also feedback loops that extend across layers of cells.

Interplexiform Cells

Interplexiform cells were first described in goldfish (*Carassius auratus*), before being observed in mammals. These are cells that appear much like amacrine cells in the inner plexiform layer, but sport a process extending into the outer plexiform layer.

There are at least two basic pharmacological types of interplexiform cell in goldfish: the dopaminergic interplexiform cell and the glycinergic interplexiform cell. The dopaminergic type was reported first, and best fits the usual concept of an interplexiform cell. It has a cell body among the amacrine cells, where it is both pre- and postsynaptic. Its dendrites have processes that ascend to the outer plexiform layer, where they are presynaptic to horizontal cells and bipolar cells. They also affect receptors, controlling their retinomotor movements. The effect of dopamine seems to be to uncouple the electrical synapses of the horizontal cells (and perhaps also the bipolar cells), thus shrinking the surround of the bipolar-cell receptive fields. Dopamine also depolarizes the horizontal cells and reduces the hyperpolarization due to light. Dopamine is apparently necessary for horizontal cell spinule formation, an anatomical change that can be observed over a relatively short time span. In this manner, interplexiform cells reduce the sensitivity of the outer retina during stimulation, which is a form of adaptation.

Centrifugal Fibers

Another feedback pathway arises in a nucleus at the lower border of the telencephalon at the olfactory bulbs (the nucleus olfactoretinalis). Axons of the cells in this nucleus join the optic nerve and terminate in the inner plexiform layer. These fibers apparently affect dopaminergic interplexiform cells, and, possibly, also the ganglion cells, amacrine cells, and bipolar cells.

The effect of the centrifugal fibers (i.e., from the brain to the retina) upon interplexiform cells is apparently to promote light adaptation in the retina. The centrifugal fibers also show rhythmic variations in their activity, which is correlated with other rhythmic firing patterns in the central nervous system. They can thereby provide the mechanism for coordinating retinal rhythms with those of the rest of the central nervous system.

Ganglion Cells

Receptive Fields

The term receptive field refers to that region of retina within which illumination affects the responses of a particular neuron. In many cases, there may be subtle effects of light over a wide region of the retina, but this discussion only considers the classical field within which light has a direct effect upon the firing rate.

Most ganglion-cell receptive fields in fish have been characterized as circularly symmetric, concentric (center and surround) fields. There are some cells that respond to motion and direction of movement, and many of the fields are rather more elongated than circular. The sensitivity across the field can be quite uneven, rather than forming a smooth profile.

There are three main types of receptive fields, with subtypes representing color coding: the ON-center, the OFF-center, and the ON–OFF fields. The fields are classified according to the type of response initiated by a small spot of light centered upon the receptive field. The response to light in the surrounding region is typically of the opposite type from that of light in the center region. As the surround region is relatively large, a small spot is often insufficient to elicit a response from it, so an annulus (ring) of light is generally used.

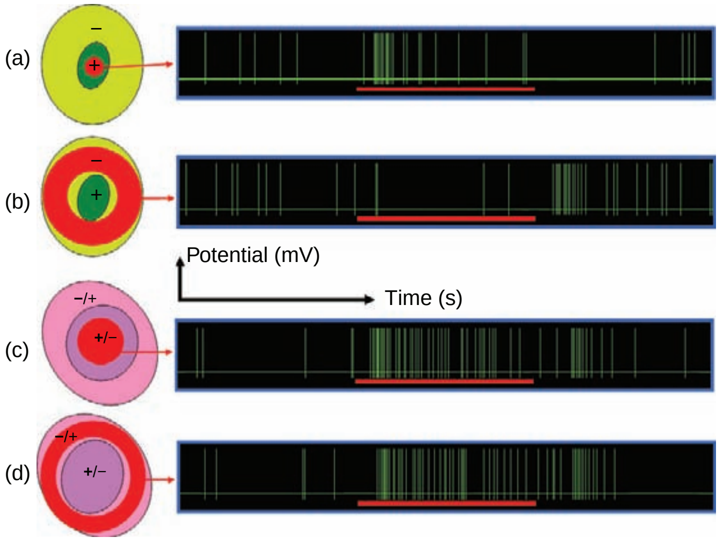

Figure 2 Responses of two ganglion cells. Receptive field sketched to the left, with '+' indicating an ON response, '–' an OFF response. Oscilloscope-like traces to the right indicate responses to the stimuli superimposed on the field sketch as a red spot (a, c) or annulus (b, d). Each vertical line is an idealized spike; the stimulus is present at the time indicated by the red bar under each trace. The cell shown in (a) and (b) is ON-center; the cell in (c) and (d) is of the ON–OFF type.

Responses of an ON-center ganglion cell in a goldfish are shown in **Figures 2(a)** and **2(b)**. (Responses of an OFF-center cell would be reversed.) The receptive field is represented by the concentric circles on the left; the plus sign in the inner circle represents the ON-responding center, while the minus sign in the outer ring represents the OFF-responding surround region. A small, centered spot of deep red light was presented at the time shown by the red bar under the upper trace, corresponding to the stimulus spot superimposed on the receptive field center in **Figure 1(a)**. The response is shown to the right as a train of spikes, as if this were an oscilloscope trace. Notice that the cell was firing irregularly in the dark before presentation of the spot (the maintained discharge, discussed later); the spot caused a burst of firing, which declined to a lower rate slightly above the firing rate in the dark. When the spot was extinguished, the firing was depressed, gradually recovering to its maintained rate in the dark. This is an ON response.

The response of the same cell to an annulus of red light is shown in **Figure 2(b)**. The onset of the annulus elicited a brief pair of spikes, followed by a suppression of firing. The offset of the stimulus caused a robust burst of firing. The slight burst preceding depression of firing is relatively common in fish ganglion cells; nevertheless, because of the major effect of depressed firing during the stimulus, this is considered an OFF response.

The opposite responses at offset of the light may reflect two factors. To some extent, it is a rebound from the previous level during stimulation; if the cell had been firing above its maintained level, removal of the excitatory signal could allow a recovery to below the normal resting level. Conversely, removal of an inhibitory signal could allow a rebound above the normal level. However, there is also statistical evidence indicating that the opposite response at light offset is actively generated. That is, there is a push–pull arrangement, in which one set of inputs is responsible for the onset response, and a different set contributes to the offset response. Anatomical considerations indicate that it is not likely that the two types of bipolar cells (hyperpolarizing and depolarizing) are directly the source of this antagonism, as is the case in cat. Rather, it appears amacrine cells contribute to the offset response.

An ON–OFF response is characterized by an increase in firing at both onset and offset of a stimulus. Cells that produce such a response typically do not distinguish a clear center and surround region, although the relative sizes of the two responses (onset and offset) may vary with stimulus configuration. Responses of an ON–OFF cell are shown in **Figures 2(c)** and **2(d)**. The distinction between traditional ON or OFF responses and the ON–OFF response is not always unambiguous.

Color Coding

Color specificity of ganglion cells was first studied in the goldfish. Some cells are not color opponent, such as the cell illustrated in **Figures 2(a)** and **2(b)**, having center and surround opponency driven mainly by the long-wavelength-sensitive cones. Note that the red light used to stimulate the ON-center cell described in the previous section (and **Figure 2**) was of

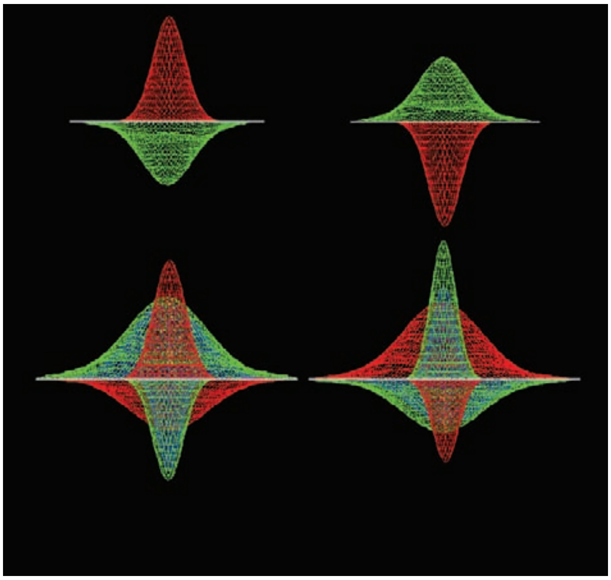

Figure 3 Color-coding of goldfish ganglion cells. Excitatory regions (ON regions) are shown as Gaussians above the gray line; inhibitory regions (OFF regions) extend below the gray line. Colors indicate the spectral sensitivities: blue for short wavelengths, green for middle wavelengths, and red for long wavelengths. Note that although the sensitivity profiles are shown as Gaussians, they are actually quite irregular. Top row: type P cells, lower row: type O cells.

sufficiently long wavelength (650 nm) such that only the long-wavelength-sensitive cones would detect it. Since goldfish have porphyropsin-based pigments, their long-wavelength-sensitive cones have a maximum spectral sensitivity close to 620 nm.

Some ganglion cells, called 'type P' (for previous), have color-opponent responses in the receptive field center, but not in the surround. Thus, a cell might produce ON responses to red light in the receptive field center, and OFF responses to green light in either the center or the surround (the reverse situation, OFF for red and ON for green, is also found; see **Figure 3**, top row). In effect, the area affected by middle-wavelength-sensitive cones is simply larger than that affected by the long-wavelength-sensitive cones.

Nearly 50% of goldfish ganglion cells are type O (for ordinary), the double-opponent cells. As for the type P cells, red and green (or blue) lights in the center region have opposite effects, but the responses are reversed for all colors in the surround (see **Figure 3**, bottom row). Such a cell displays center-surround antagonism for any particular colored light (although of the opposite types for red or green lights), and color opponency for small, centered spots. Notice that the strongest responses would arise from a red spot in a green surround (or vice versa). This is the arrangement that would best enhance simultaneous color contrast.

Another category is called type Q (for queer). These appear to be type O cells that have a very weak middle-wavelength-sensitive cone component, which can only be demonstrated by intense stimulation or chromatic adaptation to red lights (desensitizing the long-wavelength-sensitive cones). This reduction of middle-wavelength-sensitive cones may be a consequence of the physiological preparation; dissection in room light tends preferentially to desensitize all but the long-wavelength-sensitive cones.

Parallel Paths

In addition to ON-center and OFF-center and the various combinations of wavelength sensitivities, ganglion cells in goldfish may be categorized into the linear and nonlinear classes described for mammals. There are distinctly X-, Y-, and W-ganglion cells, each forming its own mosaic with complete coverage of the retina. Each of these types displays the various color-coding schemes outlined above.

The X-, Y-, and W-like cells have spatial summation properties similar to those of the X, Y, and W cells of the cat. X-like cells exhibit linear spatial summation; that is, a counterphase grating in the null position (spatial sine phase relative to the receptive field middle) elicits no response. Y-like cells do not sum signals linearly; their responses are frequency-doubled for counterphase gratings in sine phase. Unlike the situation in cat, the overall receptive fields of the X- and Y-like cells in goldfish are about the same sizes. Because of the nonlinear subunits, however, the Y-like cells respond to higher spatial frequencies with the frequency-doubled component. Many Y-like cells also show direction tuning, preferring particular directions of motion of a stimulus. W-like cells display spatial summation that is between that of the X- and Y-like types, and always show orientation and direction tuning. The latter two types originally were called 'not-X-like' cells.

Maintained Discharges

The maintained discharges of ganglion cells (sometimes referred to as spontaneous firing) are a general feature across species. In the dark or in steady uniform illumination, ganglion cells in fish fire at rates that vary (across cells) from a few spikes per second to 30 or more per second. There are two aspects of maintained discharge to consider: the simple fact that there is ongoing activity in the absence of stimulation, and the variability of that firing.

Source of maintained discharges

The fact that the ganglion cell fires in the absence of stimulation makes teleological sense: without a level against which to measure changes, decreases could not be represented. However, there remains the question of the source of that mean firing.

The main source of the maintained discharge is bombardment of the ganglion cell by presynaptic neurons (bipolar and amacrine cells, possibly also other ganglion cells). When synaptic transmission is disabled (by adding cobalt to a superfusate to block vesicular release), the maintained discharge is completely or very nearly completely abolished. There is the possibility that the surviving discharge is due to nonvesicular release (or leakage) of transmitters, but it seems more likely that a very small component of the discharge is intrinsic to the ganglion cell itself.

Variability of maintained discharges

The ganglion cell does not fire in a regular, metronome rhythm like a pacemaker cell. The intervals between successive spikes are stochastically variable. They are drawn from a positively skewed distribution that is generally more extreme than the gamma distribution that has been used to describe the distribution in mammalian ganglion cells. The distribution is often bi- or even multimodal, with a concentration of very short intervals (spikes occurring in close pairs or triplets) and another mode (or more) at longer intervals (the intervals between pairs, triplets, and solo spikes).

While the order in which intervals are drawn from this distribution during stationary maintained discharge is nearly random, a subtle ordering representing high-pass filtering is demonstrable. There are fewer strings of similar duration intervals than might be expected by chance; as a result, the average firing rate in periods of moderate duration (0.2–0.5 s) is less variable than one would expect from the distribution of the intervals. This filtering, while subtle, is less subtle than is observed in cats.

Cross-correlations within the maintained discharges

In fish, as in mammals, the firing of a ganglion cell is not entirely independent of the firing of its neighbors. Obviously, since neighbors are responding to the same stimuli, there is a coarse relationship in that they increase or decrease firing at essentially the same time. However, there is a more precise cross-correlation that is observable in maintained discharges as well as during responses.

This cross-correlation is generally not precise. The probability of one cell producing a spike at a given time increases (or decreases) within a window of 5–30 ms starting up to 15 ms after (or before) each spike in a neighboring ganglion cell. This delay and imprecision are incompatible with simple electrotonic coupling with the neighbor (as has been reported in salamanders), but is most likely the result of synaptic influence by another neuron affecting both of the cells. The common influence is not simply additive, but rather has a multiplicative effect upon the firing mechanism of each ganglion cell.

As in mammals, cross-correlation is positive between cells of the same response type, and negative for pairs of cells of opposite type. An ON-center cell is more likely to fire in near coincidence with the spikes of a neighboring ON-center cell than at other times, but less likely to fire in near coincidence with the spikes of a neighboring OFF-center cell.

The function of this cross-correlation in the mature retina is not clear. In the developing retinas (of mammals), correlated firing is essential for the proper collation of fibers in the optic nerve as they select their targets in the thalamus. Disruption of spike activity with the drug tetrodotoxin, even before there are bipolar cells to convey visual information from the receptors, prevents the proper anatomical mapping from developing in the brain. Fish eyes continue growing as the fish grows throughout life; therefore, such a process might contribute to the alignment of axons of the newly formed cells. However, most of these cells are born at the growing periphery of the retina, while cross-correlation is evident throughout the retina.

A putative function for cross-correlation is to provide additional multiplexed channels of information. That is, in addition to each cell conveying information about the stimulus attributes to which it is tuned, the coincident firing of two (or more) cells could carry information about some other attribute of the visual scene. Decoding this message would require a higher-level cell that receives input from both of the ganglion cells, and only fires when its inputs both fire within a short time window (a logical AND). However, no attempt to find what information is conveyed, or a way in which this signal might improve upon the information present in the better-tuned individual cell, has been successful. A similar failure to demonstrate usefulness has been reported for mouse.

Summary and Conclusions

The fish retina, like the retinas of other vertebrates, performs the first steps of visual processing. By the somewhat phasic nature of its responses, it begins the process of temporal tuning. The lateral antagonism of center versus surround of the receptive fields begins the process of responding to contrast rather than absolute luminance. In effect, the retina (and the visual system) is most responsive to changes in the stimulus: changes in time and space.

Two additional principles that are typical of retinas and of visual systems as a whole are also evident in the fish retina. The first is the division into parallel pathways. Cells operate in parallel to extract different aspects of the stimulus. These aspects may be temporal properties, scale (size), direction of motion, color, or contrast.

The second principle is that of feedback. Horizontal cells affect the receptors that synapse upon them; amacrine cells affect the bipolar cells that carry information from the outer plexiform layer. Interplexiform cells in the inner plexiform layer affect the state of adaptation in the outer plexiform layer, and themselves are affected by activity in more central structures via the centrifugal fibers.

Finally, fish ganglion cells display a maintained discharge against which their responses are impressed. The function of the stochastic nature of this maintained discharge is not clear.

What is the value of this convergence, processing, and encoding? The interconnection of cells comes at the expense of some precision, but with gains in efficiency. A single goldfish retina contains nearly 1.5 million cones and about 10 times as many rods, but only about 350 000 ganglion cells. If each cone enjoyed a private line to the central nervous system, the optic nerve would contain about 5 times as many axons, and would be more than twice the diameter (at least double that when including pathways for rods). The costs in energy, physical flexibility, and volume would be prohibitive. Moreover, the processing performed in the retina would have to be accomplished in the brain. The processing and encoding executed in the retina provide an economy for the fish, and a window into visual processing for the vision scientist.

Glossary

Motoneurons Neurons in the central nervous system that send their axons to muscles, controlling their contraction.

Plasticity of neural connections The alteration of synaptic connections. Injury to neurons, especially in fishes, prompts regeneration of axons which may grow into normal and abnormal target areas. Developmental and learning processes involve changes in synaptic arrangement and efficacy.

Receptive field Region of retina or visual field within which stimulation alters the activity of a neuron. An electrode that picks up activity from more than one neuron or receptor cell has a multiunit receptive field (MURF).

Reticular formation Diffusely organized neuronal groups around the core of the midbrain and brainstem involved in a wide variety of functions. Most relevant function here is as premotor intermediary between tectum and motoneurons.

Retinal ganglion cells The output neurons of the retina. Their axons, called optic fibers, terminate in tectum and nuclei of the preoptic–thalamic–pretectal (PTP) area of the brain.

Retinotopic map, organization or projection Found in brain areas, like tectum, that receive a spatially ordered set of input fibers from retina, thereby forming a representation of the retina, and the visual field of the eye. It is a particular case of topographic map. The retinotectal map is an instance.

Topographic map, organization or projection Found in brain areas that receives a spatially ordered set of input fibers from another brain structure (e.g., the connections from tectum to nucleus isthmi (NI)).

Visual looming The pattern of motion on the retina created by approaching objects. A symmetrical expansion of the retinal image presages collision.

Introduction

Looking down upon the brain of a sunfish (*Lepomis* sp.), the optic tectum appears as a pair of rounded lobes between the forebrain and the cerebellum (**Figure 1**). A side view shows how the optic nerves from the eyes cross over one another, becoming the optic tracts, each of which enters the front of its corresponding tectal lobe. This simple anatomical examination shows that the information from each eye travels directly to the tectal lobe on the opposite side. Indeed, the great majority of the optic nerve fibers, the axons of retinal ganglion cells, terminate in the tectum, making it the primary visual center in the brain.

This article focuses on the functional aspects of tectum – its role as an information processor and controller of behavior – bearing in mind that the view presented will be limited in scope. There are more than 25 000 fish species occurring in widely diverse forms and in every aquatic habitat. While the optic tectum is present in all species, it is developed to different extents. Our knowledge of tectal function derives almost entirely from a handful of teleost species, mainly perciforms (e.g., sunfish) or cyprinids (e.g., the goldfish, *Carassius auratus*), with much less information available on elasmobranchs, the cartilaginous fishes. To fill some of the gaps in our understanding, we must also look at tectum in other vertebrate groups.

The importance of tectum to a teleost fish can be shown by damaging it. Complete ablation renders the animal effectively blind. However, a partial ablation or localized lesion of one tectal lobe produces a loss of responsiveness to visual stimuli over part of the visual field of the opposite eye, showing that visual space is mapped topographically across the tectum. Damage to the tectum in teleosts also results in losses that go beyond blindness, being impaired in their ability to navigate the environment using nonvisual senses, bumping into objects in a way that eyeless fish would not because the tectum

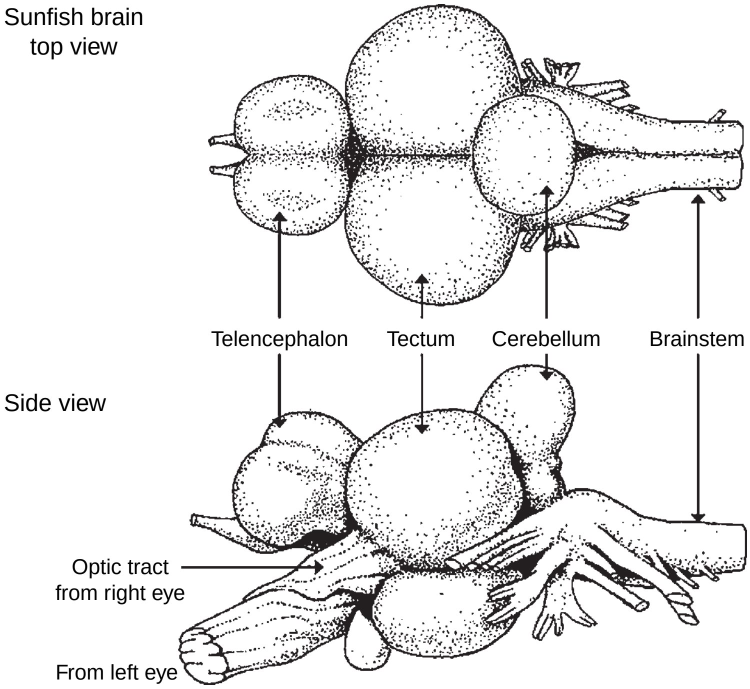

Figure 1 Top and side views of a sunfish brain (*Lepomis* sp.). Adapted from S. Karger AG, Basel from Wullimann and Northcutt (1988) Connections of the corpus cerebelli in the green sunfish and the common goldfish; A comparison of perciform and cyprinform teleosts. *Brain Behavior and Evolution* 32: 293–316.

serves other sensory modalities besides vision. In other vertebrate species, it is known that the tectum, or the mammalian equivalent, the superior colliculus, contains neurons that respond to sound and touch. Animals with exotic senses such as infrared sensitivity (e.g., rattlesnakes) and electroreception (e.g., skates and rays) possess tectal neurons that respond to these modalities too. Fishes have a well-developed system of sensitive mechanoreceptors, the lateral line organs, that detect minute water currents, enabling them to localize prey, avoid objects, and school with other fish. This valuable source of spatial information underwater is almost certainly represented in tectum too, but like many aspects of tectal function in fishes has not been investigated.

The varieties of sensory information converging upon the tectum may evoke behavioral responses via its efferent connections to motor centers of the reticular formation. The tectum, in conjunction with other brain areas, integrates sensory signals of different modalities, and, in ways not yet understood, arrives at a decision to react positively with orientation and approach, negatively with avoidance, or not to react at all.

Anatomical Overview

The tectum, the Latin for roof, covers the midbrain. In teleost fishes, it is a twin-lobed canopy of neural tissue inflated over a fluid-filled ventricle. The two lobes are connected at the midline by the tectal commissure, and at their bottom edges merge with the tegmentum, the floor of the midbrain (see **Figure 4**(**b**)). A well-developed tectum in a highly visual teleost may be 0.8 mm thick with a clearly layered appearance when examined under the microscope. The layering scheme shown in **Figure 2** represents the most common interpretation of tectal structure (tectal layers in teleosts – listed from outermost to innermost: stratum marginale (SM), stratum opticum (SO), stratum fibrosum et griseum superficiale (SFGS), stratum griseum centrale (SGC), stratum album centrale (SAC), and stratum periventriculare (SPV)). Functionally, the most important distinction is between the superficial layers (SM, SO, and SFGS) which are mainly visual, and the deep layers (SGC, SAC, and SPV) which are multimodal and motor. Some layers contain many fibers (SM, SO, and SAC), others contain some neuronal cell bodies, fibers, and synapses (SFGS and SGC), while the innermost layer (SPV) is composed of densely packed neuronal cell bodies. Around 15 morphologically distinct neuron types have been described in goldfish, a few of which are illustrated in **Figure 2**. In elasmobranch fishes, the tectum is less prominent than it is in a typical teleost, being smaller than the telencephalon or cerebellum, and its structure is less well differentiated into distinct cell types and layers. Nevertheless, the same functional distinction between superficial and deep layers seems to apply as it does in teleosts.

Dominant among the neural connections with the tectum are the optic fibers coming from the retinas, but

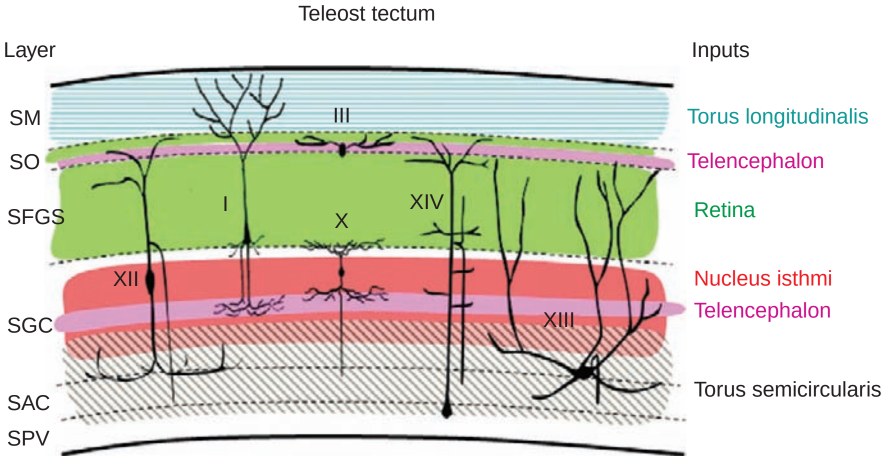

Figure 2 Laminar structure of teleost tectum, showing layer nomenclature and a few representative cell types. Roman numerals are Meek's types. Colored bands show principal termination layers of different inputs to tectum. SM, stratum marginale; SO, stratum opticum; SFGS, stratum fibrosum et griseum superficiale; SGC, stratum griseum centrale; SAC, stratum album centrale; and SPV, stratum periventriculare.

the tectum is also richly interconnected with many other brain structures. These include: (1) upstream structures, the telencephalon and the preoptic, thalamic, and pretectal (PTP) areas; (2) midbrain structures, notably the opposite tectal lobe, the torus longitudinalis (TL), nucleus isthmi (NI), torus semicircularis (TS); and (3) downstream structures: the reticular nuclei of the midbrain and brainstem that interface with motor systems. The following sections deal with these structures as part of functional subsystems in which tectum plays a central role.

The Retinotectal Projection and Visual Processing

The Retinotectal Map

Anatomical fiber tracing methods show that the great majority of the optic nerve fibers from one eye cross the midline, enter the opposite lobe of the tectum, and form terminal branches within certain tectal layers where they synapse upon tectal neurons. Optic terminals are densest in the SFGS and SO, with some being found in deeper layers, and are distributed in an orderly fashion over the tectum so as to make a map of the retina. This retinotectal map is organized so that the front, back, top, and bottom of the visual field seen by one eye are represented at the front, back, top, and bottom of the opposite tectal lobe.

The retinotectal map can also be investigated by electrophysiological recordings from tectum. A microelectrode inserted into the superficial layers of tectum (principally SFGS) picks up spikes that are evoked by visual stimulation in a particular region of the visual field of the opposite eye, called the receptive field. The receptive field is usually delineated by flashing small spots of light or moving objects against a contrasting background. **Figure 3(a)** shows the roughly circular receptive fields

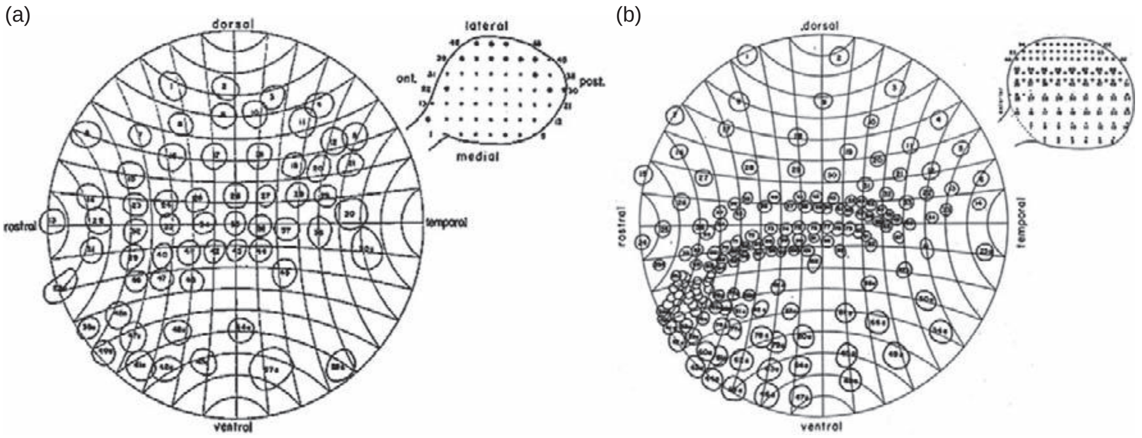

Figure 3 Retinotectal maps: (a) sunfish – uniform retina and (b) spotted sand bass (*Paralabrax maculofasciatus*) – foveate retina. Each large circle represents the visual field of the left eye superimposed with the boundaries of MURFs corresponding to each tectal recording site in the right tectal lobe (insets). Reproduced from Schwassmann HO and Kruger L (1965) Organization of the visual projection upon the optic tectum of some freshwater fish. *Journal of Comparative Neurology* 124: 113–126.

from each of a number of electrode penetrations in the tectum of a sunfish. In this animal, the receptive fields are of fairly similar size and each part of the visual field is represented by a roughly equal area of tectal surface. Thus, the tectum in sunfish, as in goldfish, receives a uniform representation of the entire visual scene. Some species, such as the rock basses, have retinas with a fovea, a region of high photoreceptor and ganglion cell density positioned in the eye for detailed forward vision. In these fish, the part of the retinotectal map corresponding to the fovea exhibits smaller receptive fields and a fivefold magnification of frontal vision compared to the rest of the visual field (see **Figure 3**(**b**)).

Retinotectal Map Development and Plasticity

The formation of the retinotectal map during development is of great interest because it provides a model for how ordered connections develop in brains generally. The retinotectal system of fishes has been a fertile field of research since the 1940s when R.W. Sperry, taking advantage of the discovery that optic nerves in fish and amphibians regenerate when severed, showed that optic axons grow back into the tectum restoring the retinotectal map, along with apparently normal visual behaviors. The chemoaffinity theory that Sperry propounded, held that individual optic fibers are labeled chemically and grow into tectum to terminate on correspondingly labeled tectal neurons. Much research has since been devoted to discovering the molecular and genetic bases for chemoaffinity underlying pathfinding and synapse formation in the retinotectal system. The facility with which optic axons regrow, and the remarkable neural plasticity that their terminals exhibit within tectum is part and parcel of the continual growth that fish undergo throughout life. Indeed, plasticity is essential to maintain a regular retinotectal map in the face of different patterns of growth in retina and tectum – the retina grows by addition of cells at its circumference, whereas the tectum grows by elongation. Of special relevance to this review is that plasticity of the retinotectal projection when experimentally manipulated can provide fresh opportunities to understand tectal function.

Visual Processing in Tectum

In the retinotectal mapping experiments of the kind shown in **Figure 3**, the spiking activity picked up by an extracellular microelectrode in superficial tectum (SO and SFGS) is not generally resolvable into action potentials of constant waveform that would be indicative of the firing of an individual neuron (or single unit), but instead consists of bursts of action potentials of different amplitudes called multiunit activity. It is evoked by stimuli, such as small spots of light flashed on or off, in roughly circular areas (5–10° across in goldfish) termed the multiunit receptive field (MURF). This activity used to be thought to come from the terminals of optic fibers. However, it can be largely eliminated by drugs that block synapses suggesting that it comes from the dendrites of tectal cells where optic fibers make synapses.

Microelectrodes may also pick up action potentials indicative of individual neurons in tectum. If such units are visually responsive, their receptive fields generally differ from the relatively small, retinotopically ordered MURFs of superficial tectum, instead taking a bewildering variety of forms. In the various cyprinid and perciform species investigated, tectal cell receptive fields probed with flashed or moving spots of light vary greatly in size, ranging from roughly circular fields 2–5° across to complex fields extending some 160°. The latter may have elongated or irregular shapes, with multiple subregions with differing stimulus preferences, such as the onset or offset of light. Experiments that scan spots of light across receptive fields have shown spikes being elicited from band-shaped regions of space, suggesting that these cells may be selective for complex shapes, perhaps the body markings of conspecifics. While most tectal cell receptive fields are centered appropriately with respect to the retinotectal map, a high proportion (22% in the perch, *Perca fluviatilis*) are displaced 45° or more, showing that tectal neurons can perform a large-scale integration of visual pattern.

In the foregoing observations, the cell types being recorded from were unidentified. A few studies recording with intracellular micropipettes have allowed the tectal cells to be stained for identification, but only the simplest characterizations of visual trigger properties have been made, adding little to our understanding of processing by tectum. The properties of some of the identified cell types shown in **Figure 2** will be dealt with in subsequent sections on tectal subsystems. In summary, most tectal cell types respond in some way to light flashes or movement, typically with large receptive fields. Tectal cell responses are also complex in the time domain, typically firing to light stimuli with successive periods of excitation and inhibition.

Little can be learned about the processing of location, motion, color, and shape of visual stimuli by making gross lesions of tectum, as these have a profoundly blinding effect. Happily, the plasticity of the retinotectal system allows more subtle interventions to be made, throwing some new light on tectal processing. When optic nerve fibers are severed by crushing, they grow back into the tectum and eventually reform a correctly oriented retinotectal map with nearly normal MURFs. The ability of a sunfish to localize a brief light flash by orienting to it is fully restored, at least where visual space is represented by an orderly retinotectal map; where space is represented by a disorderly map as a result of regenerating optic fibers going astray, orientation movements are misdirected. Map orderliness is also important to pattern processing because after optic nerve regeneration, when optic terminals are disorganized and sparser than normal, fish can discriminate coarse bar patterns, but not the fine patterns that they can normally discriminate.

The ability of goldfish to discriminate colors is also restored, apparently to normal, after optic nerve regeneration but this observation alone does not mean that tectum is involved – the PTP nuclei (see below) also receive regenerated optic fibers that could be responsible. However, recordings of tectal activity strongly suggest that tectum is involved in color processing because its neuronal responses evoked by different wavelengths of light cannot be reproduced by varying the intensity of a single wavelength, as would be the case in a colorblind system. TL (see below), which is closely interconnected with tectum, is such a colorblind system. Moreover, some tectal cells can be excited by one range of wavelengths while being inhibited by another. Such qualitative response differences indicate a color discriminating system. As in mammalian visual cortex, color processing is likely bound up with pattern and shape processing.

Motion is an important stimulus parameter for exciting tectal neurons in all vertebrates studied. In fish, recordings of neuronal activity in tectum have demonstrated directional preferences: activity is evoked most vigorously by a visual stimulus moving in one direction through a receptive field compared to all other directions tested. Most of the data suggest that directional selectivity is elaborated in tectum, although retinal units may exhibit it as well. Visual motion is a valuable source of information assisting the detection and recognition of objects and providing cues to distance, as will be seen in the discussion of the tectum–NI system.

Because the fields of view of the two eyes overlap in the front, some of frontal space is represented in both tectal lobes. A small number of optic fibers serving this part of the visual field, appropriately enough, do not cross over, but terminate in frontal tectum on the same side. This arrangement suggests that the tectum should be able to process images binocularly to help determine the distance of objects such as prey, which fish have been shown to do. Neurons that can be driven via either eye have been found in the tectum of goldfish and trout, but their large and diffuse receptive fields seem unsuited to the demands of stereoscopic depth perception.

From what is known about visual processing in the fish tectum, it seems clear that it does not work in the hierarchical fashion of mammalian visual cortex, where the visual stream ascends from one cortical region to another with a progressive enlargement of receptive fields and a progressive elaboration of trigger features. Structurally, the tectum in fishes is rather uniform across its surface, although some anatomists have seen evidence of a repeating, columnar organization. Pattern processing underlying the complex visual discriminations that fish are capable of most likely depends on tectum, at least in teleosts, because it is the only high-resolution visual center. Evidently, spatial information from the retina, such as object shape and location which is preserved by the orderly topography of the retinotectal map, is immediately broken up in tectum and recoded in ways yet to be deciphered.

Tectum–TL Subsystem

The TL, which occurs only in teleost fishes, consists of a pair of elongated cell masses connected to the medial margins of the tectum, lying just below the intertectal commissure, a thin band of fibers that connects the two tectal lobes (**Figures 4**(**a**) and **4**(**b**)). Large numbers of small neurons in each TL (100 000 in goldfish) send an abundance of fine, unmyelinated axons into the SM, the most superficial layer of the adjacent tectum, where they course in parallel over the tectal lobe (see **Figures 4**(**c**) and **5**). Indeed, SM is filled with these TL axons, called marginal fibers, together with the dendrites of tectal neurons (mainly type I) onto which they synapse. The synaptic contacts made by the marginal fibers may outnumber all other inputs to tectum. The type I neurons, with cell bodies in SFGS, have extensively branched dendritic trees that receive marginal fiber synapses. This arrangement is strongly reminiscent of cerebellum where Purkinje cells receive synapses from the parallel fiber axons of granule cells. Type I cells also receive retinal input on their basal dendrites in SFGS and send a short axon into SGC. A return pathway from tectum to TL is made by type X cells in SGC whose dendrites ramify at the SFGS/SGC boundary and in central SGC where the type I axons also terminate.

Anatomical studies in various species show that TL is composed of two main divisions which are called here dorsomedial and ventrolateral that have different connectivity and function. Electrophysiological studies have confirmed the existence of a precisely ordered loop between dorsomedial TL, tectum, and back again, and have also shown that dorsomedial TL deals with a specific kind of visual information. A microelectrode inserted into dorsomedial TL picks up sustained firing activity that is related in an inverse way to the illumination of the opposite eye, such that activity is high in the dark and is reduced by illumination. This sustained dimming activity also can be evoked by dark objects. It shows a clear retinotopic character so that an electrode in the front of TL picks up activity to dimming in the front of the visual field; positions farther back in TL have dimming receptive fields farther back in the visual field (see **Figures 4**(**c**) and **4**(**d**)). Dorsomedial TL responds to dimming with a considerably longer latency than does superficial tectum.

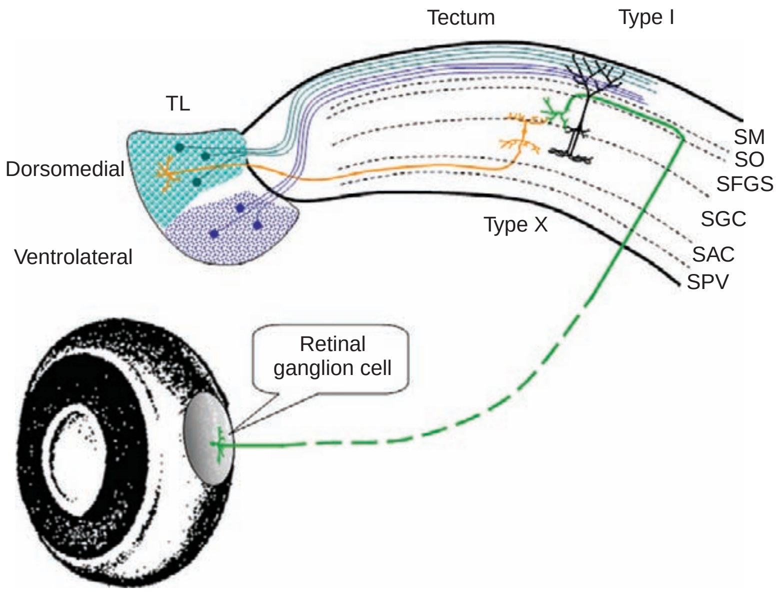

Figure 5 Tectum–TL circuitry, showing a cross section through one TL and part of adjacent tectum. A retinal ganglion cell transmits to the main visual layer of tectum, SFGS. A type X cell receives visual signals and relays to the dorsomedial TL, which transmits luminance information over tectum in SM. This is received by the dendrites of type I neurons, which are also activated by retinal input. Corollary discharge of eye movements is relayed via the ventrolateral TL in SM and also received by type I dendrites. SM, stratum marginale; SO, stratum opticum; SFGS, stratum fibrosum et griseum superficiale; SGC, stratum griseum centrale; SAC, stratum album centrale; and SPV, stratum periventriculare.

Electrical stimulation of a point in TL sends impulses along a beam of marginal fibers across tectum (see **Figure 4**(**c**)). This beam passes over a point in SFGS with a MURF that overlaps the receptive field of the TL point that was stimulated (**Figure 4**(**d**)). To complete the loop from tectum back to TL, type X cells connect topographically to dorsomedial TL. It is noteworthy that this tectum–dorsomedial–TL loop appears to be concerned only with dimming and with retinal location of a light stimulus; it is totally unconcerned with stimulus color, shape, or motion. That dimming is a separate visual submodality is underlined by the existence of a class of dimming retinal ganglion cells. Moreover, when the optic nerve regenerates after being cut in goldfish, dimming responses are the first to reappear in tectum and simultaneously in TL, followed significantly later by other kinds of visual responding (e.g., light onset).

Microelectrode recordings from ventrolateral TL yield distinctly different neural signals: bursts of firing that are synchronized with saccadic eye movements. There is evidence that TL is signaling the direction and extent of every eye movement, and presumably relaying this information to tectum via a different and deeper set of marginal fibers than those carrying the dimming signal from dorsomedial TL. These saccadic bursts are corollary discharge signals, meaning that they derive from eye movement commands; they are not actual eye movement commands because ablation of TL has no effect on the eye movements that a fish makes spontaneously. The source of the saccadic information is not tectum, but other inputs to TL, possibly nuclei in the midbrain near the midline where oculomotor nuclei reside, or nuclei connected with the cerebellum.

The role of the TL–tectum loop can only be guessed at. Comparative studies suggest that TL is highly developed in species that live in turbulent environments. One such species, the squirrel fish (*Holocentrus ascensionis*), has a marginal layer that makes up nearly half the thickness of the tectum. It lives in and around coral reefs, moving between brightly lighted and dim recesses in surging water. The TL–tectal loop may be involved in adjusting the visual processing of tectum under these circumstances.

A further clue to function is the association of marginal fibers with the type I cells, an arrangement that strikingly resembles parallel fiber systems elsewhere in the central nervous system, notably the cerebellum, and the electrosensory lobe of mormyrid electric fish. In the latter case, the neural circuitry learns to predict the consequences of the fish's own movements on the electroreceptor signals and enables the brain to discount them, perhaps thereby improving the detection of objects in the environment using its electric sense. The TL–tectal system may be doing something similar for vision according to the following scenario. Neural activity in dorsomedial TL can be thought of as a picture of the environment seen through the opposite eye. This picture is monochromatic; it is without motion enhancement; it overrepresents the visual horizon and is transmitted continuously, but with some delay, via the marginal fibers over the tectum. When the fish makes an eye movement, a corollary discharge is generated along the length of the ventrolateral TL and transmitted across tectum via the deep marginal fibers. At the same time, the eye movement shifts the luminance distribution in the scene across the retina, which, in turn, shifts the activity pattern within the main retinal termination layer, the SFGS. This activity change is picked up by the dendrites in SFGS of type I cells which fire in response; simultaneously, the dendrites of type I cells in SM are excited by a pattern of (1) marginal fiber activity representing the visual scene before eye movement and (2) the corollary discharge representing eye movement direction and amplitude. Learning takes place by strengthening and/or weakening of the marginal fiber synapses so that after a period of experience, the activity of all the type I cells constitutes a prediction of how the scene will look after the eye movement, based on what it looked like before. Subtraction of the predicted pattern from the current pattern would highlight changes in the scene that are not self-produced, and are therefore significant.

Tectum–NI Subsystem

A cross section through the brain of a teleost fish, just in front of the corpus of the cerebellum, reveals a cell mass below the TS, surrounded by fibers exiting the tectum. This is the NI. It is well developed in highly visual fish, but is still present even in blind cavefish (*Astyanax mexicanus*); however, it has not been found in elasmobranchs. It consists of a shell of tightly packed neurons surrounding a core containing dendrites, incoming fibers, and synapses (see **Figure 6**). The incoming fibers are mainly from the tectal lobe on the same side and make excitatory synapses within the core on the dendrites of the neurons whose cell bodies lie in the shell. The latter send their axons back to tectum on the same side. Anatomical tracer studies have shown that tectal neurons project to NI in topographic fashion, and that NI neurons project back to tectum topographically.

Introducing a microelectrode into NI immediately confirms that tectal input confers visual responsiveness upon NI. Extracellular microelectrodes pick up bursts of high-amplitude spiking activity that occur spontaneously or are evoked by visual stimuli shown to the opposite eye. Flashed spots of light can evoke spike burst responses but they habituate with repeated presentation. Movement is a much more effective stimulus, but its effects also habituate. NI, therefore, is excited by change or novelty. It is

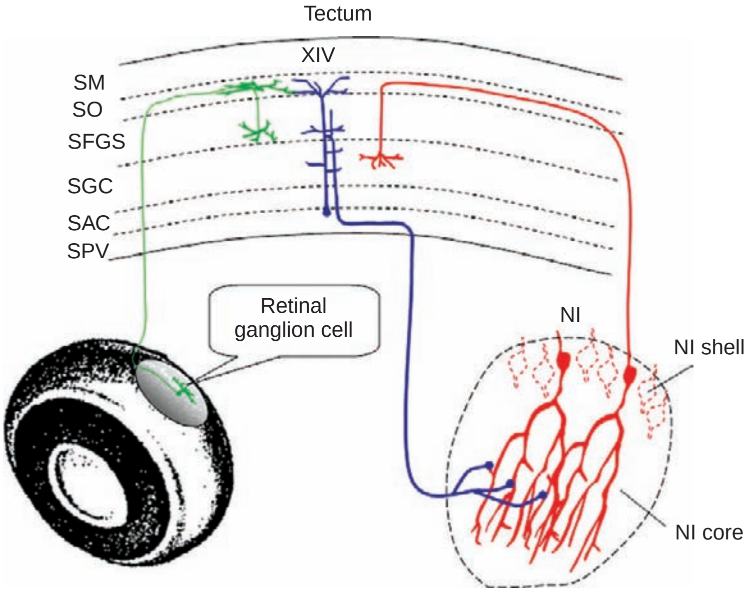

Figure 6 Tectum–NI circuitry, showing a cross section through tectum and the nucleus isthmi (NI). A retinal ganglion cell transmits to the visual layers of tectum, SO and SFGS. A type XIV cell receives visual input and relays to the core of NI. Neurons in the shell of NI send axons back to tectum, primarily SGC. SM, stratum marginale; SO, stratum opticum; SFGS, stratum fibrosum et griseum superficiale; SGC, stratum griseum centrale; SAC, stratum album centrale; and SPV, stratum periventriculare.

interesting that although the anatomical connections from tectum to NI are topographically organized, the visual responses are not: visual stimuli anywhere in the field of the opposite eye can elicit NI bursts.

The movements that especially excite NI in goldfish and sunfish are approaching objects. A checkered ball stimulus that approaches the fish evokes bursts of activity that steadily increase in vigor. When the ball stops, the activity drops off, and when it moves away, there is a brief burst of activity followed by relative silence. Averaging over several approach trials reveals a ramp-up in neural activity; faster approach gives a correspondingly faster ramp-up, suggesting that NI activity signals the closeness of the ball. The ramp-up is somewhat independent of the size of the ball, showing that the response is not simply a function of retinal image size. On the face of it, the NI-tectum circuit appears to be signaling the closeness of objects derived from monocular motion cues. NI also responds to stimulation via nonvisual stimuli (somatosensory, auditory, and lateral line), modalities that tectum also processes.

The neural circuitry of the NI–tectum subsystem involves the type XIV cells of tectum, the source of tectal input to NI (see **Figure 6**). These complex neurons which are the most numerous of the tectal cell types have cell bodies in the SPV and a long dendritic trunk that ascends to the superficial layers (SO and SFGS) where they detect retinal input. They also have dendritic branches that ramify in deeper layers (SGC), probably picking up nonvisual inputs that arrive there. The type XIV output axons originate at the SFGS/SGC boundary and then split, with one axonal branch running upward, eventually to a nucleus of the pretectal area, the other axonal branch running downward, branching again to make terminals in SGC, and then leaving tectum to make excitatory synapses on the dendrites of NI cells in the core of the nucleus. The loop is completed by the NI neurons that send axons back into the SGC of tectum.

Two factors seem to be responsible for the complete absence of any topography in the visual responses of NI, despite anatomical evidence to the contrary. The first is the likely existence of electrical synapses within the core of NI, providing low-resistance pathways between neighboring NI neurons that tend to synchronize activity across the nucleus. Experimentally, such synchronization is observed: two well-spaced electrodes within NI pick up almost identical signals, showing that NI behaves as an integrated unit. The second factor is a layer of possible connectivity between type XIV cells in the upper SGC formed by type XIV dendrites and type XIV axon branches that seem to be arranged to spread activity laterally across tectum.

The feedback from NI to tectum has interesting effects on activity in deep tectum, the significance of which is still unclear. Spiking activity recorded extracellulary at any one point in SGC correlates highly with NI spiking; it also correlates highly with any other point in SGC because of the connectivities just discussed that nullify the topography. Even more remarkable is that when NI and SGC activity is correlated, as occurs in bouts of several hundreds of milliseconds, NI and SGC spikes synchronize together within a fraction of a millisecond.

While the relationship of this synchrony to stimulation or to behavior is unknown, it appears that precise timing of neural events is critical to processing in deep tectum, whereas precise spatial topography is not.

The function of the tectum–NI loop is still a matter of surmise. The fact that NI's responses, which are evoked by novelty, motion, and especially approaching objects, are broadcast throughout tectum, suggests an alerting or attentional role. This is supported by experiments showing that the response of one NI to stimuli seen by the opposite eye can be reduced or distracted by a more salient stimulus presented to the other eye. There is evidence in fish and frogs that NI may modulate optic nerve input in the upper layers of tectum, accentuating the response to visual stimuli. In birds, too, NI has been proposed to play an attentional role. In teleosts, NI's influence is strongly manifest throughout deep tectum, perhaps allowing an assessment of particularly salient events by means of a comparison of NI signals with all current sensory representations in tectum, whatever their sensory modality, and selecting one as an object for attention or behavioral response.

Multimodal Processing and Torus Semicircularis

When the optic tectum is peeled away, one sees lying along the midline, the valvula of the cerebellum, a tongue-like protrusion of the cerebellum, and flanking it, two crescent-shaped bodies, the TS (see **Figure** 4(**b**)). Its corresponding structure in mammals is the inferior colliculus, an auditory center. On anatomic grounds, TS is another potentially important partner with the optic tectum, having reciprocal connections with it. Each TS sends axons to both tectal lobes, but each tectal lobe sends axons to TS only on the same side. TS is a large nucleus, but only a relatively small proportion of TS cells provide input to the deep layers (SGC, SAC, and SPV) of tectum. TS has a diverse set of inputs, some of which are sensory in nature: auditory, lateral line, somatosensory. In electric fishes (gymnotids and mormyrids), TS is large and well differentiated into lamina or subnuclei to process the information provided by the electrosensory receptors about surrounding objects and the electric signals of conspecifics. Other inputs to TS come from the cerebellum, the forebrain, and the opposite TS. Inputs to TS from the optic tectum arise on the same side from type XII and type XIII cells whose cell bodies lie in the deep layers (SGC, SAC).

Microelectrode recordings in TS reveal neuronal responses representing its various sensory inputs. Many neurons in TS of goldfish and trout are visually responsive, presumably as a result of tectal input. Indeed, the response characteristics of these neurons – very large receptive fields; unreliable responses to light flashes; preference for motion but without directional preference; and a propensity to habituate – reflect the visual responses recorded in deep tectum that are so closely correlated with NI activity. Other TS neurons are responsive to acoustic and/or lateral line stimulation, and some combine this acousticolateral responsiveness with the kind of visual responsiveness just described. In such bimodal neurons, the two modalities can combine in different ways – in some, responding to stimuli of either modality, in others to both in an additive fashion; sometimes the interaction is nonlinear, requiring that both stimulus modalities be present for a response. The feedback pathway from TS to tectum is therefore a conduit for introducing multimodal responsivity into deep tectal circuits. So far, there is very little physiological data on multimodal processing in tectum of fishes, although it has been studied in amphibians where visual and lateral line inputs combine to activate deep tectum. The benefit of combining different modalities within tectum may be that events and objects such as prey or conspecifics can be more easily detected and more rapidly responded to, if the mappings of the different modalities overlap in tectum allowing them access to common motor mechanisms.

TS in teleost fishes, in its role as auditory center, contains directionally selective neurons that respond to underwater sound vibrating in a particular direction. TS also contains neurons that respond to the much lower frequencies of water movement that stimulate the lateral line organs. There is a rough topography in TS so that an object causing a water disturbance near the animal will activate a population of TS cells that is specific to the location of the object. In fishes that sense objects such as prey through the small electric fields that they generate, different populations of TS cells will be activated by different positions of the field source. Finally, somatosensory signals that convey touch and pain arrive from the spinal cord, and also go directly to tectum. In each of these modalities, TS elaborates and refines differential sensitivities to the important stimulus dimensions (frequency, direction, position, etc.), relaying to the deep layers of the tectum on both sides, and potentially providing information on the whereabouts of events or objects. When these objects can be simultaneously visualized, there will be correlations between the visually evoked activation in tectum and the TS signals. Plasticity of the TS connections in tectum could then generate a topographic map that is in register with the visual map, which is what is found in other vertebrate groups, but yet to be properly demonstrated in fish tectum.

Ascending Connections – via PTP

Between the optic tectum and the forebrain are a number of nuclei forming the brain regions called the PTP (see **Figure** 7). It is inappropriate to detail all of these

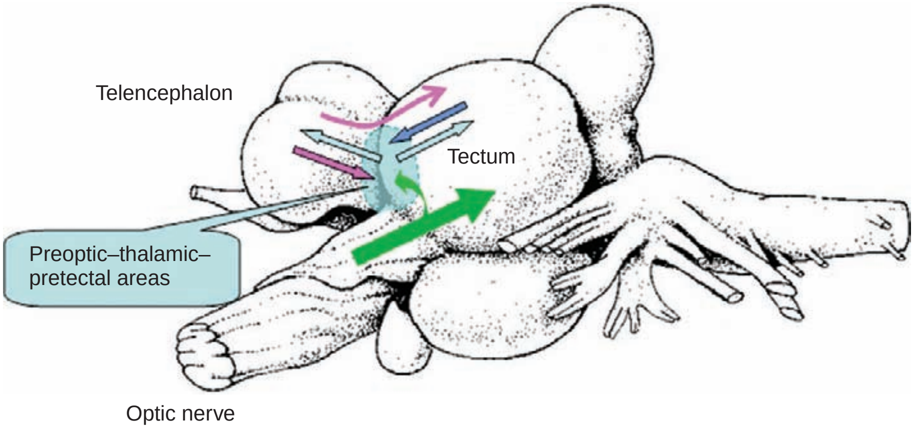

Figure 7 Teleost brain showing the preoptic–thalamic–pretectal (PTP) areas forming an interface between retina, tectum, and telencephalon. Adapted from S. Karger AG, Basel from Wullimann MF and Northcutt RG (1988) Connections of the corpus cerebelli in the green sunfish and the common goldfish: A comparison of perciform and cypriniform teleosts. *Brain Behaviour and Evolution* 32: 293–316.

here (there are 10 or more), especially as there is considerable variation in nuclear composition of the region between species, and in the nomenclature used to describe them. The importance of this region for present purposes is that some nuclei receive direct retinal input, some relay visual information on to the telencephalon or on to the tectum. In addition, some of the nuclei receive tectal input and relay to the telencephalon, many with reciprocal connections back from tectum and telencephalon. The region can therefore be seen as a way station for retinal information traveling to telencephalon, and for tectally processed information, probably multimodal, traveling to telencephalon. Finally, telencephalic regions provide an input to tectum, both directly and via the PTP. The direct telencephalic input is concentrated in SO and in the middle of the SGC of tectum where it could contact the dendritic branches of intrinsic neurons such as the type I, as well as several types with output axons (X, XII, XIII, XIV) (see **Figure 2**).

The fact that our own sensory abilities of recognition and localization are performed by telencephalic cortical areas raises questions about the relative importance of the telencephalon versus the tectum in fishes. In teleost fishes, the ablation of the entire telencephalon has little effect on behavior, at least to the casual observer. Goldfish, for example, after telencephalic ablation successfully identify prey objects and pursue them, so their vision is not obviously impaired. However, after total tectal ablation, they appear completely blind, indeed more disabled than eyeless fish because their use of nonvisual senses for navigating their environment is also impaired.

The very few physiological studies on the PTP nuclei in teleosts show that most of the visually responsive neurons have large receptive fields. Some PTP nuclei do have small receptive fields but contain relatively few cells and these nuclei possess nothing like the detailed retinotopic map that tectum boasts. Evidently, the extratectal pathways via PTP to telencephalon lack the necessary bandwidth for detailed vision and may lack access to motor systems for sensorimotor behavior. The sensory information sent to telencephalon by tectum is probably important for the higher-order tasks that telencephalon performs, such as spatial place learning or the recognition of conspecifics and their displays. This tectally processed information is likely to be highly abstracted, rather than a detailed point-by-point representation of the scene, given what we know about the diffuse character of deep tectal activity, the source of telencephalic input.

The situation in elasmobranchs may well be different. It has been reported that sharks after tectal ablation are still capable of behaviorally discriminating between visually presented shapes. There are also other indicators of the relatively greater importance of telencephalon versus tectum in elasmobranchs. Species of shark that depend heavily on vision, as judged by their mode of hunting in well-lit habitats, have tilted their brain development more toward telencephalon than tectum; highly visual teleosts, on the other hand, seem to have done the reverse.

Descending Connections and Motor Control

The behaviors that depend upon tectum are initiated or guided by sensory input and require a fair degree of spatial resolution. These behaviors include food and prey seeking, navigating around obstacles in the environment, avoidance of approaching objects, schooling, and the ability to swim with a moving textured background (the optomotor response). The tectal outputs mediating these behaviors stem from neurons such as the type XIII with cell bodies in the SGC and dendrites distributed in SFGS and SGC. These neurons send their axons down into the reticular formation of the midbrain and brainstem on both sides, making synapses upon cell groups that activate motoneurons, either in the oculomotor nuclei for eye movements, or in the spinal cord for body movements.

In the absence of direct recordings of the tectal output neurons, the transformations that take place between topographic sensory mappings and muscle movements can only be inferred, mostly from experiments involving electrical stimulation. Trains of electrical shocks evoke behavioral responses most easily in the deep layers of tectum (SGC, SAC). Despite the artificiality of electrical stimulation delivered to a point in tectum, the behaviors elicited in a free-swimming fish may look natural, coordinated, and even purposeful. Stimulation of rostral tectum causes convergence of the eyes and forward swimming in a pattern resembling food searching. Stimulation at sites farther back produce contraversive turning (opposite to the side of stimulation) of eyes and body, similar to a strike at a fly cast, and at high stimulus intensities, movements resembling escape.

By electrically stimulating the tectum of restrained goldfish and measuring the evoked eye movements, it has been possible to draw a detailed vector map showing the direction and amplitude of eye movements evoked from different regions of one tectal lobe (**Figure 8**). The largest, medial zone of tectum elicits movements of both eyes in a contraversive direction. As the stimulation point is moved toward the midline, a greater vertical eye movement component appears; as it is moved caudally, a greater horizontal component appears. This is what would be expected if stimulation is directing movement toward corresponding points in the retinotectal map, where medial tectal positions represent upper field and caudal tectal positions represent caudal field. Stimulation in the posterior zone gives eye movements that are almost entirely horizontal; in the anteromedial zone eye movements do not follow a fixed vector but move toward a goal in frontal space, and in the most anterior region, the two eyes converge inward. In should be pointed out that because goldfish, like most other fishes, do not possess a retinal fovea, these eye movements are not fixating in the sense that our eyes do when scrutinizing something, but are part of a coordinated eye–body movement that orients the whole fish.

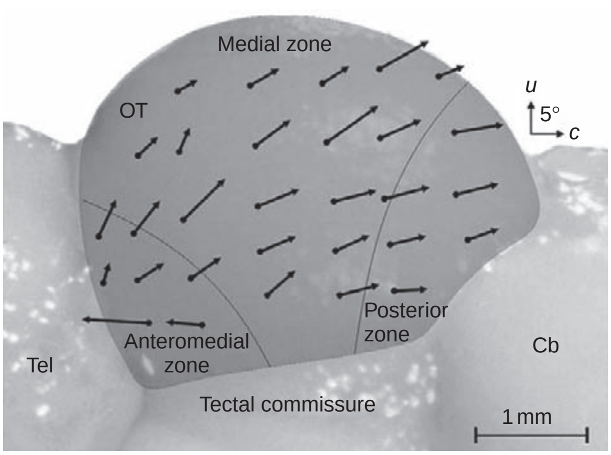

Figure 8 Eye movement vector map on right tectal lobe in goldfish. Arrows show the direction of eye movements evoked by electrical stimulation of different points in tectum. Tel, telencephalon; OT, tectum; Cb, cerebellum. Reproduced from Salas *et al.* (1997) *Neuroscience* 78: 271–288.

While these experiments show conclusively that it is the place of tectal stimulation that determines the direction of the fish's orientation and motion, it is not understood how place might be translated into an intensive neural code, that is, one that specifies the force and duration of muscular contractions. The tectal output fibers do not project to the reticular nuclei with any obvious topography, except that rostral tectal fibers terminate preferentially in rostral reticular areas of the midbrain, a region that seems to contain vertical eye movement generators, while caudal tectal fibers terminate in caudal reticular areas containing horizontal movement generators.

The translation from place to intensive coding appears to be modifiable, perhaps through experience. This is shown by experiments involving plastic rewiring of the retinotectal system. When the optic nerve is crushed and allowed to regenerate into a tectal lobe whose caudal half has been removed, the visual field eventually comes to be represented in compressed form on the remaining rostral half. Sunfish after such surgical rearrangement oriented with normal accuracy to flashed lights in the parts of the visual field that were represented in a compressed retinotectal map. Accurate orienting could also be performed with an expanded retinotectal map produced by removing half the retina and allowing the remaining half to spread its connections across an intact tectal lobe. Evidently, a vector map like that in **Figure 8** is not fixed in the tectum but can be expanded or compressed in compensatory fashion, perhaps by changing the gain of the intensive code. A continual adjustment of this kind through trial-and-error experience would be valuable for keeping prey catching and other motor behaviors well calibrated to the position of objects in space.

The tectum in fishes, as in other vertebrate groups, also plays a part in initiating avoidance and escape behaviors. Moving shadows, especially overhead, and looming objects elicit flight reactions that can be abolished by tectal lesions. Similar defensive reactions can be produced by strong electrical stimulation of tectum. Visual looming stimuli, detected by tectum, probably enabled by NI, activate the giant Mauthner cells in the brainstem that trigger a very rapid and vigorous body flexion, moving the fish out of harm's way.

Conclusions

The basic function of tectum in fishes, as in most other vertebrates groups, is to form moment-to-moment representations of the immediate surroundings, using primarily the visual modality, with back-up from the somatosensory, auditory, lateral line, and electrosensory modalities. These body-centered representations – as distinct from the world-centered (allocentric) representations that telencephalon develops – connect with motor centers, enabling fish to react swiftly in an appropriate direction, whether it be in prey capture, avoidance of objects or predators, or in complex social maneuvers. Interactions among tectum, its satellite nuclei, PTP, and telencephalon help pick out salient objects or events for a possible response. Retinal input provides a detailed and panoramic image of the surroundings to the superficial layers of tectum, making tectum a likely site for pattern recognition. There are units in tectum with oddly shaped receptive fields that may represent selectivity for important image shapes, but no evidence so far of a systematic parsing of features in a hierarchy of specialized regions such as is found in mammalian visual cortex. Virtually nothing is known of the learning capabilities of tectum in fishes, although it has the requisite machinery such as long-term potentiation of synaptic strengths and *N*-methyl-D-aspartic acid (NMDA) receptors. It does, however, demonstrate plasticity of its retinal input connections and possibly its motor output connections, which may be vital for keeping sensorimotor functions in good calibration, especially as the bodies and brains of fishes continue to grow throughout life.

Glossary

Color constancy The capability to assign a unique color to an object, regardless of the spectrum of the illuminating light.

Dorsal light reflex A response to light in which fish try to tilt so as to keep the sun upright.

Heart rate conditioning If an electric shock that slows down heart rate is repeatedly paired with a stimulus, the stimulus alone will slow down heart rate.

Optokinetic nystagmus When the eyeball rotates to track a moving extended pattern.

Optomotor response When an extended visual pattern moves, animals often reduce retinal image motion by moving themselves.

Size constancy Assigning the absolute size of an object, irrespective of its distance from the eye.

Template matching A simple recognition strategy that lacks viewpoint invariance.

Two-alternative forced choice A paradigm in which the animal unequivocally selects between two options.

Introduction

With more than 30 000 species inhabiting nearly every aquatic environment on earth, fish provide a rich source for studying fundamental aspects of visual processing (**see also Sensory Systems, Perception, and Learning**: Communication Behavior: Visual Signals and **Vision**: Vision in Fishes: An Introduction). Many fish show highly sophisticated visual behaviors that often allow the analysis of unique visual specializations. Furthermore, most fish can readily be trained. This was masterly used to dismount the claim that lower vertebrates and invertebrates could not see color. Interestingly, later Nobel laureate Karl von Frisch first succeeded to show this in fish, before his famous work on bees. In this article, we will illustrate a number of behavioral approaches that have been used successfully to tackle most aspects of fish vision. We hope that our brief survey is both stimulating and useful for scientists wishing to study the visual capabilities of their particular species.

Many methods can simply be adapted to study vision in the species that have not yet entered the laboratories and are certain to hold great discoveries in store. Some of the methods can easily be adapted to any species of fish and even to their larvae. Others require sophisticated learning capabilities of the fish and even more so of the investigator. Sometimes methods can be tailored to particular species, elegantly making use of sophisticated naturally occurring behavior that relies on vision. Here, we present these methods on the way through a brief overview of the visual capabilities of fish. We are well aware of the many excellent accounts on visual behavior and visual capabilities of fish and have therefore focused on a few examples and more recent discoveries.

Recognizing Objects

The first studies on learning in fish addressed their ability to recognize visual objects. Two-alternative forced-choice tasks were most commonly used. In these, the fish views two different objects (or two-dimensional images of objects) and has to decide which object to approach. Often, the objects are placed outside the tank to provide no other than visual cues for the task. Sometimes a divider between the possible paths is used to really force the choice (see e.g., **Figure 1(a)**). The approach to one of the two objects is rewarded. Many species of fish have been trained this way, providing a great wealth of data not only on the spatial resolution and representation of shape and color, but also on the way fish represent more abstract features such as the texture of a

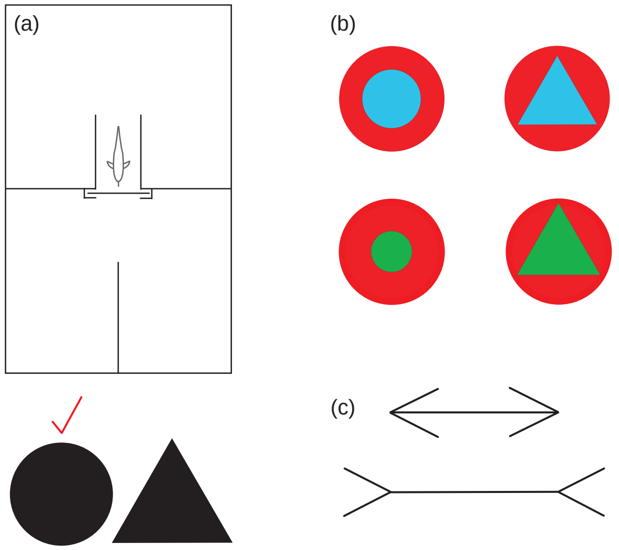

Figure 1 Two-alternative forced-choice tasks can be used to study visual pattern recognition. (a) Setup (top view) used to train the electric fish *Gnathonemus* to select one of the two visual patterns – in this case a circle – from a fixed vantage point. The fish views the patterns from its shelter and is rewarded upon moving to the circle. (b) Evidence suggesting simple template matching in *Gnathonemus*. Although successfully trained to a circle, fish chose both figures (top pair, blue) when they equally matched a putative snapshot (red) taken of the training circle. A triangle was preferred when it better matched the putative snapshot (bottom pair, green). (c) Several fish share the Müller–Lyer illusion with human observers. Though both horizontal lines are of equal length, the lower one is considered longer.

pattern or the number of elements in a pattern (e.g., the number of vertical lines). Some earlier studies even attempted to demonstrate a representation of more abstract topological features such as the closeness of a line.

While fish certainly have highly sophisticated capabilities to represent visual patterns, it is always important to keep Ockham's razor sharp and to look for the simplest explanation. A study on pattern recognition in a nocturnal electric fish, *Gnathonemus petersii*, reminds us that fish can discriminate shapes without necessarily using a concept of shape. In a typical two-alternative forced-choice arrangement, *Gnathonemus* viewed two visual patterns, a set distance away, through a transparent screen from its daytime shelter. When the screen was lifted, the fish swam to one of the patterns to receive a reward or to be driven back into the shelter (**Figure 1(a)**). It was possible to train the fish to discriminate visual patterns but specifically the visual (as opposed to e.g., electrosensory) training worked only at low ambient light intensities of about 10 lx and when the patterns subtended angles larger than about 3°. After the fish were able to discriminate visual patterns, transfer tests were run in which the training patterns were replaced by other patterns (**Figure 1(b)**). This way the features could be identified that the fish had used to discriminate the patterns. Surprisingly, the results of such tests suggested an extremely simple way of storing the rewarded pattern: template matching. In this strategy (whose use is much better documented in insects), the fish stores the view of the rewarded pattern from its fixed vantage point and then chooses that one of the two other patterns whose retinal appearance best matches the stored view. These experiments may illustrate the power of a forced-choice arrangement: with fixing the decision point and suitably arranging transfer tests, much can be learned about the way and accuracy in which fish represent visual patterns.

Nonetheless, most fish use much more sophisticated visual representations and seem even to share certain visual illusions with us. The Müller–Lyer illusion, for instance, has been repeatedly demonstrated by Herter in the 1930s and the 1950s in minnows (*Phoxinus phoxinus*), sunfish (*Lepomis* sp.), and in the Siamese fighting fish (*Betta splendens*). He trained fish, for instance, to select the longer of the two stripes and then tested them with a Müller–Lyer pair of figures that were of equal length but appear to have different lengths for a human observer (**Figure 1(c)**). Herter ran two important controls to support his conclusion: in one the total lengths were equal, whereas in the other the lines were just changed in length so as to make the figures appear of equal length to a human observer. The outcome fully supports the equivalence of humans and fish as far as the Müller–Lyer illusion is concerned. It will be a very interesting future research direction to further probe the degree to which the visual system of fish parallels human performance. To our knowledge no work has specifically been done to disclose the number of images that can be stored over extended periods of time. Early work on acoustically trained fish in the laboratory of

Karl von Frisch suggests that acoustical memories last up to 1 year. Perhaps the visual system of some fish parallels that of the primates also in terms of the number of objects that can be stored during the lifetime of these fish.

Detecting Color

Spectral Sensitivity

The range of wavelengths, that stimulate the eye, can be probed, in principle, by testing which wavelength composition is capable of eliciting a particular visually mediated behavior (**see also Vision**: Photoreceptors and Visual Pigments and Adaptations of Photoreceptors and Visual Pigments). An interesting behavior that has been used is the dorsal light reaction of most teleosts (shared also by other swimming or flying animals) – a reflexive tendency to tilt about the longitudinal axis to keep the sun directly overhead. **Figure 2**(**a**) shows how it can be employed as a typical null method in which the animal is made to compare two stimuli. The fish receives light from two sources. One provides reference light, which is kept constant, whereas the other provides a probing light of known spectral range and intensity. This probing light is adjusted in intensity such as to balance the fish: if the probing light is too strong, the fish will tilt its dorsal part toward the probing light; if it is too weak, it will tilt to the reference light. This simple and clever method avoids a large number of problems one would run into if spectral efficiency were measured with only one light source and the angle of tilt being the measure of sensitivity. This approach is instructive as an example of how easy it can be to interrogate a fish about matching stimuli.

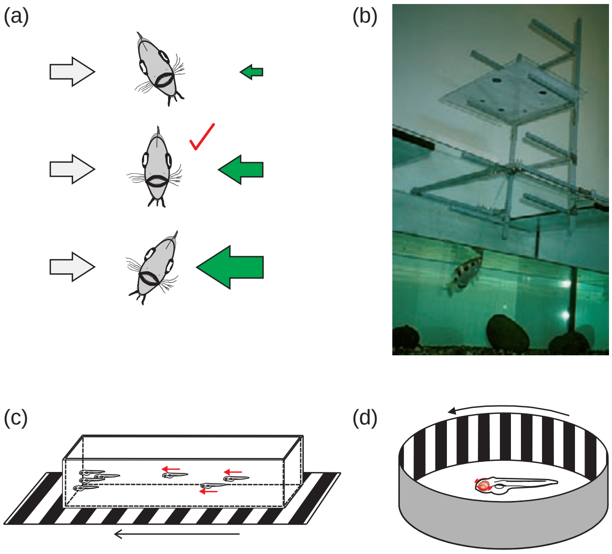

Figure 2 Making use of spontaneously occurring behaviors. (a) Many fish show a dorsal light reflex in which they partly turn their dorsal side toward the light. By shining reference light (constant, gray) from one side and probing monochromatic light (intensity varied, green) of wavelength λ from the other, it is possible to use this response to make the fish tell when both the light stimuli are equal. (b) Size constancy, and how it is acquired, can be analyzed using the natural shooting behavior of archerfish that requires no coupling between reward and target. The fish receives a reward only upon selecting, regardless of presentation height and its own horizontal distance from the target, a disk of fixed absolute size. (c) A way in which the optomotor response can be used for screening zebrafish larvae for visual defects. When a stripe pattern moves on the ground of the tank, fish with intact vision (and locomotion) follow it and can be collected on one side. (d) The optokinetic nystagmus (OKN) has profitably been used in zebrafish larvae. A larva is embedded in agar and follows the movement of a grating with its eyes. (b) Adapted from Fig. 1 in Schuster S, Rossel S, Schmidtmann A, Jäger I, and Poralla J (2004) Archer fish learn to compensate complex optical distortions to determine the absolute size of their aerial prey. *Current Biology* 14: 1565–1568.

Discriminating Colors

Many more methods have been employed to measure the action spectrum of various behaviors, that is, the efficiency of different wavelengths to drive the behavior. None of these *per se* demonstrates the capability of the animal to discriminate color. For color vision, circuitry is needed that compares the output of at least two photoreceptors with different spectral absorption peaks (**see also Vision**: Photoreceptors and Visual Pigments and Optic Tectum). Such circuitry is useful for detecting objects against a differently colored background in very much the same way as circuitry for detecting coherent movement aids in figure–ground discrimination. Perhaps for this reason, all major taxa use color for detecting and discriminating objects. In fish, color vision was demonstrated by von Frisch and ever since many clever behavioral experiments have been performed to test for color vision in fish. In the following, we describe a set of particularly carefully designed experiments by Neumeyer and colleagues that demonstrated tetrachromatic color vision in goldfish (*Carassius auratus*).

In a typical two-alternative forced-choice training, Neumeyer's goldfish first had to choose between the two test fields that were homogeneously illuminated with monochromatic light of different wavelength. For some fish, the task was to select that one of the two test fields which had the shorter wavelength. Other fish had to select the field with the longer wavelength of the two. For a given training wavelength, these experiments yielded the minimum difference, $\Delta\lambda$, the two wavelengths needed to have so that not less then 75% choices were correct. By then shifting the training wavelength in small steps – eventually through the complete spectrum – Neumeyer was able to determine the wavelength dependency of the required difference, $\Delta\lambda$, the so-called $\Delta\lambda$-function. Interestingly, wavelength discrimination was best (i.e., the required difference in wavelengths,

$\Delta\lambda$, was lowest) at 400, 500, and 600 nm. The high discrimination ability in the ultraviolet (UV) range was surprising because only three cone types were known before, with maximum absorption at about 450, 530, and 620 nm, but not in the UV range. The behavioral finding, thus, was compatible either with a new fourth cone type with an absorption maximum in the UV range or with a secondary absorption peak in the sensitivity curve of the long-wave cone type.

Neumeyer settled this question in elegant color-mixing experiments. Suppose the long-wave cone had a (previously unnoticed) secondary UV absorption peak so that UV discrimination could be mediated by an interaction of the long-wave and a short-wave cone. If that is the case, then it should be possible to create a mixture of blue light (absorbed by one of the two players, the short-wavelength cone) and far-red light (absorbed by the other player) with just intensities matched so that the mixture excites the two cones exactly so as presenting monochromatic light of 404 nm would. In other words, there should be a suitable mixture of blue and red light that the goldfish should not be able to discriminate against monochromatic light of wavelength 404 nm. However, no such mixture could be found – at every intensity combination tested, the goldfish always detected the monochromatic light. A second set of color-mixing experiments tested directly if an UV receptor mediated the goldfish's performance. In this case, 404 nm should not be distinguishable from a suitable mixture of blue and UV. This was indeed found to be the case. Therefore, in very simple but well-designed behavioral experiments and with some patience, it was possible to discover a new UV receptor.

Color Constancy

An important challenge in color vision is that the spectrum of the illuminating light can change dramatically. To label an apple and a banana unequivocally with the attribute color requires independence of the label with respect to these changes. The ability of our visual system in achieving this is impressive: when the illumination is changed such that now a banana reflects more red light then was previously reflected by a nearby apple, we basically perceive the colors unchanged. This property is described by the term color constancy. In primates, the visual cortex is thought to mediate color constancy. Nonetheless, in fish – that lack a cortex – color constancy was demonstrated not long after the von Frisch's discovery of color vision in fish. More recently, a thorough study by Neumeyer and colleagues has probed in great detail the full extent to which color constancy of the goldfish parallels that of the humans. Such findings are important and can, taken together, suggest that color constancy is a rather basic trait that does not rely on a visual cortex but can be realized with the circuitry at hand (**see also Vision**: Optic Tectum).

Spatial Vision

Knowing the distance of objects can be decisive in the selection of an adapted behavior: How close is the predator – is it better to hide or to escape? Is the prey close enough to launch an attack (**see also Sensory Systems, Perception, and Learning**: Spatial Orientation: How do Fish Find their Way Around?) When food (or being fed on) is involved in an interesting visually guided natural behavior, it often can be used to characterize information about distance that the visual system provides. A good example is the archerfish (*Toxotes* sp.) that is famous for shooting water at aerial prey to dislodge it from its substrate and to catch and devour it at the water surface. Because these fish do not fire from directly below their prey, they cannot simply send their shot straight up. Rather the fish must set angle and speed of the water jet, depending on their vertical and horizontal distance from their target, so that it passes through the target location. Because in well-trained fish the jet is sharp and because the fish can hit from large vertical and horizontal offsets, this requires the fish to have precise distance information. The fish also use information on distance to infer the absolute size of their aerial targets, regardless of their horizontal and vertical distance (**Figure 2(b)**). Archerfish learn this in surprisingly efficient ways and achieve accuracy in estimated absolute size of at least 1 mm for targets presented 80 cm above the water surface, thereby fully accounting for the fact that the judging eye is under water while the target is in air. Training of the fish is easy because their natural feeding behavior requires neither identity of the reward with the object they fire at, nor strict temporal congruency of shot and reward. Furthermore, the fish are opportunistic and can be made to fire at anything that is rewarded. Thus, the spontaneous firing behavior of this fish can readily be used to assay size constancy. For archerfish, having size constancy is very useful to set the caliber of their shot: the maximal attachment force of prey tends to increase linearly with absolute size. Therefore, knowing size is useful for scaling the investment. Size constancy has also been shown in goldfish in a less dramatic setting without the complications introduced by a water–air boundary. Using a two-alternative forced-choice training, it was possible to show that size constancy in goldfish does not even require binocular vision. This suggests that the distance information is already provided by monocular cues (at least when binocular cues are absent).

Detecting and Analyzing Movement

Large Field Motion

When a fish drifts in a stream, the image of its surroundings moves coherently across its retina. Fish can compensate for drift by detecting this coherent motion and adjusting their forward speed so that the image motion vanishes. This is the basis of the so-called optomotor response (OMR) shown by most fish, but widely distributed among animals and is also present in humans. A standard paradigm used to characterize motion vision is to place the fish in the center of a rotating drum. The drum is lined, for instance, with a vertical grating of alternating black and white stripes. Using a suitable projector, the drum can also display a moving computer-generated pattern. If the eyes of the fish do not move themselves, the fish then attempts to move so as to minimize image motion. Ideally, this would make the fish circle at the pattern's angular speed. Many variations of this setting have been used. A very convenient method is, for instance, to project a computer-generated pattern on the bottom of the tank (**Figure 2(c)**). The movement can then be just in one direction or swinging back and forth.

A second useful behavior in response to visual large field motion is the optokinetic nystagmus (OKN; **Figure 2(d)**). Here, the large-field retinal image motion is not compensated by moving the whole body but by following the moving pattern with the eye. Obviously, this cannot go on forever. The typical OKN therefore consists of periods in which the eyeball rotates to track the pattern motion and brief intervals when the eyeball is rapidly rotated back. Both the OMR and the OKN can be done noninvasively, do not require training, and can be probed over extended periods of time. This makes these methods very useful for probing the time course of light adaption, the spectral input to the pathways that drive the OMR/OKN, or the robustness of large-field motion detection with respect to floating particles (visual noise) in the foreground. The OMR has also been useful to probe functional specializations in species such as the four-eyed fish (*Anableps anableps*) that views its aerial and underwater world with different pairs of eyes and in which the OMR is predominantly driven by aerial motion. In light of all its advantages, it should not be forgotten that fish are not reflex machines that are under the strict command of moving stripe patterns. Fish use their OMR as a tool serving an intended movement but not preventing it. In intended locomotion from one location to another, the function of the OMR is to stabilize the chosen path through a stream. It is therefore important to check the readiness of the chosen species to cooperate in the given setup. Our lab has, for instance, failed in demonstrating and using an OMR in seahorses (*Hippocampus reidi*).

Nevertheless, OMR and OKN work well for most fish and, most surprisingly, even in some larvae. In zebrafish larvae (*Danio rerio*), this helps to assay genes important for retinal function and for assembly and maintenance of postretinal processing. With the visual system fully developed already 5 days after fertilization, the larvae already show visually guided behaviors. Because many techniques can readily be applied to larvae but not to adults, it is important to see which features of the fully developed system in adults are already functioning in the larva. Zebrafish larvae respond to visual motion very early on. Surprisingly, they not only detect the so-called first-order motion in which a pattern is defined by a spatial intensity gradient (e.g., in the case of the classic grating). The larvae even detect second-order motion of contours that are defined by changes in texture or flicker but leave the spatial distribution of luminance constant. Detecting such more elaborate ways of movement is – in primates – often considered a task for the visual cortex in which separately processed information on first- and second-order motion is combined. It is an exciting finding that the zebrafish larva is already fully equipped to detect second-order motion. This suggests that the computations can be done much more peripherally and, perhaps, even within the retina.

Small Field Motion: Perceiving the Speed of Objects

Fish can also assess the speed of objects but little is known on how accurate they are. A good alternative to starting a forced-choice training setup is to look for naturally occurring behaviors that rely on information about speed. A particularly rewarding subject in this regard is the archerfish whose unique hunting technique requires it – in at least two ways – to represent the speed of small target objects. Archerfish can learn to hit moving aerial targets (**Figure 3(a)**) that travel considerably during the rise time of their shot. This requires the fish to adjust their shots to target speed. In the respective experiments, target motion was shown only in a small area. Surprisingly, fish that had been trained exclusively with horizontal motion also fired appropriately when the target had a vertical component of speed whose neglect would have been experimentally detectable. This suggests that they can represent three-dimensional speed, at least in ways that can readily be used to set the appropriate combination of shooting angle and horizontal distance from the target that is required to hit.

A different context in which it is important for the fish to judge the speed of small objects is in their predictive start. Archerfish launch a rapid start toward their prey's later impact point as soon as they estimate the direction and speed of their dislodged prey (**Figure 3(b)**). They can estimate speed well enough in an impressively short

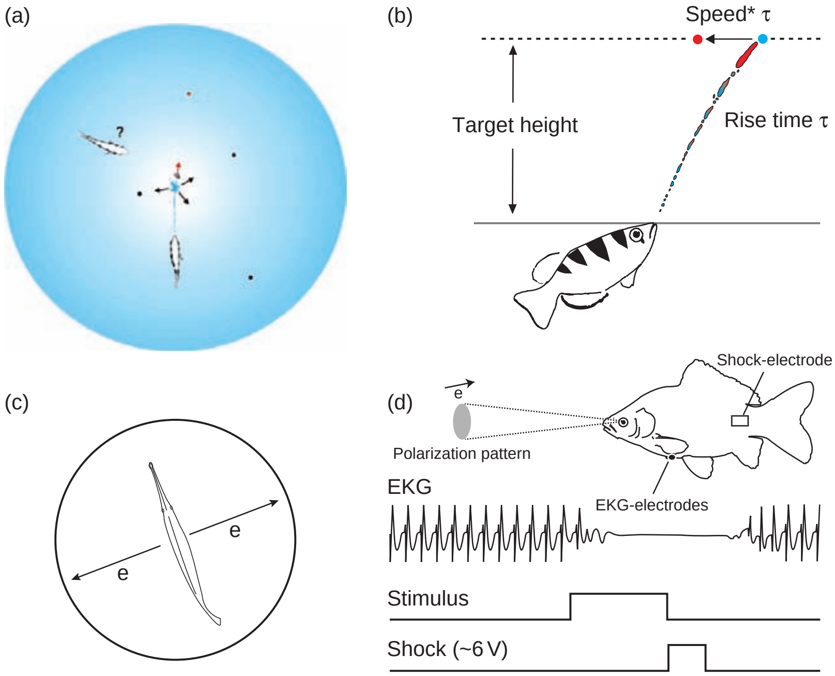

Figure 3 Naturally occurring behavior and classical conditioning. (a), (b) Two naturally occurring behaviors that help to assess how fish represent the motion of small objects. (a) Top view of prey catching in archerfish. The moment a shot is fired the fish do not know at what speed and in which direction its prey is going to move when dislodged. Archerfish therefore monitor initial motion and then turn and start so as to be at the right time at the inferred later point of catch. This behavior involves accurate representation of speed and direction. (b) Representing speed also is needed when the fish learn to hit a target that moves, in a restricted area, at constant speed. Depending on target height the fish must learn to account for the speed-dependent displacement of their target during the rise time of their shot. (c, d) Using behavior to demonstrate that fish detect polarized light. (c) *Zenarchopterus* spontaneously orient their body axes according to the e-vector of linearly polarized light. (d) Heart-rate conditioning: by pairing a visual stimulus with a mild electric shock fish eventually suppress their heart-beat activity when stimulated with polarized light. The conditioned response can then be used to obtain threshold levels and to correlate them with photoreceptor distribution in that spot of the retina that has been stimulated. (a) Adapted from Fig. 1 in Schlegel T and Schuster S (2008) Small circuits for large tasks: High-speed decision-making in archerfish. *Science* 319: 104–106. (b) Adapted from Fig. 1(a) in Schuster S, Wöhl S, Griebsch M, and Klostermeier I (2006) Animal cognition: How archer fish learn to down rapidly moving targets. *Current Biology* 16: 378–383.

interval of time. Experiments in which the fish are confronted with falling objects of novel sizes, in which the background behind the objects has a novel distance and in which novel vertical speed components are added to the movement currently, suggest that archerfish use an estimate of absolute speed to drive their predictive start.

Detecting Polarized Light

Behavioral methods have also demonstrated that fish can detect the polarization of light. This was surprising because in vertebrate eyes the morphological foundation of this sense is less conspicuous than in the compound eyes of the arthropods: chromophores in the disks of vertebrate photoreceptors are not aligned as they are in the microvilli structures of arthropod rhabdoms and can move freely within the disk membranes in the outer segments. The first evidence came from orientation behavior of *Zenarchopterus dispar* and *Z. buffoni* under illumination with linearly polarized light. *Zenarchopterus* preferred heading directions perpendicular or parallel to the e-vector (**Figure 3(c)**). This and other results disclosed the ability of fish to detect the polarization of light and to use this attribute for orientation. Furthermore, contrast enhancement, for example, for prey detection, was suggested as a further advantage of polarization vision in fish (**see also Vision**: Photoreceptors and Visual Pigments and Adaptations of Photoreceptors and Visual Pigments).

Behavioral studies also revealed the morphological basis of polarization vision in fish. One successful approach used the so-called heart-rate conditioning. In this classical conditioning method, fish are trained to associate a stimulus, in this case a polarization pattern (conditioned stimulus) with a harmless electric shock (unconditioned stimulus). Fish respond to mild shocks (about 6 V) by a short interruption of heart activity (**Figure 3(d)**), mostly combined with suppression of respiration activity. Monitoring the electrocardiogram of trained fish thus offers the possibility to measure precise thresholds of polarized light detection. By comparing the sensitivity thresholds for polarized light with the absorption spectrum and the arrangement of double cones in the retina of the sunfish (*Lepomis cyanellus*), it became evident that the double cones are responsible for polarization vision in at least some fish.

Conclusion

A rich repertoire of behavioral approaches is ready for use for future discovery. It is important, however, to keep in mind the simple fact that behavioral approaches elucidate those aspects of visual information that are fed into the behavior at hand. To demonstrate color vision, for instance, one must select a behavior that (if the fish has color vision at all) would probably be driven based on color information. For example, using the OMR would be a bad choice here: in goldfish, the OMR is colorblind. However, suitable training of the fish readily reveals its tetrachromatic color vision. Similarly, placing an archerfish into rotating stripe drums would not allow us discovering its many exciting capabilities.

We predict that behavior will continue to play an important role in the future of fish vision:

1. A promising direction is comparing visual capabilities of fish with those of primates. Such studies can show that many apparently complex tasks can be solved quite early by comparatively simple circuitry. Zebrafish larvae, for instance, readily detect second-order motion and may use circuitry right within their retinae to detect this more abstract form of motion.
2. Exploiting the visual behaviors in the larvae of zebrafish will continue to be a promising direction for future research that provides key factors required for the assembly and higher functions of the visual system.
3. The behavioral analysis of visually specialized species will provide further surprises in visual information processing that force us to reconsider our notions on basic physiological processes.
4. Finally, vision is not simply a prerequisite of behavior but is tightly interwoven with it: fish move to obtain visual information, modulate incoming sensory information during intended movements, and integrate vision with other sensory information to most efficiently pursue their goals. In fish, these aspects are well accessible to behavioral dissection.

Aposematic Warning signal; aposematic coloration is often bright or conspicuous, warning potential predators that animal is toxic or in some other way unpalatable.

Color An object's color is determined by its spectral reflectance, the spectral sensitivity of the visual system viewing the object, and the way in which these signals are interpreted by the brain. This varies substantially among animals depending on the composition of photoreceptors and their connections.

Cone The sensory cell type in the eye (photoreceptor) involved in color vision and bright light conditions.

Irradiance The amount of light or electromagnetic radiation at a surface. Spectral irradiance is used here to describe the light incident on the reef available for vision.

Radiance A radiometry term to describe the amount of light, emitted from a particular area and from a defined solid angle or direction.

Rod A rod-shaped photoreceptor type in the eyes of vertebrates that functions in dim light conditions so may allow night vision. The photoreceptor molecule within rods generally absorbs light in the middle of the spectrum giving it a spectral sensitivity around 500 nm.

Spectral reflectance The wavelengths of light reflected, and therefore not absorbed or transmitted, through an object, as determined by the pigmentary or physical structure of the objects surface. For visual purposes this often expressed as a curve from ultraviolet to far red (300–700 nm).

Spectral sensitivity The specific spectral region, usually a bell-shaped curve, within which a photoreceptor absorbs light. This includes the absorptive effect of any photostable pigment, such as a yellow lens, on the absorbance of the visual pigment molecule within the photoreceptor.

Introduction

Anyone who has snorkelled or dived on a coral reef always surfaces exclaiming about the beauty of the fish. These jewelled inhabitants of this shallow tropical habitat have been a source of wonder and interest since the first reef was encountered. Both Darwin and Wallace, the grandfathers of the theory of evolution, were so worried by the diversity of what they saw on reefs that both questioned if their new idea could explain the myriad colors of the reef inhabitants. Today, the more we learn about the language of reef fish colors and the design of the eyes that decode their message, the more astonishing this aquatic world becomes.

It is important to realize that in fact there is no such thing as color out in the environment. Objects reflect the spectrum of light that reaches them differently, depending on the physical or pigmentary properties of their surface. Photoreceptors, usually cones for color vision, absorb this light according to the spectral absorption of the visual pigment molecule within them and convert this to an electrical message that is sent to the brain. These steps and the way in which the brain combines and interprets these messages is what gives us the sensation of colors and, as made clear later in this article, this varies substantially between animals.

Few of the color codes on the reef have been explained well, but the basic principles of evolution, natural selection, and sexual selection help us to understand some of the functions of reef color (**Figure 1**). New technology and spectrophotometric (light measuring) methods have also advanced our knowledge of the ways in which fish see and how they use color in the context of their marine environment for survival.

Coral reefs are the densest packed ecosystem on the planet for animal life per cubic meter and this gives one clue to the explanation behind the color diversity of the fish and other animals living there. As recognized by last

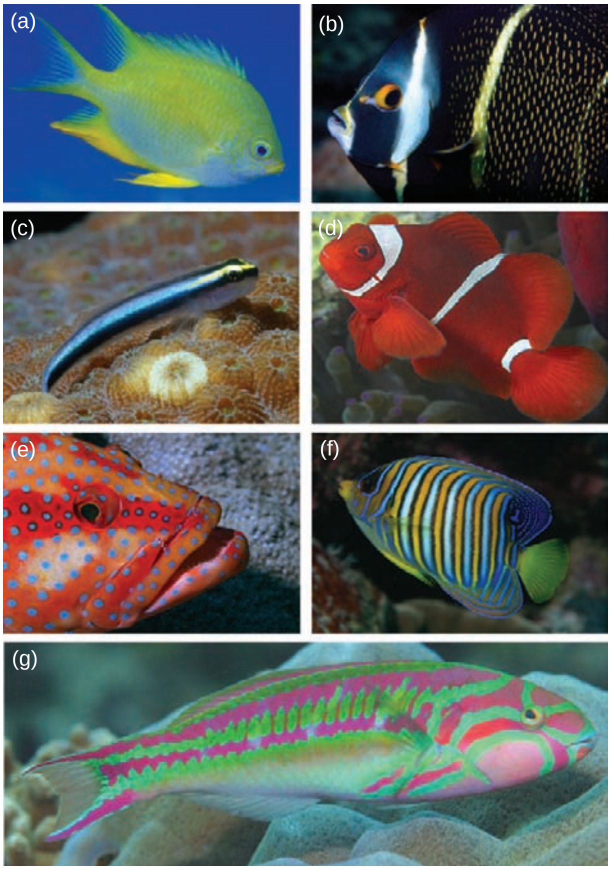

Figure 1 Reef fish and their color patterns. (a) The yellow color of the golden damselfish *Amblyglyphidodon aureus* is highly contrasting against a blue ocean background. (b) French angelfish *Pomacanthus paru* uses strongly contrasting colors to disrupt its body outline. (c) Cleaner goby *Elacatinus evelynae* combines yellow and blue to construct a cleaner fish guild flag. (d) Anemonefish *Premnas biaculeatus* uses strongly contrasting color patterns possibly for disruptive camouflage and for aposematic ('I am distasteful') communication in different circumstances. (e) Coral cod *Cephalopholis miniata* is covered in small spots of color that are highly contrasting at close range but mix additively with the background color of the rest of the fish at a distance for camouflage. (f) The angelfish *Pygoplites diacanthus* uses yellow and blue, contrast-enhanced with white and black stripes for communication and camouflage. (g) The unusual colors of five stripe wrasse *Thalassoma quinquevittatum* are strikingly complementary at close range and blend to match water color at a distance.

century's keen observers of the reef such as Longley, Thayer, Cott, and later on Lorenz, reef inhabitants are in constant communication or anti-communication with each other. Konrad Lorenz, who taught us many of the principles of how to observe animal behavior, said of reefs that "There is in all the world, no other biotope which has produced .... in so closely allied groups of animals, an equal number of extremely specialised forms." He was mostly talking about the fish and their variety of form and color, and this led him to the idea of poster coloration in reef fish, bright colors that enabled fish to sort themselves out into species types and a hierarchical social structure. That is, conspicuous colors and patterns encode species identity enabling close cohabitants to rapidly decide what to do when encountering each other as far as aggression, defense, and the desire to mate are concerned. However, this idea has yet to be explicitly tested.

Anti-communication, an attempt to conceal or camouflage, is intricately woven into the physical nature of light on coral reefs and the eyes that attempt to recognize camouflaged individuals for various reasons. The same close relationship exists between light and color used in deliberate communication and this article gives examples of both communication and camouflage.

Communication methods may be loud and very specific, as noted by Lorenz. Many reef fish are probably colored aposematically, meaning that they use bright coloration to advertise toxicity, or other spiny reasons that make them difficult to swallow. The importance of considering all these possible ways of hiding and conveying information through 'the eyes of the beholder' cannot be overstated and an understanding of the visual capabilities of reef fish, rather than using our own eyes for analyzing particular colors or patterns, is critical.

This article also provides a brief review of the visual ecology of the reef and examines some of the recent advances in our knowledge of the eyes and colors of reef fish. Visual ecology, an area of biology most elegantly explained by John Lythgoe, links the physics of light and color of an environment to the visual system and signaling systems that have evolved there, and lastly examines the visually driven behaviors a species exhibits (**Figure 2**). This must be done not only from the perspective of the visual system observing the color and pattern, but also from the scale of the species under consideration.

The fish we see when we go to a reef represent a small proportion of the biomass of fish that live there. Most fish on the reef are less than 3 cm long and many of them are cryptic (hiding) or shy. However, because we are relatively large animals, we tend to see relatively large fish, perhaps a velvet blue-yellow angelfish defending his territory of sponges and pink-purple parrot fish male with his drab harem of females in tow.

Another subjective problem is partial color blindness because some reef fish have a very different color vision than we do. Humans are primates and our color vision evolved for the tasks of survival in forests and other terrestrial environments looking to find ripe fruit or young red leaves. Put a primate in a mask and snorkel on the reef and the first things they often notice are all banana-colored objects (**Figure 1**(**a**)) at the long-wavelength end of the spectrum, which get our special attention.

In the relatively clear blue waters of the reef, one thing any diver knows is that by the time he gets to 20 m or so, a red snorkel has become greenish-black and blood looks dark green. The reason for this is that the absorption (or more accurately the total attenuation which includes scatter) of water at 20 m has removed red light (**Figure 2**). This would make the red-belly signaling system of a stickleback male ineffective here. Reef fish have evolved communication colors and visual systems set by the physical envelope of light wavelengths that their water transmits best. Their world is very ultraviolet (UV)/blue/green dominated (**Figure 2**). Because their reef visual systems are adapted to see well in this spectral range, yellow, orange, and red may be less conspicuous and indeed match the general reef background.

Camouflage may be achieved by directly matching the color, intensity, and sometimes the texture of the reef substrate (**Figure 1**). As superbly detailed by Cott in his 1940s book *Adaptive Coloration in Animals*, it also pays to have highly contrasting even seemingly ridiculous bold body patterns where the background is bold and highly contrasting (**Figure 3**). The tropical sun coming through the waves, coral branches, coral plates and other reef structures creates a very high contrast environment, and reef fish colors and patterns must be considered in this context. The coffee-table-book flash photography does not achieve this. The colors of the background are deliberately masked or de-focused and the bold colors of the fish picked out with full spectrum light to show them off as best as possible. This topic of color contrast and visual adaptation deserves attention, as many reef inhabitants clearly use this principle of disruptive camouflage, but it is not detailed any further here.

Camouflage and Communication on the Reef

Yellow and Blue, Reef and Water

The underwater visual scene at around 10 m is quite different to land. Directly up to an angle of 43° (Brewster's angle beyond which total internal reflection starts), there is the bright shimmering surface, through which the sky may be more or less visible depending on the waves. Below this is a relatively uniform and dimmer blue, diffuse background body of water into which vision cannot penetrate more than a few tens of meters. The coral and other reef structures appear at a various heights, depending on the ruggedness of the reef and the observer's own size. In shallow water habitats over light reflective sand, looking down may also be very bright, a terrestrial condition experienced only when light reflects off the surface of snow.

The aquatic world is also more three dimensional. Observers and signalers are more dispersed and this is important when considering what angle to view others at and when trying to be camouflaged from all angles. Many reef animals also tend to 'hug the ground' or hide in the reef structure for protection and camouflage. Nonetheless, reef fish may take off into the water column at some stage or indeed some species do spend most of their life there, and this can be dangerous but a good way to advertise your presence. Ultimately, the intrinsic

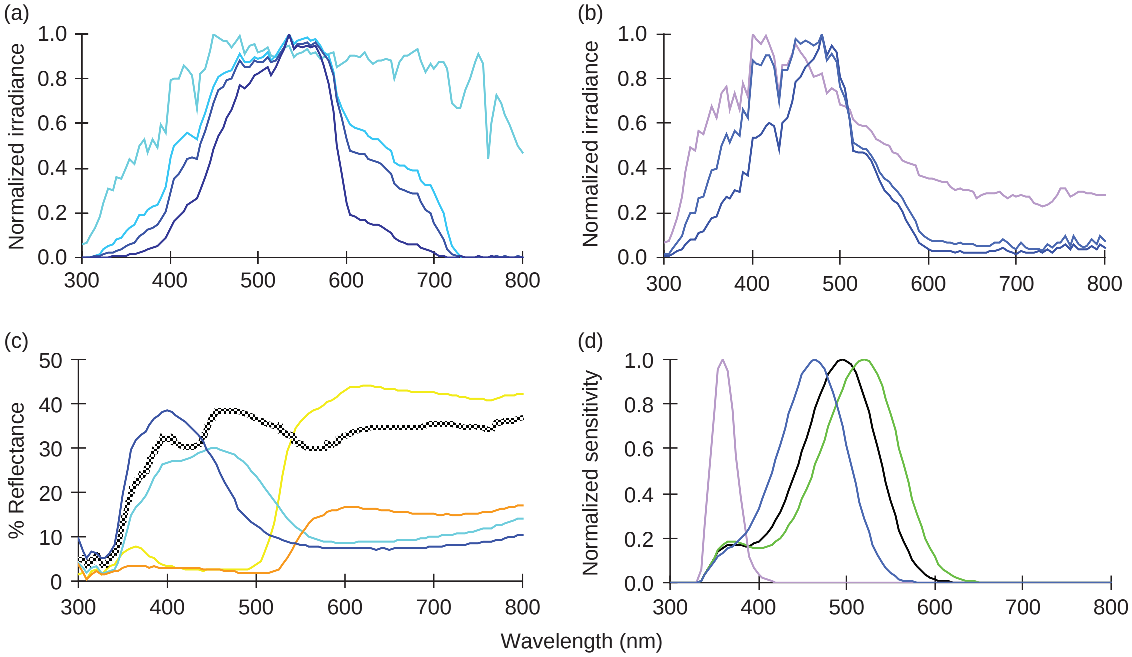

Figure 2 (Continued)

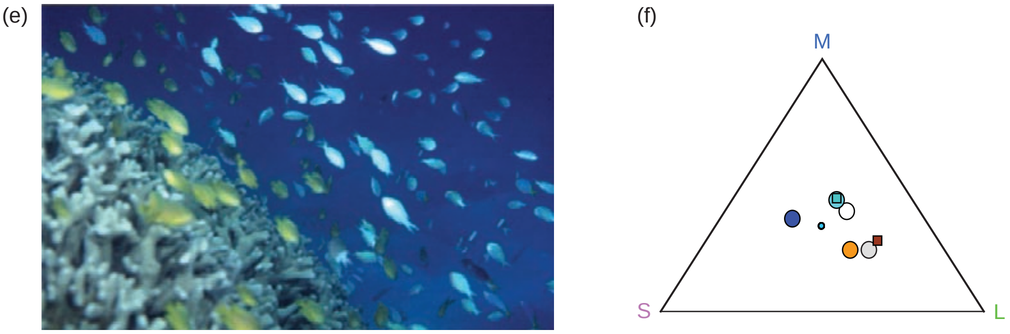

Figure 2 Extended caption – visual ecology. In order to understand and quantify the way in which other animals see the colors of their world, four bits of information are required. (1) The environmental light envelope may be quite different meaning that some parts of the spectrum are not available and therefore not worth investing visual sensitivity in. This is especially so in different water environments. On the coral reef, wavelengths from near UV (350 nm) to yellow (600 nm) are most useful. (2) The colors produced must be measured as their spectral shape can reveal much about how the color is used and combined. Complex colors, that have two or more areas of reflection, may make use of both regions of chromatic reflection or one area may be irrelevant. This seems to be the case for many reef fish colors that contain a long-wavelength component (**Figure 5**). (3) Visual systems on the reef are very different to those on land and indeed than those in freshwater environments. Color vision can be constructed by two or more cones and reef fish show a diversity of color vision types ranging from apparent dichromacy to apparent tetrachromacy. One new observation that has not been explained is the astonishing diversity of spectral sensitivity mechanisms in reef fish. (4) A good understanding of the behavior of the species is essential to appreciate how their visual system and color communication or camouflage systems have evolved. This includes basic observations such as depth range and habitat (does the fish spend its time under a coral ledge, in mid-water, or hidden in holes in the reef) as well as the more complex inter- and intraspecific interactions for predation, defense, and reproduction. The above components and observations can then be used to make predictions and model ideas of how reef fish colors can be used. This sort of calculation is often plotted in a visual space and an example of that is shown here for the colors of angelfish *P. diacanthus* and its possible background colors. (a) Downwelling irradiance or spectral distribution of light on the reef at different depths (0, 3, 5, and 10 m – light blue to dark blue lines). With increasing depth, the filtering and scattering effect of water filters out wavelengths at either end of the spectrum, resulting in a narrowed spectral envelope or light habitat, depending on depth and water type. (b) Radiance or light that might directly reflect from a fish from different angles at a depth of 1 m (purple, from above; light blue, from the side; and dark blue, from below). This directional difference in light background demonstrates the variability of light on reefs, even at a single depth. (c) The spectral reflectance or colors of *P. diacanthus* (**Figure 1(f)**). Reef fish colors can be measured with a reflectance spectrophotometer and the resulting peaks and steps and complex colors enable us to nonsubjectively quantify how colors are used. Line colors are color coded to match approximately the colors of the fish in life (**Figure 1(f)**). (d) The spectral sensitivities of rods (black line) and cones (purple, blue, and green lines) of reef fish must be known before a good understanding of their visual ecology can be built up. This may be achieved through a variety of methods and defines the species color vision range and complexity. (e) Behavioral observation of how colors are used and the context of their use are essential. Here damselfish alerted to the photographer, sort themselves against different backgrounds that provide more effective camouflage for their respective basic body colors. (f) The measurements (a)–(c) above can be combined in visual models to estimate how different colors are used or are effective in the visual world of different species. The Vorobiev/Osorio model is often used and essentially combines light, spectral sensitivity, and spectral reflection in a weighted scatter-plot as seen here. Each data point represents how the fish with visual system in (d) sees the colors of the angelfish colors in (c). The small black circle in the center is the white point and achromatic colors fall close to this point. Note how the white of the fish (gray line in (c)) does not fall near the white point in this visual space as the fish visualizing these colors has UV sensitivity (d). The distance between the data points on this plot is related to how easy each color is to distinguish. Where color vision is potentially trichromatic, with three photoreceptor types or cones, the plot falls into a triangle with each corner representing one of the three spectral sensitivities and labeled here S, M, and L for short, medium, and long wavelength, respectively, and color coded as in (d). The plot shown here is called a Maxwell triangle. The round symbols are the fish colors in (c) and are color coded the same as the colors they represent. This is also their approximate color in life (**Figure 1(f)**). The square symbols are background reef colors shown in **Figure 4**, water background (blue square) and an average of 255 coral and algae found on the reef (brown square). Note how closely the fish yellow matches coral color and how closely one of the fish blues matches water color. This is also demonstrated in **Figure 4**.

turbidity and absorbance of water over a reef precludes the need for long-distance vision and also breaks down fine color patterns at relatively small distances.

Thus, the horizontally divided, distance-truncated three-dimensional habitat of the reef has resulted in a number of specific visual and signaling adaptations. Reef fish lack the high visual acuity of many land animals (most reef fish have resolving power around 10 times worse than humans) and some have evolved relatively simple color vision with only two cone types or color channels. These dichromatic fish are much like many mammals on land and are in some ways similar to a red–green color blind human. These two-channel color vision systems can extract enough information from the world for survival on just one color axis. In behavioral tests for humans, this is called the blue-yellow axis, and for all dichromatic

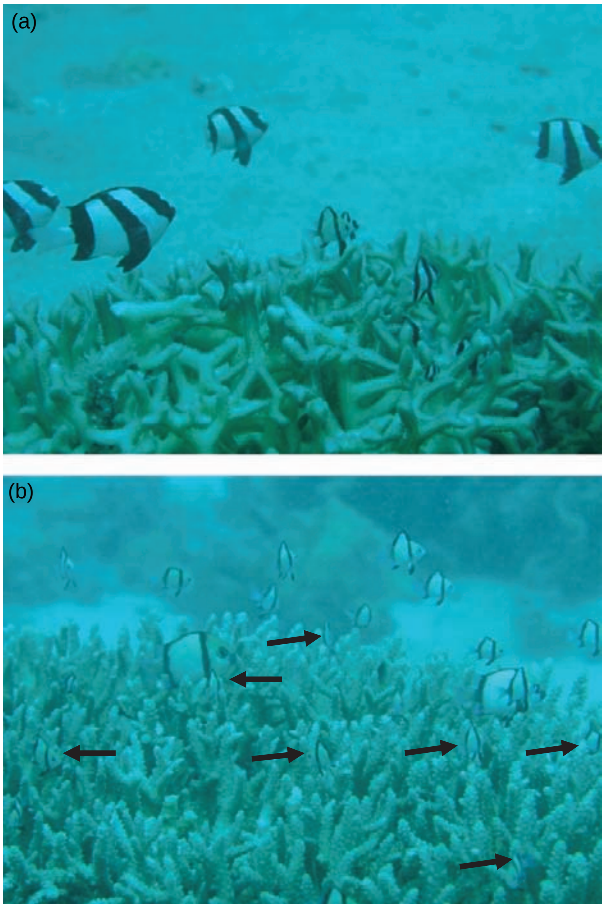

Figure 3 Apparently conspicuous fish in natural surroundings with natural illumination are well camouflaged. Black and white provides the strongest contrast and potential for conspicuousness. (a) Humbugs (*Dascyllus aruanus*) above the coral head in which they live are maximally conspicuous and this may help communication within the school. (b) The damselfish *Dascyllus reticulatus* also inhabits coral heads and when these or *D. aruanus* drop down into the coral branches, they merge with the background through disruptive camouflage. This is especially effective in juvenile *D. reticulatus*, which also mimic the coral fingers. Arrows indicate individual fish.

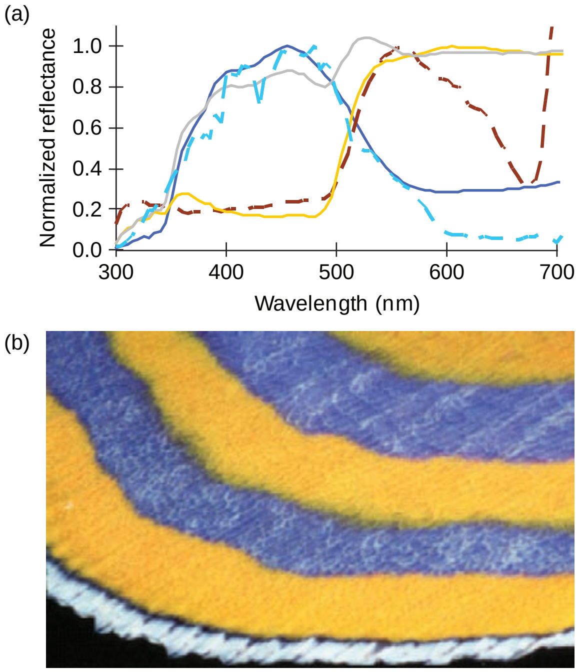

Figure 4 Yellow and blue colors within reef fish body patterns may combine in an additive mixture to reflect gray. This only works when the pattern is constructed of fine stripes or spots which blend at a distance as the resolving power of the eye fails. (a) Reflectance spectra of the yellow/orange and blue anal fin of angelfish *P. diacanthus* (**Figure 1(f)**) shown in (b). Yellow/orange and blue solid lines are color coded to match the body colors in (b). Gray solid line is the additive mix of these two colors. This would appear gray to both fish and humans lacking UV spectral sensitivity as it reflects fairly evenly from 400 to 700 nm. Dotted blue line is side-welling radiance of reef water (**Figure 2(b)**); dotted brown line is average coral and algae reflectance (255 samples). Note the spectrally close match between these colors and the fish colors (**Figure 2(f)**). (b) The anal fin of *P. diacanthus* (**Figure 1(f)**).

species it is constructed from a photoreceptor sensitive to the short wavelength or blue part of the spectrum and one sensitive to longer wavelength around yellow. Color detection or discrimination that requires information from the red–green axis has resulted in the addition of a third color channel or cone mechanism in some primates, allowing, for example, better determination of ripening fruit and other tasks. Some reef fish become trichromatic, and others possess four color channels. At depth, the whole color world is more restricted to wavelengths shorter than yellow (see **Figure 2** and extended caption for further explanation). However, a fish living very close to the reef top will experience close to full spectrum daylight, like that on land. As a result, if their lifestyle demands it, coral reef fishes clearly take advantage of the colors available and increase their color sampling range.

The color code adopted for effective camouflage and communication in this habitat is biased toward yellow and blue (**Figure 4**). Several small reef fish species, notably in the damselfish (Pomacentridae), are colored mostly blue, blue-green, or yellow all over. Other larger fish, such as the angelfish (Pomacanthidae) or surgeonfish (Acanthuridae), use stripes or large blocks of yellow and blue colors (**Figure 1**). These complementary colors are clearly being used to communicate. Complementary colors are ones that contrast strongly with each other, the result of them reflecting in opposing parts of the spectrum (**Figures 4** and **5**). To almost any color vision system, these yellow and blue colors, seen side by side, stand out and it is not just fish such as *P. diacanthus* (**Figures 1** and **4**) that parade this combination in agonistic and sexual displays. Smaller reef fish that are blue all over can get the same effect by positioning themselves against the

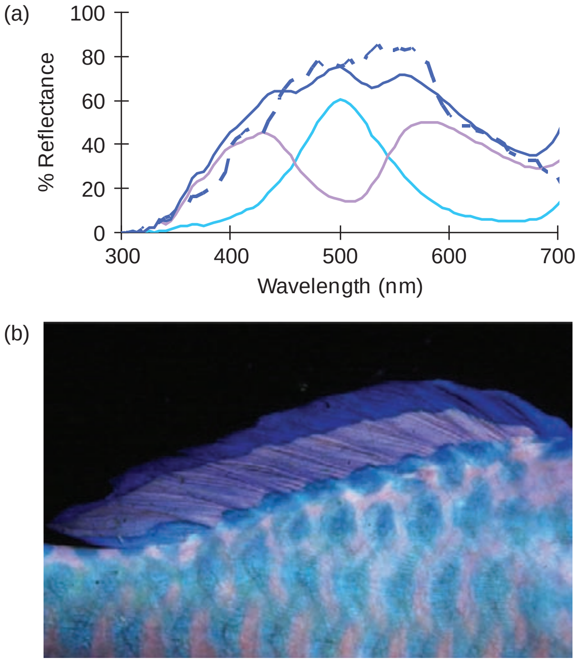

Figure 5 The unusual colors of parrotfish and wrasse can combine to give broadband blue, a good match to background water color. These colors are often intense green and purple/pink (see also **Figure 1**(**g**)) and are complementary as they reflect in different regions of the spectrum. This makes them highly conspicuous at close range. (a) Reflectance spectra of green and purple/pink scales of parrotfish *Chlororus sordidus*. Green, purple/pink solid lines are color coded to match the body colors in (b). Blue solid line is the additive mix of these two colors. Dotted blue line is reef-top water color (radiance) where these fish are often found. Note the spectrally close match between this additive color and the background allowing such fish to be well camouflaged at distance.

yellow-brown of coral and yellow fish can do the same against the blue water background (**Figure 1**).

Lythgoe, Loew, McFarland, and other investigators have also pointed out that yellow and blue colors transmit information a long distance in marine waters, mainly because their regions of largest spectral change fall within the marine environment lighting envelope. The frequently used colors on the reef are also those that can transmit information over a long distance while also remaining good for camouflage in certain circumstances.

Reef fish containing yellow and blue within their body patterns are not doomed to be constant beacons of communication and open to predation. Little fish become instantly well camouflaged, blue-green against blue-green water and yellow against yellow-brown coral. Larger reef fish can take advantage of one of the important scaling factors previously discussed. In an enlarged close-up, many striking patterns are quite finely detailed with spots or stripes (**Figure 1**) that are ideal for close encounters with the opposite sex, or in aggressive displays over mates, food, and territory ownership. From further away, however, this fine detail becomes blurred. Here the complementary nature of the colors is of benefit, as their spectra combine (additive color mixing), and the resulting color is gray and dull because it now reflects over the whole spectrum (**Figure 4**). The relatively poor resolving power of potential predators means that at only a few meters away brilliantly colored angelfish becomes a shadow.

Pointillism in Parrotfish and Other Reef Fish

There is another, more subtle, color mix story found in the parrotfish (Scaridae) and wrasse (Labridae). These fish often possess rather spectrally complex colors with many peaks and troughs (**Figures 2** and **5**) that appear striking pink and green to our eyes. These are also complementary colors and may function differently to yellow and blue. These colors combined do not just render the fish dull and gray, but make it an astonishingly good match to background water color (**Figure 5**). This is again additive color mixing, resulting in a good match to the blue-green water background, which may be a more effective camouflage against the distant eyes of predators and more in line with the lifestyle of these species. Whereas angelfish often lurk in the overhangs and shadows of the reef and may want to appear like a shadow, parrotfish and wrasse patrol over the top of the reef, in the case of the former looking for coral and algae to graze, and, for the latter, looking for crustaceans and other food. As a result, the social function colors of wrasse and parrotfish are unknown, but one function in the parrotfish seems to be to keep the drab female harem together and to signal competitively to other males.

It is worth pointing out that the impressionist painters, particularly the pointillists, secondarily discovered the usefulness of adding small dots and stripes of color to appear one way when observed in close proximity, and another way when observed further away. Seurat and Signac were disappointed with the dullness of the result, as they were searching for ways to make colors more vibrant. Instead, they ended up with dull blues and grays, which eventually they learned were useful to represent the blue-gray cast of shadow, just like an angelfish or a parrotfish at a distance.

Communication and Deception

Cleaner Blue (and Yellow)

Reef fish can be divided into guilds, or color clubs that, according to either behavior or habitat, could explain some of the color diversity. Eibl-Eibesfeldt, Losey, and others have suggested that there is a blue cleaner fish guild. Cleaner fish, often wrasse or gobies, are relatively small and offer a skin, teeth, and gill cleaning services to clients. Fish cannot easily preen themselves of the many invertebrate parasites, such as worms and crustaceans. Cleaner fish exploit the protein banquet by picking off these itchy hitch-hikers and cleaning dead skin and scales from wounds from generally larger reef, or clients. This mutualistic relationship is a delicate one, as the small fish must enter the mouths of predators to pick off parasites and damaged skin. If the predators swallowed the cleaner, or if the cleaner ripped off more than just the required bit, the relationship would never have evolved.

Cleaners may set up a cleaner station on the reef and clients learn where to come to be cleaned. Part of this service involves advertising by the cleaners and there are stereotyped movements and dances cleaner fish perform over their station to show off what they offer. Many cleaner fish from diverse families are yellow and blue, normally in longitudinal stripes and often with black to increase contrast (**Figures 1**(**c**) and **6**). The idea of a cleaner blue guild that arose was untested until recently. Not surprisingly from what we know of yellow and blue on the reef, through a combination of behavioral tests and visual system models, the cleaner fish colors, including blue, were indeed shown to be an effective advertisement color combination, and likely instrumental in setting up the mutualism required. Thus, the cleaner blue guild has given way to a cleaner yellow-blue guild, in many cases emphasized with black.

Deception and the Use of Your Neighbors Color Message

Any relationship, even the cleaner–client mutualism, is open to exploitation. For example, some fangblennies imitate the colors and patterns of cleaner fish. *A. taeniatus* is a remarkable blenny mimic of the cleaner wrasse, *L. dimidiatus*, borrowing the blue-yellow-black stripe uniform of the cleaner (**Figure 6**). This sabre-toothed fish visually deceives unsuspecting clients, biting off chunks of skin as well as feeding on cleaner fish eggs.

Another fangblenny, *Plagiotremus rhinorhynchos*, also closely resembles juvenile *L. dimidiatus* and can rapidly change its body coloration through the neural control of melanophores and possibly other skin cells that produce color. By putting on different colors to prevent detection, the fangblenny effectively camouflages itself against the cleaner fish or within the school, and then darts out to bite unsuspecting victims. This matching and adaptable color change may also help them avoid retaliatory predation.

The UV Communication Channel and the Diversity of Reef Fish Vision

Around half the reef fish species that have the potential to see UV, unlike humans. This ability is often enabled with a cone having a spectral sensitivity between 300 and 400 nm. What is the advantage of UV vision, given the potential disadvantages of UV photodamage to the retina and poor UV transmission in water (**Figure 2**)? Small reef fish may benefit from short-range partially private or covert communication. The extra contrast and patterns are evident in the UV image of a damselfish *Pomacentrus ambionensis* (range 340–400 nm, **Figure 7**) would only be available to other fish with UV sensitivity. Large reef fish, often the predators, lack UV transmitting ocular media (lens and cornea) and cannot see the UV patterns of smaller fish.

UV facial patterns have recently been shown to be important in sexual selection of the UV-detecting

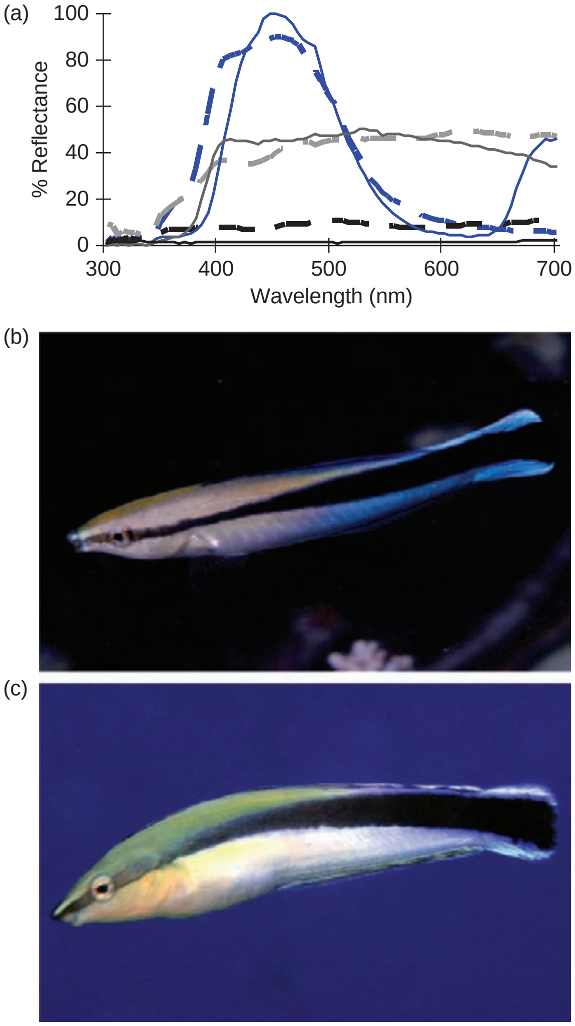

Figure 6 Mimic fangblenny *Aspidontus taeniatus* takes on the color pattern of a cleaner fish *Labroides dimidiatus* to fool clients and cleaner fish allowing them close enough to rip off scales and eat eggs. (a) Reflectance spectra of cleaner fish and fangblenny. Solid lines, cleaner fish colors; dotted lines, fangblenny. Lines are color coded to match the fish colors. (b) Cleaner wrasse *L. dimidiatus*. (c) Fangblenny *A. taeniatus*.

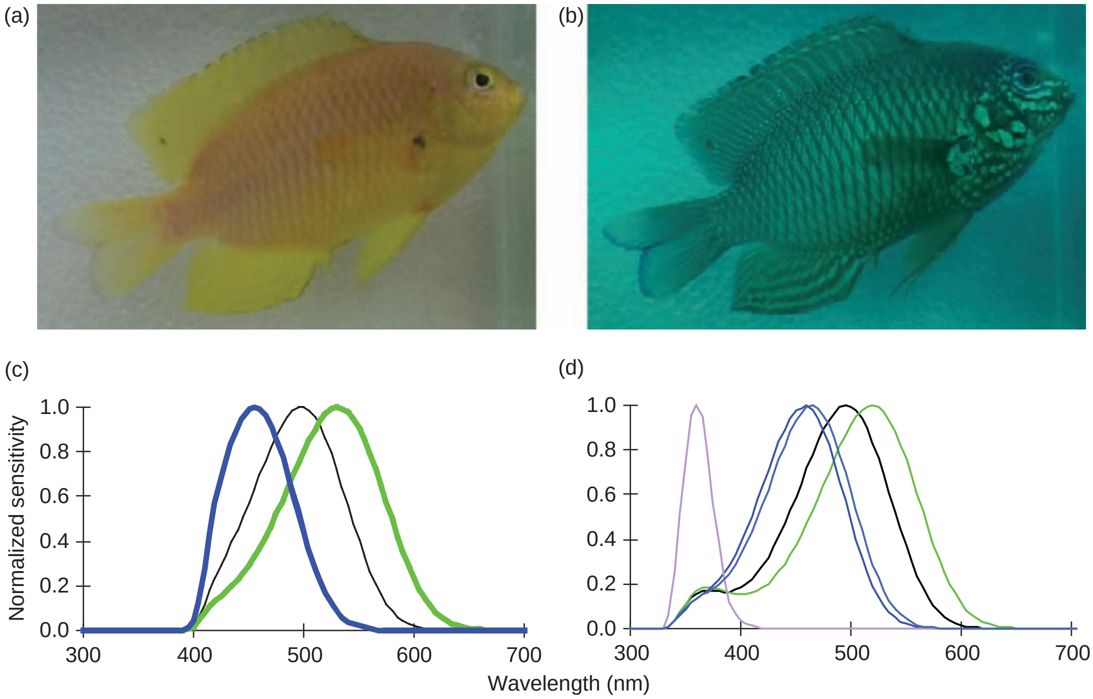

Figure 7 UV colors on damselfish are made visible with a UV camera sensitive to light from 350 to 400 nm. (a) Ambon damselfish *P. ambionensis* as non-UV sensitive humans or fish might see them. (b) Same fish viewed with UV sensitive camera reveals a pattern of high-contrast UV-reflective colors that are available for this and other damselfish species with UV sensitivity. The fish would not appear this way as this frame shows only contrast in the UV. (c) Spectral sensitivity of the barracuda *Sphyraena helleri* which, like humans, lacks UV sensitivity and would not be able to see these UV colors. (d) Spectral sensitivities of damselfish, which includes a dedicated UV cone. This sensitivity would enable these fish to see and communicate in this waveband.

damselfish *P. ambionensis*. UV patterns are effective over the short communication distances of males defending territories from other males. Such signals are therefore an effective close-up signal for little fish whose displays could attract unwanted attention from far away.

Conclusion

Both the number and spectral sensitivity of cone mechanisms are very diverse on the reef and so far we have no clear understanding of what drives this variability. Ideas of basic visual ecology can only explain some of the general trends such as the UV, blue, green bias of reef fish visual systems that broadly matches water transmission characteristics. Phylogenetic trends are very general and are also populated with general loose observations such as 'damselfish often have UV vision'.

The idea of co-evolution of colors and color vision has been proposed for a number of animals. Some correlation does exist between the spectral positioning of reef fish colors and cone sensitivity placement as noted by Marshall, McFarland, Losey, Loew, and others; however, this has many exceptions. There are no cases of fish possessing a color vision system that is designed specifically for its colors, and as reef fish colors are so diverse and there being many tasks that require color vision, this is perhaps no surprise.

We are still left with the mystery of why reef fish possess such apparently diverse color vision types. Aside from those fish in the deeper regions, or those species that are crepuscular or nocturnally active, the general light environment is the same for all species. As a result, to find the answer, we must further study the individual species on the reef and learn more about their specific ways of living.

Glossary

Circadian rhythm An internal rhythm, freerunning under constant conditions with a period slightly differing from the environmental 24-h cycle.

Diencephalon The caudal part of the prosencephalon (forebrain) associated with the third ventricle. The general subdivisions are (from dorsal to ventral): epithalamus, dorsal thalamus, subthalamus, and hypothalamus. The epithalamus is composed of the pineal gland and the habenular nuclear complex. The peripheral parts of the visual system including the retina of the lateral eyes are also derived from the diencephalon.

Ependyma The ciliated neuroepithelial cells lining the ventricular system. In the embryonic optic vesicle of the eye, cilia are of the sensory type and give rise to the outer segments of photoreceptor cells, the membranes of which contain the visual pigments.

Epithalamus The dorsal part of the diencephalon comprising the habenulae as part of the paleolimbic system and the pineal complex with associated structures such as the dorsal sac and the parapineal.

Hypothalamus The ventral part of the diencephalon comprising nuclei controlling vegetative functions either by direct neural connections or via the intermediary of the pituitary gland.

Melatonin The neurohormone synthesized and released in the dark by photoreceptor cells (or their derivatives, pinealocytes) in the retina and the pineal gland.

Opsin The membrane-bound G-protein-coupled receptor protein found in photoreceptors in the retina, which when combined to the chromophore retinal, forms a visual pigment.

Photopigment The labile molecules that change conformation upon absorbing light, thereby triggering various secondary-reaction cascades, with transducin and arrestin as intermediate enzymes. In photoreceptive cells, photopigments are composed of a protein moiety (generally called opsin) and a nonprotein chromophore part called retinal. Retinal-based opsins are called rhodopsins. The wavelength of the absorption maximum can be tuned by modifications of the amino acid sequence of the opsin molecule, and/or substituting retinal by dehydroretinal.

Pineal gland Part of the diencephalic epithalamus with cells specialized in the production of melatonin. In fish, it is composed of a stalk and a hollow vesicle located underneath a transparent window in the skull. The cellular components include photoreceptor and nerve cells.

Introduction

Photoreceptors are cells specialized to detect light, for example, the rods and cones of the retina of the eye. However, vertebrates have photoreceptors in addition to those located in the retina, referred to as extraretinal photoreceptors, and these form the focus of this article. These extraretinal photoreceptors have a cell structure similar to that of rods and cones and contain molecules that respond to light that are similar to those in rods and cones. There are extraretinal photoreceptors located in the skin, the cornea, the iris, and in the central nervous system (CNS). The structure and function of these photoreceptors located in the CNS are the subject of the present article. They are located in the brain itself and comprise the pineal gland, with associated structures, and a cluster of diverse nuclei, referred to as the deep-brain photoreceptive system, which is absent in mammals (**Figure 1**). Thus, in addition to vision, photoreception has an additional, and arguably even more fundamental, and phylogenetically more ancient role in all organisms, namely to synchronize them to the various cycles imposed on the earth by its position in the solar system, most importantly the daily and seasonal cycles of the temperate latitudes.

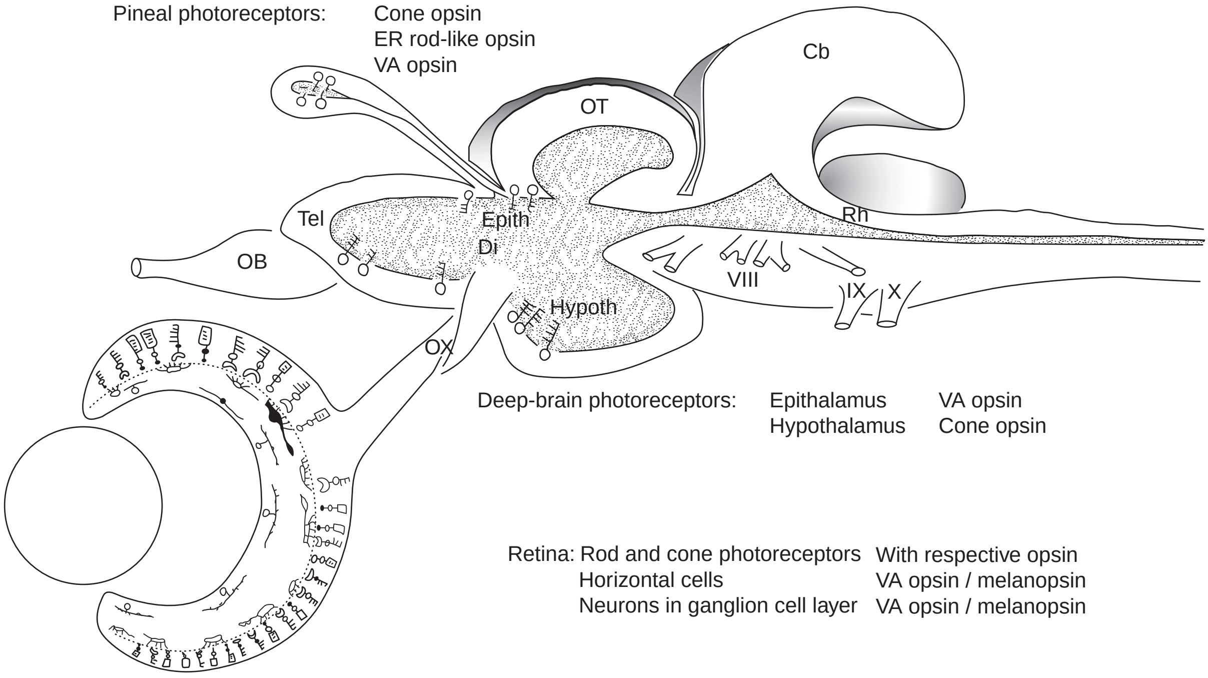

Figure 1 Semi-schematic drawing of a fish brain in midsagittal view including the retina, indicating the location of photoreceptive cells. OB, olfactory bulb; OT, optic tectum; OX, optic chiasm; Cb, cerebellum; Di, diencephalon, Rh, rhombencephalon; Tel, telencephalon; Epith, epithalamus; Hypoth, hypothalamus; VIII, IX, and X, cranial nerves.

The two different photoreceptor systems have been referred to as image forming or cognitive and nonimage forming or vegetative. In the vertebrate CNS, light sensitivity is a property of certain cells located in the part of the brain called the 'diencephalon'. Therefore, both the cognitive and the vegetative photoreceptive systems are derived from the same part of the brain. The forebrain of fishes consists of the more anterior telencephalon and the caudal diencephalon. The diencephalon is further subdivided into four parts: from dorsal to ventral they are the epithalamus, dorsal thalamus, ventral thalamus, and hypothalamus. Deep photosensitivity is found in several areas of the lower diencephalon, a part of the hypothalamus. The photoreceptor cells are modified ependymal cells of the eyecup and the pineal vesicle. In the eye, the retinal primordium induces the formation of a complex image-forming optic apparatus, and the epithalamic pineal vesicle lacks this property; instead, it is associated with a transparent or translucent window in the skull. Light sensitivity in both cases is mediated by visual pigments called 'opsins', the molecular composition and the absorption spectra of which, while pointing to a common ancestral origin, show clear differences.

Deep-Brain Photosensitivity

While the pineal gland and its functional significance have been a matter of speculation and intense debate for several centuries, deep-brain light sensitivity has been recognized only since the beginning of the twentieth century. About 100 years ago, KV Frisch, working with minnows (*Phoxinus laevis*), observed that these fish could change color in response to light and darkness although they had had their eyes and pineal organs removed. Further lesion experiments led him to conclude that photosensitivity was localized in the basal hypothalamus, and he proposed that the ependymal cells lining the third ventricle were the probable functional units. Comparative studies subsequently showed functional light responsiveness in the deep forebrain of many other vertebrates ranging from lampreys to birds. Only after antibodies against various opsins, or transducin and arrestin, became available was it possible to take the search for deep-brain photosensitivity to the cellular level. **Figure 1** shows the location of the extraretinal photoreceptors.

In cyclostomes, representing an ancestral stage of vertebrate evolution, these markers labeled neurons in various regions of the diencephalon, such as the hypothalamus, the epithalamus, and posterior diencephalic areas. Such a heterogeneous and distributed localization might enable the receptor cells to be associated directly with their respective effector system.

Among teleosts, salmonids have been best studied for their organization of the deep-brain photosensory system. The epithalamic habenular region, situated close to the origin of the pineal stalk, contains the most prominent nuclei in this group. In the Atlantic salmon, *Salmo salar*, a member of the photopigment family of vertebrate ancient (VA) opsins is expressed in subependymal cells from the habenulae to the posterior commissure. This indicates a local and autonomous photosensitivity in a region that is the target of both retinal and pineal projections. The habenular region may therefore act as an integration site where the inputs from the retina and the pineal organ are compared with intrinsic signals. The role of this area as a paleolimbic relay center is also confirmed by its afferents and efferents: the habenulae receive afferent inputs from the entopeduncular nucleus in the preoptic region, the hypothalamic tuberculohabenular nucleus, and the preoptic region. Its efferents form the fasciculus retroflexus and target the interpeduncular nucleus, the isthmal raphe, and the central gray. In this manner, the habenulae would be in a position to integrate olfactory and photic stimuli to control feeding and reproductive behavior.

Apart from the habenular region, cells in several nuclei of the anterior hypothalamus, such as the suprachiasmatic nucleus and the magnocellular and parvocellular preopticus nuclei, are also photosensitive. However, they contain a photopigment different from the VA opsin in the habenular area; that is, they showed immunoreactivity against anti-cone opsin.

Yet another kind of photopigment was detected in the ventral telencephalon: anti-transducin antibodies labeled cells within the ventral telencephalon, a region implicated in photoreception in both reptiles and birds.

There appears to be no single and simple explanation for the diversity of photoreceptive systems deep in the fish brain. It has been speculated that various kinds of visual pigments may serve to broaden the range of wavelengths to be captured and also analyze the diurnal changes in the spectral composition of light. The differential receptive stimuli could then bring about specific vegetative and/or behavioral responses.

The Pineal Complex

In nonmammalian vertebrates, the pineal complex develops from the roof of the diencephalic forebrain, that is, the epithalamus. Generally, this is a bipartite intracranial complex composed of the pineal and the parapineal organ. In vertebrates where there is only one part of the complex, it is the pineal organ that is retained. In some vertebrates, there may be an extracranial component, which in frogs is termed as frontal organ or stirnorgan; however, in lizards, it becomes the parietal organ or parietal eye (the third eye). Typically, the pineal complex is located directly underneath the meninges and the skull. In mammals, by contrast, the pineal stalk is short and the large increase of the telencephalic hemispheres hides the pineal organ in the deep recess associated with the cerebellar tentorium and the large cerebral vein.

Parapineal and Pineal Organs in Lamprey

In hagfish, the habenulae form the most prominent epithalamic nuclear complex and a further differentiation into a pineal complex is absent. However, other cyclostomes, such as the river lamprey, show the typical components of the pineal complex. These include the epithelial saccus dorsalis, an ependymal diverticulum of the roof of the third ventricle, the pineal organ situated in the midline dorsal of the saccus dorsalis, and a more ventral parapineal organ (except in *Mordacia praecox*). The pineal and parapineal organs develop from a common precursor, a bilateral evagination from the epithalamus with the pineal forming the right, and the parapineal the left part. Both consist of a hollow terminal vesicle and a stalk, the lumen of which obliterates during development. The pineal vesicle is located directly underneath a melanocyte-free transparent window of the skull and epidermis.

Electrophysiological recordings indicate the presence of at least two classes of photoreceptors, a dominant group with a photopigment of a maximal sensitivity or peak absorption (λ_{max}) between 505 and 545 nm, and a second group with a photopigment of a λ_{max} around 380 nm implying ultraviolet (UV) sensitivity. The broad spectral range of the first group is due to species-specific differences and caused by varying ratios of retinal1/retinal2-based chromophores. These two populations of pineal photoreceptors (short-wave (UV) sensitive, and a middle-wave (green) sensitive) have also been detected by immunocytochemistry. In the underlying neuroepithelium of the pineal vesicle, neurons have been identified that transform the input of the two chromatic types of photoreceptors into a color-opponent response. In addition, there were neurons with an achromatic response.

Molecular work on genomic DNA in lampreys showed the presence of an opsin family that shared only 40% identity with the rod and cone opsins of the lateral eyes. Further analysis revealed that this lamprey opsin belonged to the teleost VA opsin family. In addition, complementary DNA (cDNA) sequencing identified another non-rod, non-cone opsin in the lamprey pineal complex belonging to the parapinopsin family. This photopigment was located in the dorsal region of both the pineal and parapineal organs, whereas rhodopsin was found in the ventral regions. The lamprey parapinopsin has a λ_{max} of about 370 nm and is bistable, because it is converted by UV light into a stable green-sensitive photoproduct with λ_{max} at 515 nm that in turn reverts to the UV pigment on absorption of middle-wave light, a unique case for a vertebrate opsin-based pigment. The behavior of the bistable pigment explains the electrophysiological responses of the chromatic secondary neuron type in lamprey pineal complex, whereas the rhodopsin would account for the achromatic neurons.

The Pineal of Teleosts

In holosteans and teleosts, the general organization of the pineal complex does not differ markedly from that of the lampreys, because we find a pineal and parapineal organ surrounded by the dorsal sac epithelium and situated dorsally underneath a translucent window of the bony or cartilaginous skull. Its role as a photosensory organ was first established in the rainbow trout (*Oncorhynchus mykiss*). Subsequent electron microscopic studies confirmed the presence of photoreceptor cells in the inner lining of the pineal vesicle whose morphology was in many aspects strikingly similar to their retinal counterparts. The discovery in trout pineal of hydroxyindole-*O*-methyl transferase, a key enzyme for the synthesis of melatonin, suggested that the pineal in fish represented a neuroendocrine organ capable of perceiving the photoperiod and using melatonin as the signaling mechanism with systemic targets. At least with respect to this last role, the pineal in fish is equivalent to that in the other vertebrates, but photosensitivity of pineal cells has been lost in the evolution of mammals.

The pineal gland of teleosts is connected to the habenular nuclei by the pineal stalk, which contains mostly efferent projections. Further targets include visual targets in the diencephalon such as the periventricular pretectum, the dorsal thalamus, the ventral thalamus, the posterior periventricular nucleus, and the mesencephalic tegmentum. Like the retina, the teleost pineal also receives afferent innervation via Phe-Met-Arg-Phe-NH2 (FMRFamide) immunoreactive fibers, originating in the nucleus olfactoretinalis (ventral telencephalon). The pineal organ is surrounded by a plexus of small capillaries.

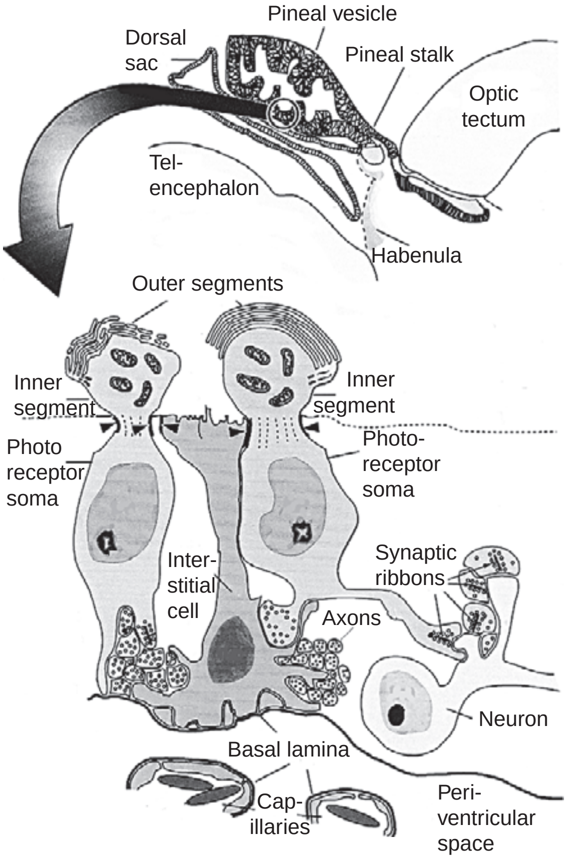

Figure 2 (Top) Schematic midsagittal section through the epithalamic region showing the pineal organ, the dorsal sac, and the habenula. (Bottom) Summary diagram of the cell types in the sensory epithelium of the pineal vesicle; arrowheads indicate tight junctions forming a barrier against the cerebrospinal fluid of the pineal lumen. Modified from Ekström P and Meissl H (1997) The pineal organ of teleost fishes. *Reviews in Fish Biology and Fisheries* 7: 199–284.

Structure and ultrastructure

The general morphology and ultrastructure of the pineal gland (vesicle) is characterized by the following features (**Figure 2**): two types of cells line the central lumen, ependymal-derived photoreceptor cells and radial glia cells spanning the entire width of the vesicle wall. The morphology of photoreceptors is variable and, unlike the retina, it is difficult to identify different types based on their structural appearance. The cell body is situated inside the neural epithelium and contains numerous mitochondria, endoplasmic reticulum, and Golgi apparatus, surrounding the nucleus. Like rod and cone cells, they have an inner and outer segment. The inner segment bulges into the central lumen and gives rise to a short outer segment. In contrast to rods and cones, the shape of the outer segment resembles an inverted cup, resulting in a concentric arrangement of the inner segment surrounded by a ring of outer segment disks in cross sections. Inner and outer segments are joined by the typical sensory cilium containing nine doublets of microtubules. The number of disks that makes up the outer segment varies considerably, between about 10 and 100. The outer segments are thus surrounded by cerebrospinal fluid and not by an epithelial sheath corresponding to the retinal pigment epithelium. The axon of the pineal photoreceptor may contact secondary neurons located in the wall of the pineal vesicle; alternatively, it may terminate against the basal membrane of the external limiting membrane and abut on the capillaries in the surrounding subarachnoidal space, or enter the pineal stalk and terminate in the brain. The wall of the pineal vesicle also contains interstitial neurons, and a neuropil of axonal, and dendritic processes in addition to glial processes. While it has been shown that some of these neurons project to targets in the brain via axons in the pineal stalk, it is as yet unclear whether there are also intrinsic or short axon interneurons, similar to retinal horizontal, bipolar, or amacrine cells that would provide for intrapineal signal processing. Synaptic contacts have been observed mainly between photoreceptors and these neurons. They have the typical hallmark of photoreceptor synapses, 'synaptic ribbons', that is, electron-dense plate-like presynaptic structures, which are surrounded by a dense halo of clear synaptic vesicles. Occasionally, conventional reciprocal synapses have been observed from interstitial neurons back onto photoreceptors.

More than 25 000 species of fish occupy photic environments, ranging from coral reefs exposed to tropical sun to dark caves and the abyssal and hadal depths outside the reach of sunlight. Therefore, it is not surprising that this diversity is reflected in an adaptive radiation of pineal morphology. Pineals of more than 100 species have been studied to date. Differences are found at all structural levels, including the shape (cylinder- to mushroom-like) and sheer volume of the pineal vesicles. Furthermore, the vesicle wall ranges from less than 20 μm to more than 100 μm in thickness and the lumen varies between widely patent to nearly occluded. The density of photoreceptors is as variable as the number of outer segment disks (see above). In a number of studies on deep-sea fish pineals, it has been proposed that the pineal increased in size as the fish inhabit deeper, and, therefore, dimmer environments, implying an increasing sensitivity associated with larger size. Such a correlation was, however, not confirmed in a subsequent comparison of 10 species of abyssal demersal fish, where species with small and large pineal organs were found living at similar depths. A more relevant observation in fish species living in continual darkness concerns the parallel differentiation of eyes and their retina, and the pineal. Whenever fish had large eyes and a highly differentiated retina, a well-developed pineal organ was found. By contrast, in the few species with reduced lateral eyes (spiderfish *Bathypterois dubius* and Southern cavefish *Typhlichthyes subterraneus*), a small and rudimentary pineal was observed. In the Mexican blind cavefish (*Astyanax mexicanus*), a fully functional pineal organ persists in spite of the complete degeneration of the eyes. They have fully developed photoreceptors, which confer a residual photosensitivity to the animal. Interestingly, during ontogeny, the pineal and its photoreceptors clearly precede the emergence of the lateral eyes, further supporting the notion of a considerable independence of the two systems (**Figure 3**).

Physiology: Light-evoked responses

Pineal photoreceptors function as luminance detectors, because the window in the skin and skull as well as the irregular organization and convolutions of the pineal epithelium allow only diffuse light to reach pineal photoreceptors. The absolute sensitivity of pineal photoreceptors and the time course of dark adaptation are in the same range as in retinal rods. However, the overall response characteristic is markedly different: pineal photoreceptors maintain the same response amplitude during the entire illumination period and maintain an intensity-related steady membrane potential. In terms of spectral sensitivity, most isolated photoreceptors from trout pineal showed peak responses between 520 and 530 nm; a minor population of cells had a λ_{max} of about 500 nm indicating a heterogeneity of visual pigments.

Extracellular and intracellular recordings from pineal neurons confirmed the function of the entire organ as a luminance detector. In goldfish (*Carassius auratus*) and pike (*Esox lucius*), spontaneously active cells were found whose discharge frequency was almost an exact mirror image of the intensity of the incident light. Electrotonic coupling of photoreceptors via gap junctions as well as a network of chemical synapses between the secondary pineal neurons provide two independent average systems that ensure a homogenous neural output. In pike and rainbow trout, antagonistic chromatic responses have been recorded from pineal neurons, where short-wavelength light caused inhibition, and long wavelengths resulted in excitation, with reciprocal sign-inverting interaction between the responses. As the spectral composition of the ambient light is different at dawn and dusk from that during the rest of the day, the antagonistic spectral organization would enhance the sensitivity of the pineal gland to perceive the change from scoto- to photophase (i.e., from night to day) and vice versa.

Visual pigments

The electrophysiological experiments on chromatic activity in teleost pineals were complemented by microspectrophotometric analyses on the absorption properties of visual pigments. Two photopigments were identified in trout (λ_{max} 460 and 560 nm), possibly three in pike (λ_{max} 380, 530, and 620 nm), but only one in cyprinids (λ_{max} 530 nm). Immunocytochemical work indicated that these pineal visual pigments were closely related to rod and/or cone-like visual pigments of retinal origin. However, while there was similarity because they were either rhodopsins or porphyropsins, there were also clear differences, because in no case were the absorption maxima of the visual pigments in a given species identical in the retina and in the pineal organ.

More recently, additional opsins have been identified in fish pineals that were either different from their retinal counterparts or not expressed at all in the retina. These include VA opsins and parapinopsin. Furthermore, an extraretinal rod-like opsin (referred to as errlo), first characterized in zebrafish (*Danio rerio*) is now assumed to be ubiquitous in teleost pineal organs. An interesting analogy to retinal opsin is, however, that the pineal errlo shows a similar wide degree of variation. In some shallow-water fish species, such as the goldfish and the blind cavefish, the

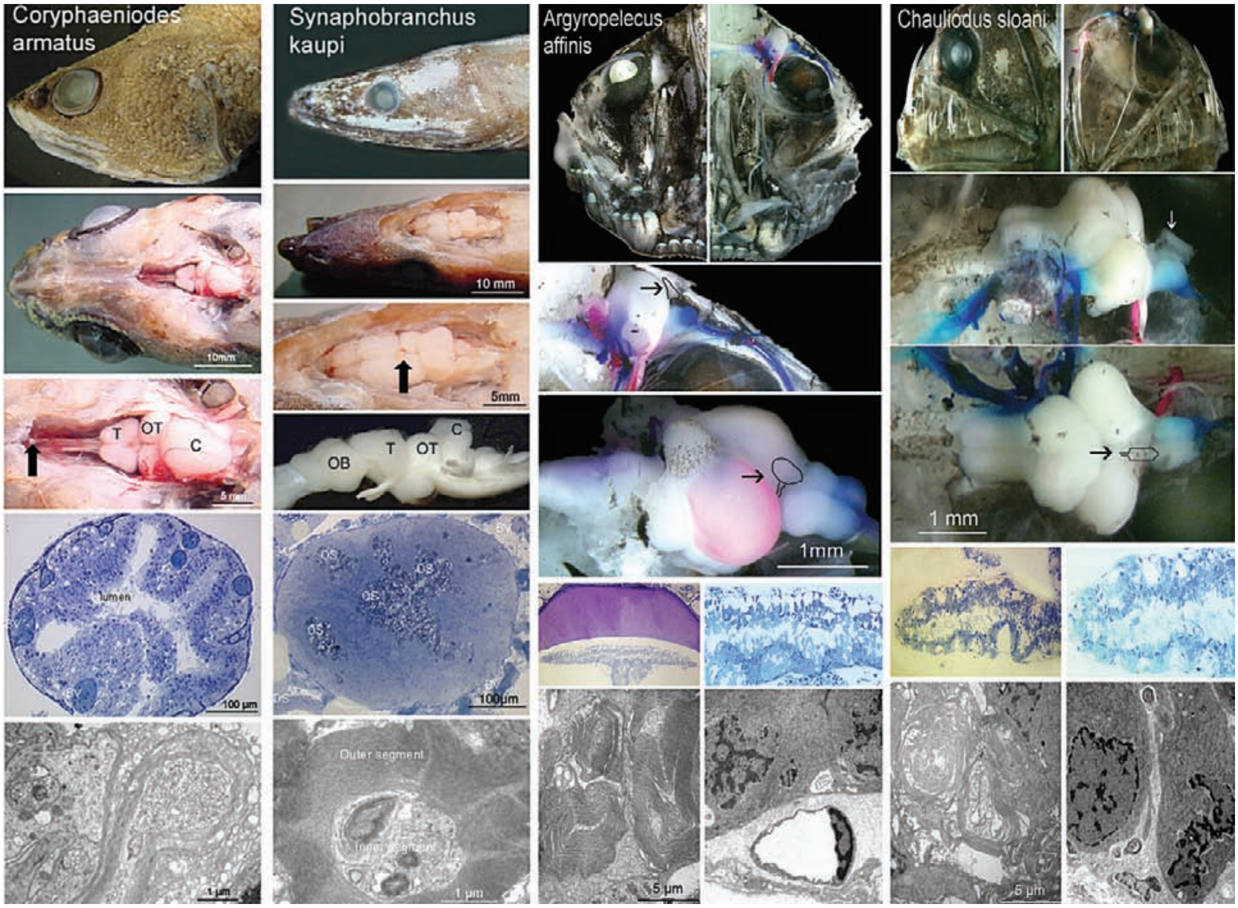

Figure 3 Morphology and fine structure of the pineal organs in four species of deep-sea fish. The columns show grenadier (*Coryphaenoides armatus*), deep-sea eel (*Synaphobranchus kaupii*), hatchetfish (*Argyropelecus affinis*), and viperfish (*Chauliodus sloani*). From top to bottom, each column shows the following panels: head, intact and with dissection of the brain to demonstrate the location of the pineal (arrows) in the cranial cavity. Some of the brains are labeled by carbocyanine dyes for unrelated experiments; light micrographs of cross sections of the pineal vesicles (methylene blue stain); electron micrographs of pineal photoreceptors and neurons. T, telencephalon; OT, optic tectum; C, cerebellum; OB, olfactory bulb.

λ_{max} of pinealocytes was shorter than in retinal rods, whereas in the orfe it was longer. This was mostly due to variations in the ratio of rhodopsin and porphyropsin. While the spectral composition of light reaching the pinealocytes in shallow-water habitats depends on the quality of the water body and the time of day (see above), and thus might account for this variability, photic conditions in the deep sea are much more constant, being centered around 480 nm below 200 m of depth. Surprisingly, however, a similar degree of variability and divergence was found in the errlo visual pigments in a comparative study of mesopelagic fish. While the rod visual pigments had λ_{max} peaks between 478 and 485 nm, the errlo λ_{max} was consistently displaced toward longer wavelengths between 485 and 505 nm, in one species (from below 2000 m) even as far as 515 nm. The great majority of the shallow- and deep-water species only had a single kind of visual pigment; however, the deep-sea hatchetfish had two populations of pinealocyte with visual pigment λ_{max} about 12 nm apart. Consequently, the variability of visual pigments in the pinealocytes of deep-sea fish was considerably greater than in the retinal rods. It is difficult to interpret this observation because there is general agreement that light intensities in the deep sea are not sufficient to penetrate the window in the skull and stimulate the pinealocytes in adult specimens. Possibly, pineal photoreceptivity had been functional during the larval stage, during which many deep-sea fish live at shallower depths. Alternatively, one may speculate that since light appears to be of no importance in deep-sea fish pineal organs, they are no longer subject to adaptational constraints to tune the sensitivity of their visual pigments to the wavelength of the downwelling light, a situation that would lead to the wide spread of λ_{max}. This is different from the situation in the highly specialized and functional eyes, whose rod rhodopsins cluster closely around the emission spectra of bioluminescence and the downwelling light of the sun.

The teleost pineal as a transducer of circadian rhythms

Vertebrate photoreceptor cells use two major neuroactive substances to transmit light-evoked changes of their membrane potential: in the retina, glutamate binds to receptor molecules on bipolar and horizontal cells, whereas melatonin acts as a neuromodulator and is involved in increasing sensitivity during dark adaptation. Although evidence for a role as neurotransmitter for glutamate in pinealocytes is available only in mammals, there is no reason to assume that the situation is different in fish. However, while the targets for melatonin in the retina are local, pineal melatonin takes on a systemic relevance. Through the blood stream, it reaches targets in the entire organism and is thus in a strategic position to synchronize or reset the multiple and individual endogenous oscillators (biological clocks) in the peripheral tissues and organs to the actual photoperiod perceived directly through the window in the skull and the photoreceptors.

Conclusion

Non-image-forming extraretinal photoreception via deep brain cells and/or the pineal organ is crucial for the control of rhythmic processes and behaviors in fish. They synchronize internal molecular clocks to the environment and are therefore involved in the organization of circadian, seasonal, and circannual rhythms. In this manner, they contribute fundamentally to daily feeding and seasonal reproductive behavior, and also to developmental processes associated with seasonal or circannual migration and/or smoltification. Results from this research are also of applied relevance and have contributed to the design of lighting system used for fish farming with the aim of influencing growth processes.

Glossary

Benthic On or near, the seafloor.

Bioluminescence Light produced by living organisms by physiological processes and without heat.

Diverticulum An out-pocketing, or blind-ending sac, branching out from a hollow anatomical structure, here used to refer to ventrolaterally facing 'accessory eyes' of some mesopelagic fish with dorsally directed tubular eyes.

Electroretinogram (ERG) A recording of the retina's electrical activity in response to light, usually recorded on either the cornea or retinal surface.

Endosymbiont An organism that lives symbiotically within the body of another.

G protein A large class of intracellular, membrane-associated, proteins that act as second messengers for a wide range of receptors (including visual pigments) and transduce receptor signals by activating a chain of cellular events resulting in amplification and cell signaling.

Hadal Biogeographic region of the ocean bottom below the abyssal zone; typically, ocean trenches deeper than *c.* 6500 m depth.

Hyposchromic Change in the wavelength of maximum absorption, transmission, reflection, etc. of a molecule toward higher frequencies or shorter wavelengths (sometimes called a 'blue shift').

Mesopelagic A biogeographic region of open oceans between 200- and 1000-m depth and not near the ocean floor.

Myctophid A family of teleosts, known as lantern fish, whose name originates from their conspicuous bioluminescent photophores. They account for up to 65% of the deep-sea fish biomass and are among the most widely distributed and populous of all vertebrates.

The deep sea encompasses those parts of the ocean below 200 m, where insufficient sunlight penetrates to allow photosynthesis. Due to its high pressure (0.1 MPa or *c.* 1 atm for every 10 m of depth), low temperature, and relative lack of light (**Figure 1**), it is often regarded as an unusual and extreme environment. However, this is true only when seen from the viewpoint of a terrestrial animal. The often higher temperatures and particularly the intense (and potentially damaging) sunlight to which land animals are exposed could be regarded as equally extreme. As the ocean covers over 70% of the Earth's surface with an average depth of around 4000 m, over 99% of habitable space on the planet is deep sea making it anything but unusual. Neither is the deep sea lifeless. Teleosts have recently been filmed in some of the deepest Hadal trenches at nearly 8000 m (although jawless and cartilaginous fish are absent below 4000 m). Not surprisingly, given its vast volume, the deep sea is the home of the world's most abundant vertebrate genus, *Cyclothone*, and many of the species that live there far outnumber human beings (**see also Deep-Sea Fishes**).

Despite its importance, the deep sea is the least understood environment on Earth. Although animals can be observed *in situ* by remotely operated vehicles, autonomous landers, and submersible, these generally utilize bright lights and generate significant physical disturbance. Also, laboratory observation of deep-sea fish is not feasible as it is impossible to ensure the long-term survival of captured animals. As a consequence, the behavior of deep-sea animals remains relatively unexplored. However, since most animal behaviors are at least influenced by, and often the direct result of, visual stimuli, much can be inferred indirectly about the life of deep-sea creatures by examining their eyes. Volumetric analysis of various sensory brain regions indicates that although chemical and mechanical sensory modalities are important to deep-sea fish, the most important sense for most demersal and mesopelagic species is vision.

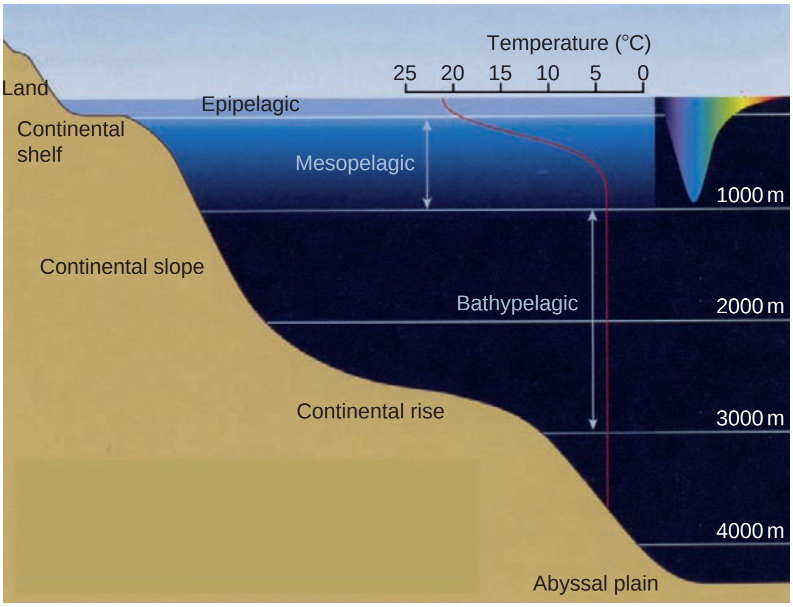

Figure 1 Diagram of the oceanic environment highlighting the amount of light (shades of blue/black), the temperature and the visible spectrum with increasing depth. From Douglas RH (2006) Visions of the deep. *Biological Sciences Review* 19(1): 36–41.

The Deep-Sea Light Environment

The presence of large eyes in the majority of fish inhabiting the deep sea is clear testament that their environment is not the realm of perpetual darkness often imagined. During the day, sunlight illuminates the upper reaches of the water column. However, its intensity rapidly decreases and its spectral composition becomes restricted with depth. By 600–700 m in depth, light levels are approaching those provided by starlight at the water surface and, in even the clearest water, at depths exceeding 1000 m, there is insufficient sunlight energy to stimulate photoreceptors and enable vision. As most waters have a degree of turbidity, vision using sunlight usually becomes impossible in waters shallower than this. Long and, to a lesser extent, short wavelengths are attenuated more by the sea than other wavelengths, so that at depth the predominant part of the light spectrum is narrowed to around 460–480 nm (**Figure 1**).

However, the light produced by most species in the deep sea is arguably a more important source of visual information than sunlight. Although during the day in shallower water the contrast of this bioluminescence is too low for it to be significant, it becomes more important with depth and at night as the veiling sunlight is removed.

In most fish bioluminescence is produced when an enzyme (luciferase) catalyzes the oxidation of a substrate (luciferin) within light organs (photophores) on the animal's body (**Figure 2(c)**), but in a few species it results from endosymbiotic bacteria (**Figure 2(d)**) (**see also The Skin**: Bioluminescence in Fishes). Bioluminescence has many potential functions including: the simple illumination of an otherwise dark world, attracting mates, avoiding predation, and aiding the capture of prey (**Figure 2**). The peak emissions of most bioluminescence, although in a similar part of the spectrum to the residual sunlight, cover a wider range (450–510 nm) and their bandwidth may be broader.

Thus, what animals view changes depending on their depth, the water clarity, and the time of day; from extended sunlit visual scenes near the water surface during the day to bioluminescent point sources in deeper water and at night.

Deep-Sea Eyes Are Adapted to a Photon-Limited Environment

There is not much light in the deep sea; not only does sunlight rapidly decrease in intensity with depth, but also bioluminescence is not as frequent as might be supposed when descending the water column in a submersible. Although one is surrounded by the 'fireworks' emitted by a plethora of animals, they are reacting to the presence of the submersible. When the submersible stops, darkness returns. Since bioluminescence is 'expensive' to produce it is usually only emitted sporadically. The relative paucity of light in the deep sea means that most visual adaptations of the fish living there serve to increase sensitivity.

Visual sensitivity to extended sources is maximized by a large aperture, each photoreceptor sampling a large volume of visual space and absorbing as much light incident on the photoreceptor as possible. The eyes of many mesopelagic deep-sea fish, therefore, have enlarged pupils, a short focal length lens, and long/wide photoreceptors with a high

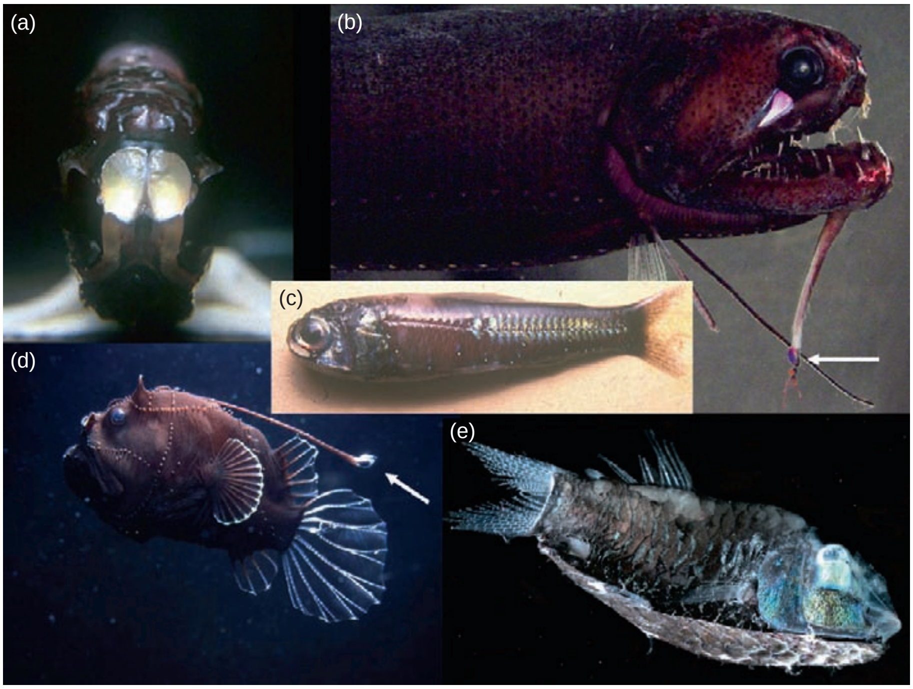

Figure 2 The functions of bioluminescence in deep-sea fish. (a) The 'headlamps' on this myctophid (*Diaphus* sp.) seen from head on, emit diffuse light illuminating the water ahead of the animal. (b) Photophores are often positioned below the eye, as in *Echiostoma barbatum*, so that the object being looked at is illuminated. Such photophores radiate over a wide angle and would be seen from many directions. *Echistoma* also has a bioluminescent barble hanging below its lower jaw (arrow) presumably to act as a lure to attract prey or mates as in the angler fish (see (d)). (c) Researchers often use the pattern of photophores on the body of a fish as a guide to identification. Perhaps fish, such as this myctophid (*Diaphus holti*), can also do this? The majority of the animal's lateral photophores are outside its own visual field and it is tempting to suggest that they are for communication. However, most of the emission is downward, suggesting that communication may be secondary to ventral camouflage (see **Figure 2(e)**). (d) Angler fish, such as this *Phrynichthys wedli*, hang a bioluminescent esca (arrow) in front of their mouth as a lure to attract prey. (e) Seen from below animals will cast a dark silhouette against the residual sunlight. *Opisthoproctus soleatus* obscures the silhouette of its very wide ventral 'sole' with bioluminescence produced by symbiotic bacteria within an anal pouch. Bioluminescence thus serves as a form of counterillumination camouflage. (a) Photo courtesy of S. Collin. (b) Photo courtesy of T. Frank. (c, d) Photo courtesy of J. Marshall. (e) Photo courtesy of E. Widder.

absorption coefficient coupled to a reflective tapetum. Sensitivity can be further enhanced by both temporal and spatial summation of photoreceptor outputs. Consequently, deep-sea fishes are approximately 120 times more sensitive to extended sources than man.

However, a point source will be focused to a similar point on the retina (assuming little scatter and few aberrations). Thus, although wide pupils and large, highly absorbent, photoreceptors will enhance sensitivity whatever the light source, increasing the volume of visual space sampled by each photoreceptor through a short focal length lens and spatial summation of photoreceptor output will not increase sensitivity to bioluminescent point sources.

Unfortunately, adaptations that enhance sensitivity are often detrimental for spatial resolution. However, most deep-sea fish must also be able to resolve some degree of spatial information to, for example, locate bioluminescent point sources in deeper water and at night, or resolve spatial detail within the extended visual scenes produced by sunlight. Thus, while most of the retina in deep-sea fish is indeed adapted to optimize sensitivity, some species also possess regions of increased spatial acuity.

Ocular Anatomy of Deep-Sea Fish

Outline of the Teleost Eye

The eyes of the vast majority of vertebrates have a similar construction with a single cornea and lens forming an image on a light-sensitive retina (**see also Vision**: Physiological Optics in Fishes). While the eyes of a few deep-sea fish are reduced or degenerate, most are broadly similar to those of more familiar fish (**Figure 3**). Such eyes generally have a tough outer sclera composed mainly of cartilage and collagen, which anteriorally, along with a layer derived from the skin, forms a transparent cornea. Throughout much of the eye a reflective argentea lies internal to the sclera, separating it from the vascular uveal tract. This uveal layer is composed posteriorally of the choroid, which

anteriorally is continuous with a small ciliary region and an inward projecting iris forming the pupil, which in most teleosts is immobile. The internal surface of the posterior globe is covered by the light-sensitive retina which receives a focused image formed by a large spherical lens, whose plane of focus can be adjusted (accommodation) by altering its distance from the retina with one or two retractor muscles. However, within this basic framework, the eyes of deep-sea fish show specific adaptations in comparison to their shallower dwelling relatives.

Eye Shape

The eyes of most shallow water fish, with some exceptions such as flatfish, roughly approximate a laterally flattened sphere and are usually situated laterally on the head (**Figure 4**(**a**)). The same is true for most deep-sea fish, although some mesopelagic species have very differently shaped, dorsally positioned eyes (**Figure 4**(**b**)).

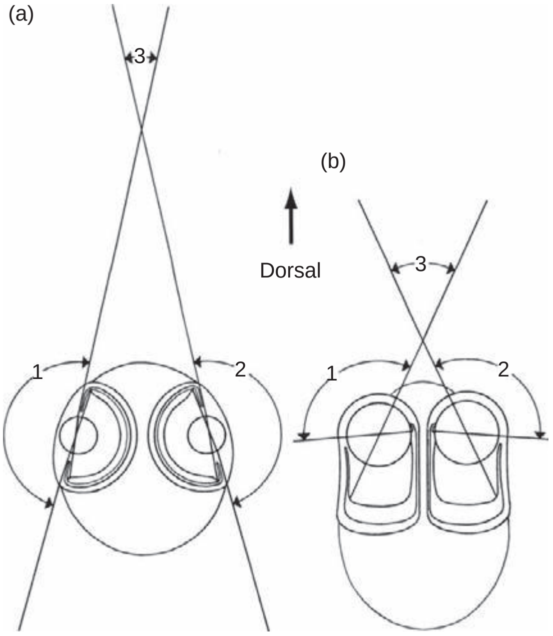

Figure 4 The two major eye ‘designs’ of mesopelagic fish. (a) ‘Typical’ laterally placed eyes with large lateral monocular fields of view (1 and 2) and a small frontal binocular field (3). (b) Dorsally directed ‘tubular eyes’ with restricted lateral monocular field (1 and 2) but a larger dorsally situated area of binocular vision (3). From Warrant EJ, Collin SP, and Locket NA (2003) Eye design and vision in deep-sea fish. In: Collin SP and Marshall NB (eds.) *Sensory Processing in Aquatic Environments*, pp. 303–322. New York, NY: Springer.

Tubular eyes

Sunlight in the open ocean is several hundred times more intense from above than below. In order to maximize sensitivity to the relatively brighter downwelling sunlight, to see in silhouette animals above them, and to increase the binocular overlap of their eyes thus aiding both sensitivity and range finding, some mesopelagic fish have upwardly directed tubular eyes (**Figures 4**(**b**), **5**, and **6**).

Although in most cases such eyes are directed toward the water surface (**Figures 2**(**e**) and **5**(**a**)–**5**(**d**)), their orientation is not always fixed. The barreleye, *Macropinna microstoma*, for instance, is able to rotate its normally dorsally directed tubular eyes rostrally, directing its eyes toward its horizontally orientated mouth. It is possible that other fish with tubular eyes are also able to move their eyes in a similar manner.

The base of a tubular eye is covered by a well-developed ‘main’ retina, which terminates abruptly at the medial wall of the cylinder that is mostly covered by a thinner ‘accessory’ retina (**Figures 6**(**b**), **7**, **8**, and **10**(**b**)).

A conventional eye with a comparable f-number would require a much larger head. (b) Outline of a tubular eye (1) superimposed on that of a normal fish eye (2) with the same size of lens (3). The main retina of the tubular eye (4) corresponds to the central part of the normal eye. 5, Accessory retina of the tubular eye. (a) Photo courtesy of J. Marshall. (b) From Locket NA (1977) Adaptations to the deep-sea environment. In: Crescitelli F (ed.) *Handbook of Sensory Physiology*, *Vol. VII/5. The Visual System in Vertebrates*, pp. 67–192. Berlin: Springer.

The other walls of the cylinder are mainly covered by a thin layer of epithelial, uveal, and argenteal layers that line the sclera.

In fish, a well-focused image is produced when the retina is approximately 2.55 lens radii from the center of the lens (Matthiessen's ratio). In tubular eyes, this is the case only for the main retina. The accessory retina covering the medial wall is too close to the lens to receive a focused image and thus serves simple light detection.

A tubular eye with a given pupil size will take up far less space than a conventional eye with the

similarly sized aperture (**Figure 6**), thus avoiding the need for a disproportionately large head when optimizing sensitivity. The penalty, however, is a reduced field of view.

Methods of enlarging the visual field

If the sun was the only light in the deep sea, tubular eyes, with their restricted dorsally facing visual field, would be optimal (**Figure 4(b)**). However, bioluminescence, arguably the most important source of illumination in the deep sea, occurs with equal frequency and intensity all around an animal and, consequently, much of it would remain undetected by fish with upward pointing tubular eyes. Some mesopelagic fish with tubular eyes, therefore, have various devices for extending their visual fields laterally and ventrally.

Members of the Scopelarchidae (**Figure 5(a)**), for example, have a 'lens pad' in the lateral wall of their tubular eye that directs ventro-lateral illumination onto the accessory retina (**Figure 7**). A similar function is achieved by the epidermally derived optical fold in Evermannellids. Alternatively, seven genera have extended their visual fields by diverticula on the eyes' lateral walls, where light enters through an unpigmented outward-facing wall reflecting onto a laterally facing area of retina (**Figure 8**). *Bathylychnops exilis*, although it does not have tubular eyes, also has an extensive diverticulum into which light enters through a scleral lens (**Figure 9**). However, in all these species (except perhaps *Bathylychnops*), these devices only provide unfocused images with little spatial resolution.

Uniquely, *Dolichopteryx longipes* has a bipartite eye composed of a conventional tubular eye and a lateral diverticulum that light enters through a ventro-laterally facing cornea (**Figure 10**). The retina of the diverticulum is positioned laterally and light is reflected onto it by a mirror, derived from the retinal tapetum that separates the diverticulum and the tubular portion of the eye (**Figure 10**). A focused image is generated by thousands of reflective plates whose orientation varies depending on their location within the mirror. This is the only

known instance of image formation by a mirror in a vertebrate and allows the spookfish to see focused images both dorsally, with the refractive tubular eye, and ventro-laterally, with the reflective diverticulum.

Lenses

In terrestrial animals the major refractive component is the cornea. Underwater, however, as the cornea has a similar refractive index to water, it is optically ineffective and most refraction in fish is performed by an optically powerful, spherical, lens.

Counterintuitively, the lenses of some mesopelagic fish absorb short wavelengths (**Figure 11**) and thus appear bright yellow (**Figures 5(a)**, **5(b)**, **5(d)**, and **6(a)**). Intraocular short-wave-absorbing filters are common in shallow water and terrestrial animals, where light levels are high and they serve to protect the retina from damaging short wavelengths and improve image quality by decreasing the amount of Rayleigh scatter and chromatic aberration. Deep-sea fish, in their light-limited environment, are unlikely to benefit from these functions. In fact, such lenses potentially decrease sensitivity in an already photon-limited environment. The chemical diversity of the pigmentation in yellow lenses, however, suggests that they have evolved on a number of occasions in mesopelagic species and implies that they are important. Perhaps they increase the contrast, and hence visibility, of relatively long-wave-rich bioluminescent signals seen against the short-wave-dominated background radiation.

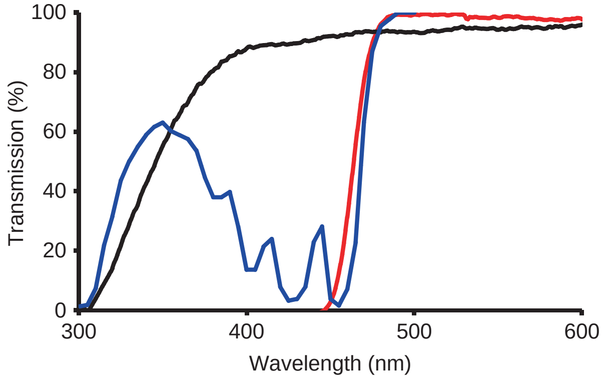

Figure 11 Spectral transmission of the lenses of three mesopelagic teleosts. The unpigmented lenses of *Protomyctophum germanium* (black) are as transparent as a vertebrate lens can be, transmitting all radiation down to around 300 nm, below which the structural proteins and nucleic acids absorb the radiation. The lenses of *Argyropelecus sladeni* (blue) appear yellow to the human eye and contain carotenoids that remove most light between 400 and 460 nm. *Benthalbella macropinna* lenses (red) also appear yellow and absorb most light below 450 nm.

Retinal Structure

The retina of deep-sea fish is similar to that of other vertebrates, consisting of six neural cell types and neuroglia arranged in 10 more or less well-defined layers (**Figure 12**) (**see also Vision**: Inner Retina and Ganglion Cells). Light traverses the retina and is absorbed by visual pigments housed within the membranes of disks located in the outer segments of photoreceptors, which lie adjacent to a simple epithelial layer, the retinal pigment epithelium (RPE). The resulting electrophysiological signal is transmitted vitreally through the remainder of the photoreceptor, whose output is processed by the other cells of the retina before being transferred to the brain by ganglion cells whose axons form the bulk of the optic nerve.

Most vertebrates, including surface dwelling fish, have two types of image-forming photoreceptors: rods and cones (**see also Vision**: Photoreceptors and Visual Pigments and Adaptations of Photoreceptors and Visual Pigments). The high packing density of cones, their relatively low degree of postreceptor convergence, and the inhibitory interactions between different spectral cone types provide color perception with high spatial and temporal resolution. However, detailed color vision is a luxury only afforded by high (photopic) light levels. In photon-limited (scotopic) environments a more fundamental requirement is to capture enough light to enable any vision at all. This is provided by the rods, whose extensive temporal and spatial summation provide vision with high sensitivity.

Fish living near the water surface have both rods and cones and switch from one to the other using a variety of physiological, biochemical, and morphological processes at twilight. Although rods far outnumber cones in most species, nocturnal animals have relatively more rods but as they are still occasionally exposed to higher light levels, they retain a significant number of cones. Although a few species of deep-sea fish possess a small population of cones, especially as larvae when they may live in shallower water, and a few species even have a cone-dominated retinae, the majority of deep-sea fishes never experience photopic illumination and thus have pure-rod retinae.

Retinal modifications to increase sensitivity

Photon capture in many deep-sea fish is increased in comparison with other vertebrates by either an increase in length and/or width of the rod outer segments (**Figure 13(C)**) or the possession of several layers of rod outer segments which are of similar size to those of other animals (**Figures 13(B)** and **14**). Thus, their photoreceptor layer is considerably thicker (*c.* 120–180 μm) than that of other vertebrates. The relatively lower density of ganglion cells in deep-sea species, as evidenced by the relatively thinner inner retinal layers, results in the output of many photoreceptors converging onto relatively

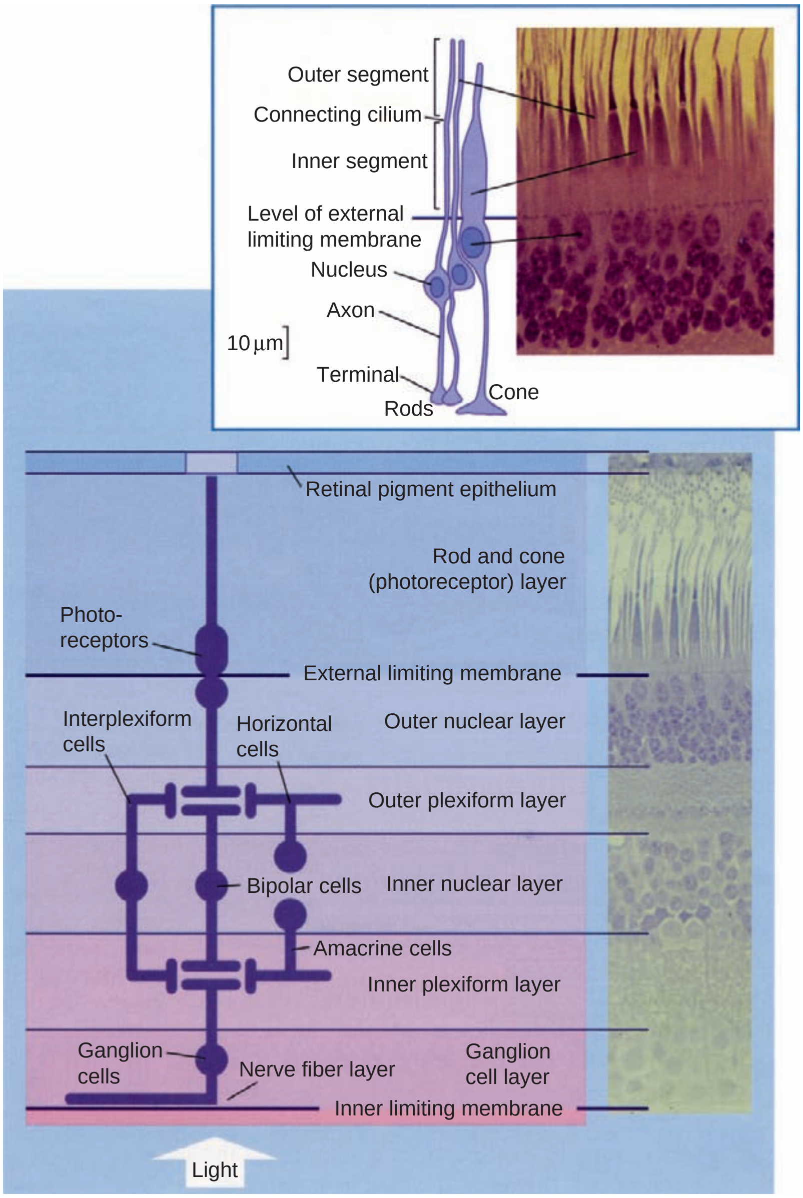

Figure 12 Section of a human retina with a diagram of the six neural cell types within it. Details of rods and cones are shown in the inset. From Douglas RH (2006) Visions of the deep. *Biological Sciences Review* 19(1): 36–41.

few ganglion cells – a further adaptation to enhance sensitivity. The density of visual pigment in deep-sea rods is also higher than in shallower water species, further increasing their sensitivity.

Photoreceptor renewal

In vertebrates, new photoreceptor disks are continually being formed at the base of the outer segment and older ones are pushed toward the RPE eventually to be phagocytosed by it. Furthermore, following its isomerization by light, the rod visual pigment chromophore travels to the RPE to be reisomerized.

However, in comparison to their shallow water relatives, the RPE of deep-sea fish is much reduced (**Figure 13**). This, and the possession in some species of a multibanked retina whose vitreal rods are not in contact with the RPE (**Figures 13**(**B**) and **14**), leads to the question of how, or if, the visual pigments of deep-sea fish regenerate and older outer segment disks are phagocytosed. Perhaps as the number of rod layers in multibanked retinae increases with age, the rods do not undergo renewal and a new layer is simply added once the current one has been exhausted. This idea receives some support because ERG recordings from the multibanked retina of conger eels indicate that only the most vitread layer of

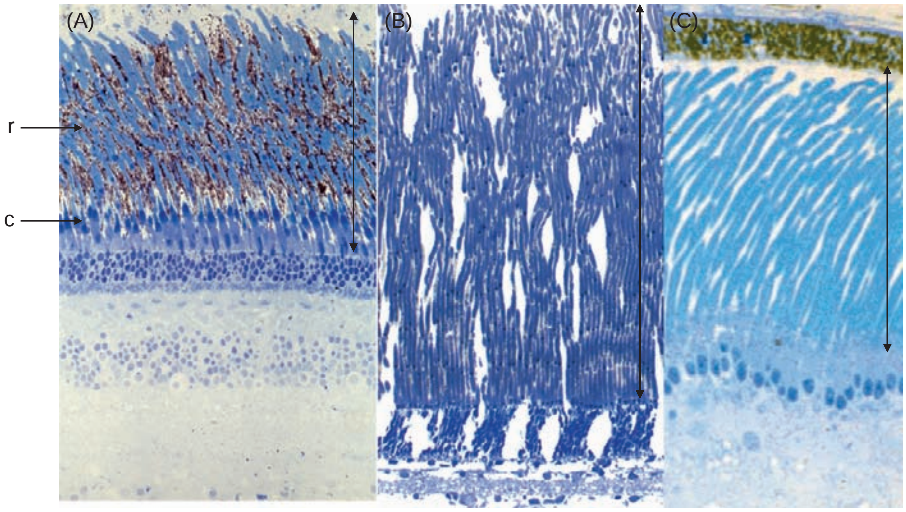

Figure 13 The retinal structure of various teleosts to show how deep-sea fish optimize sensitivity. (A) A shallower water fish, the tench (*Tinca tinca*), has both cones (c) and relatively smaller rods (r). (B) The deep-sea dragonfish (*Aristostomias grimaldi*) increases light capture with rods arranged in several banks. (C) The deep-sea bluntsnout smooth-head (*Xenodermichthys copei*), on the other hand, increases photon capture with very long rod outer segments. The two deep-sea species have a much wider region of rod outer segments (double headed arrow) relative to the rest of the retina. Their retinal pigment epithelium (brown pigmented area) is also much reduced in comparison with the shallow water tench and, unlike the tench, they have no cones. (B, C) Photo courtesy of H.-J. Wagner.

rods is active. Anatomical studies also suggest that, although all outer segment tiers in a multibanked retina show some signs of membrane synthesis, this is greatest in the most vitreal rods, and markers for rod proliferation indicate greater activity in the rods immediately adjacent to the external limiting membrane. However, all deep-sea species studied showed some phagosomes within the RPE, indicating a degree of photoreceptor disk-shedding even in deep-sea fish.

Regional retinal specializations

The distribution of vertebrate photoreceptors is not uniform and most terrestrial animals and shallower water species, for example, have areas of higher cone density providing increased spatial resolving power. Such high acuity areas are associated with high ganglion cell densities, while high-sensitivity regions have relatively fewer ganglion cells due to increased convergence of photoreceptor output.

Superficially, deep-sea fish, with their pure rod retinae, would seem to have no need for high spatial resolution. However, without an ability to appreciate spatial detail they would not be able to estimate the location of point source bioluminescence or image the more extended visual scenes of shallower water. Clearly, deep-sea fish would benefit from retinal regions for maximizing acuity. The retinal location of any such regions indicates the area of visual space of significance to an animal, revealing clues about the behavior of species whose observation *in situ* is very difficult. Furthermore, the spatial separation of photoreceptors and/or ganglion cells in terrestrial and shallow water animals are good predictors of behaviorally determined acuities. Similar measures in deep-sea fish, therefore, provide a reliable indication of spatial acuity in animals not accessible to psychophysical measurements.

Although some deep-sea fish have a uniform mosaic of ganglion cells throughout the retina, many possess one or more regions of increased ganglion cell density specialized for increased resolving power. The benthic tripod fish, *Bathypterois dubius*, for example, has a small centripetal gradient of ganglion cell density and two areae retinae characterized by a higher density of ganglion cells (**Figure 15(a)**). Thus, it views prey both behind and in front with increased precision as it perches above the sea floor on its elongated pelvic fins awaiting passing crustaceans. In some species, the inner retinal layers are pushed aside to minimize light scatter, forming either shallow (concaviclivate) or deeper (convexiclivate) (**Figure 16**) depressions. The fovea in the temporal retina of *Rouleina attrita*, for example (**Figure 15(b)**), gives it a binocular area of high spatial resolution in front of the mouth. Such deep fovea might, as in some birds and reptiles, also function to magnify the image, further increasing resolution.

Some of the most complex mesopelagic eyes are the dorsally directed eyes of the Scopelarchidae (**Figures 5(a)**, **5(b)**, **6(a)**, and **7**). Seven distinct retinal specializations are apparent in *Scopelarchus michaelsarsi* (**Figure 17**), including an area centralis whose ganglion cell density could yield a resolving power of 7.4 cycles per degree, which is surprisingly better than the spatial acuity

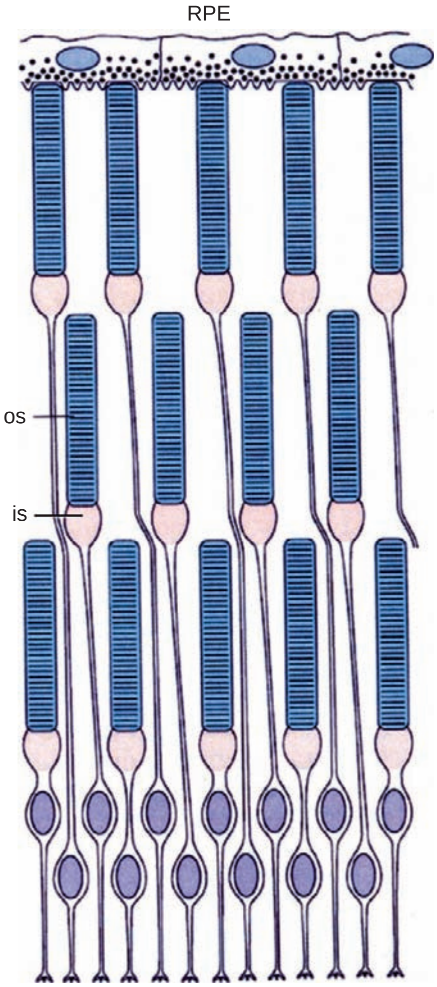

Figure 14 Schematic diagram of the outer part of a retina with three banks of rod outer segments (os) showing the thin retinal pigment epithelium (RPE). is, photoreceptor inner segment. From Warrant E (2004) Vision in the dimmest habitats on Earth. *Journal of Comparative Physiology A* 19: 765–789.

of many shallow-water fish and comparable to that of some predatory reef species. Scopelarchid retinae also contain areas in which *c.* 35 rods are grouped into bundles isolated by reflective tapetal cups within the RPE. Light entering such cups will be trapped and undergo multiple reflections ensuring maximal stimulation of all rods within a bundle, so that each group of rods functions as a highly sensitive, albeit coarse grain, macro-receptor. Similarly grouped receptors are found in other deep-sea species as well as a few shallow-water animals living in turbid environments.

In some deep-sea species, a local increase in thickness of the photoreceptor layer, caused either by an increase in outer segment length or by the formation of multiple banks of rods, causes a bulge in the sclera. In *Bajacalifornia drakei* this fovea externa is composed of 21–28 rows of rods, while the rest of the retina is made up of only two such banks. However, these structures are not associated with an increased ganglion cell density and the resulting high convergence of photoreceptor outputs indicates that they subserve enhanced sensitivity rather than acuity.

The deeper a species lives, the more important bioluminescence is as a source of visual information. Because sensitivity to such point sources is not increased by spatial summation, deeper-dwelling species generally have higher ganglion cell densities than shallower-dwelling mesopelagic fish. The increased acuity afforded by a lack of such convergence will allow accurate localization of bioluminescent signals.

Tapeta

Sensitivity in many deep-sea fish is enhanced by a reflective layer in either the RPE or choroid. Such tapeta, which are responsible for the 'eye shine' seen in many nocturnal animals (**Figures 10**(**a**) and **18**), give photons not absorbed by the visual pigments when first incident on the retina, a second chance of activating the rods. Reflection can be either broadband, resulting in silver/white tapeta, or more spectrally selective, producing eyeshine whose color is related to the animal's photic environment (**Figure 19**).

Visual Pigments

Light incident on the photoreceptors is absorbed by visual pigments which in darkness are composed of a protein, opsin, bound to a light-absorbing vitamin A-derived chromophore, in a 'bent' 11-*cis* configuration (**see also Vision**: Photoreceptors and Visual Pigments and Adaptations of Photoreceptors and Visual Pigments). On absorption of a photon the chromophore 'straightens' into an *all-trans* isoform and separates from the opsin which itself changes shape, setting in motion a G-protein-coupled enzyme cascade that ultimately results in the hyperpolarization of the photoreceptor, which is the primary event of vertebrate vision.

In most species, the chromophore is the vitamin A_1-derived retinal, forming a class of pigments known as rhodopsins. In some animals the chromophore is the longer wavelength absorbing vitamin A_2-derived 3,4-di-dehydroretinal, forming porphyropsin visual pigments. If an animal possesses two different visual pigments based on a single opsin combined with either retinal or 3,4-di-dehydroretinal, these form a so-called rhodopsin/porphyropsin pigment pair.

Vertebrate visual pigments have a smooth, bell-shaped absorption spectrum that peaks at a wavelength of maximum absorption ($\lambda_{\max}$) (**Figure 20**).

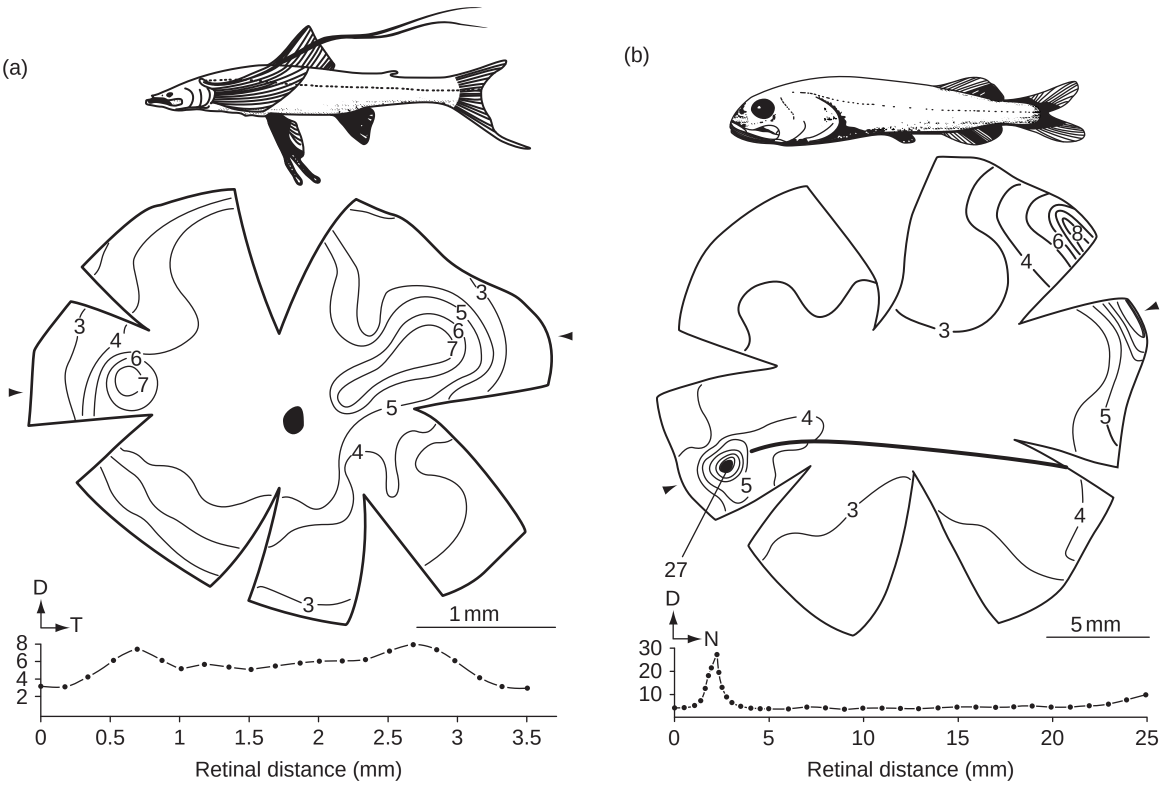

Figure 15 Ganglion cell density in the eyes of (a) *Bathypterois dubius* and (b) *Rouleina attrita*. The isodensity contour maps show the density of neurons in the ganglion cell layer in retinal whole mounts. All densities are $\times 10^3$ cells mm^{-3}. The spectral properties of a visual pigment are determined both by the nature of its chromophore and the structure of its opsin, which, in vertebrates, is composed of a single chain of around 350 amino acids that forms seven transmembrane α-helical loops within the outer segment disk membrane. These loops form a bundle surrounding a hollow cavity, the chromophore-binding pocket. On their own the chromophores retinal and 3,4-di-dehydroretinal absorb maximally at 380 and 400 nm, respectively. Interactions between these

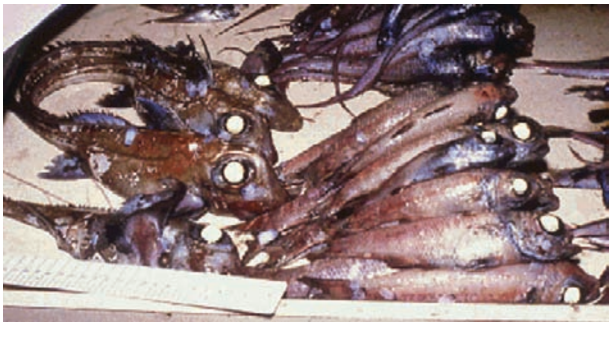

Figure 18 'Eyeshine' caused by a reflective tapetum in freshly caught deep-sea chimaerids (left) and teleosts (right).

chromophores and the opsin amino acid residues in the vicinity of the binding pocket generally results in wavelengths of maximum absorption being displaced to longer wavelengths. As few as nine opsin amino acid sites are responsible for the hypsochromatic shift of most deep-sea fish visual pigments.

Species with a Single Visual Pigment

In 1936, Clarke and Bayliss independently suggested that in order to maximize their sensitivity, deep-sea fish may have their maximum sensitivity shifted toward shorter wavelengths by comparison with shallow-water species, that is, matching the shorter wavelength spectral distribution of the residual sunlight. The available data seem to confirm a hypsochromic shift in deep-sea fish visual pigment λ_{max}. Among 248 species of deep-sea fish examined to date, 219 contain a single visual pigment whose absorption maximum falls, as predicted, between 470 and 495 nm (**Figure 21**). This superficial matching of deep-sea visual pigments to the residual sunlight is often cited as a classic adaptation of a sensory system to a specific environment. However, recent modeling suggests that, in the majority of the World's oceans, maximum sensitivity to residual sunlight requires visual pigments absorbing at even shorter wavelengths and that the observed visual pigments are better suited for the visualization of bioluminescence, that could be visible at distances of up to 30 m.

Multipigment Species

Only 12% of deep-sea species examined have two and rarely three visual pigments whose λ_{max} values are often at longer or, rarely, shorter wavelengths than those of single-pigment species (**Figure 21**). Seven of these multi-pigment species are stomiid dragonfish that are discussed below. Of the remaining 22 species, only *Scopelarchus analis* has three visual pigments (λ_{max} 444, 479, and 505 nm), which is in line with its complex ocular morphology (see above); the rest have two with an average difference in λ_{max} of 26 nm (**Figure 22**).

The possession of more than one spectral type of visual pigment will extend the spectral range of an animal and, if the outputs of the photoreceptors are summed, will improve its overall sensitivity if the spectral environment is sufficiently broad. Color vision is possible following opponent interactions between two photoreceptors with different spectral sensitivities. As some nocturnal terrestrial species have color vision at low light levels, it is conceivable multiple pigments in deep-sea fish could form the basis of a rod-based color vision system. However, such opponency would inevitably decrease absolute sensitivity, which is at a premium in the deep sea. Significantly, the arrangement and complexity of horizontal cells in the retinae of deep-sea fish is very different to that in shallow-water species where antagonistic interaction between chromatic channels is normally associated with color vision. Thus, deep-sea fish lack the traditional neural circuitry associated with

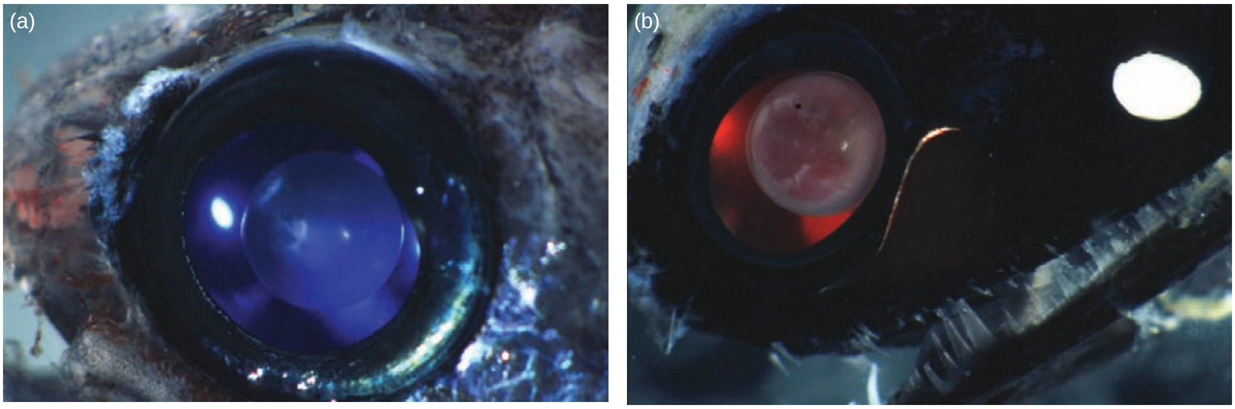

Figure 19 Tapetal reflection in (a) a myctophid and (b) the stomiid *Malacosteus niger*. The coloration is the 'eye shine' produced by reflected light from the tapetum. The short wavelengths reflected by the myctophid match those predominant in both residual sunlight and bioluminescence and are coincident with the maximum sensitivity of most deep-sea fish. The red tapetum of *Malacosteus niger* is one of several adaptations that enable this species to see its own far-red bioluminescence. Photos courtesy of J. Marshall.

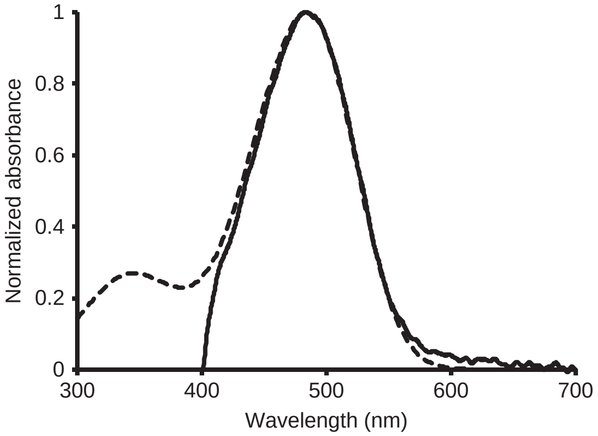

Figure 20 The single rhodopsin visual pigment of the longjaw bigscale (*Scopeloberyx robusts*). This fish can live at depths in excess of 4000 m and has a visual pigment typical of a deep-sea fish. The solid curve is the difference spectrum obtained by subtracting the absorption of a fully bleached detergent retinal extract from a dark adapted spectrum of the same extract before the bleach. The dotted curve represents the best fitting visual pigment template ($\lambda_{\max}$ 484.3 nm). In subsequent figures only the visual pigment templates are shown.

color vision. Unfortunately, the behavioral experiments necessary to show color vision are impossible in captured deep-sea fish.

Long-Wave Sensitivity

Stomiid dragonfish of the genera *Aristostomias*, *Pachystomias*, and *Malacosteus* not only produce blue/green bioluminescence similar to that emitted by other deep-sea species from postorbital photophores, but uniquely also emit long-wave light from photophores located below their eyes (**Figure 23**). Deep-sea species with conventional visual pigments with $\lambda_{\max}$ values around 480 nm (**Figure 20**) will be insensitive to this far-red bioluminescence whose emission spectrum peaks sharply beyond 700 nm (**Figures 24** and **25**). The dragonfish, however, are sensitive in this part of the spectrum and, thus, have what can be regarded as a private waveband they can use for intraspecific signaling or the illumination of prey, immune from detection by other animals.

Retinal extracts show all three genera of dragonfish possess a minimum of two visual pigments, forming a rhodopsin/porphyropsin pigment pair, with absorption maxima shifted toward longer wavelengths in comparison with other deep-sea fish (**Figures 24** and **25**). However, retinal whole mounts and microspectrophotometry of *Aristostomias* reveal an additional third visual pigment maximally sensitive around 581 nm (**Figure 24**), further enhancing photosensitivity to long wavelengths.

Dragonfish of the genus *Malacosteus*, although they posses two of the long-wave shifted visual pigments found in *Aristostomias* lack the third, most long-wave-shifted pigment (**Figure 25**). Uniquely, however, their photoreceptors contain bacteriochlorophyll-derivatives that absorb strongly around 670 nm and act as a photosensitizer that bleaches the visual pigment following the absorption of far-red illumination. Perhaps surprisingly, chlorophyll derivatives, when added to salamander rods and bovine rhodopsin *in vitro,* can enhance long-wave sensitivity considerably despite the fact that such species do not normally contain chlorophylls. This suggests all

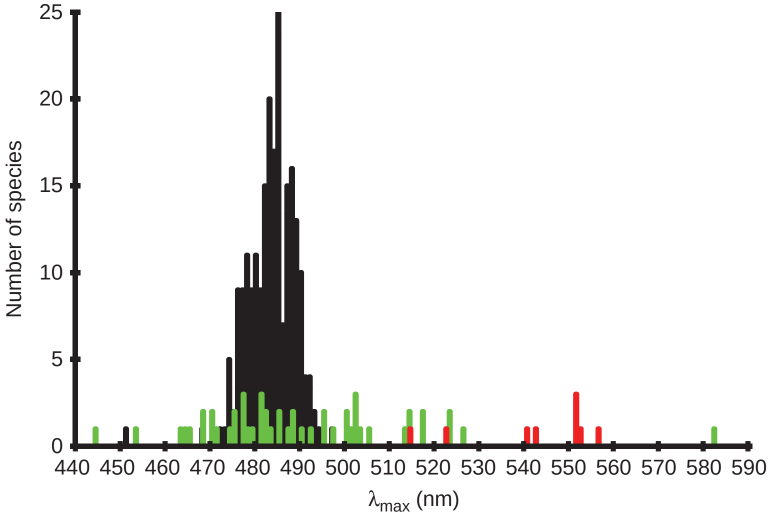

Figure 21 Wavelength of maximum absorption ($\lambda_{\max}$) of 279 visual pigments isolated from the eyes of 248 species of deep-sea fish by either extraction or microspectrophotometry. Where possible we have used data obtained in our laboratory (173 species published and 39 species unpublished). The data for the remaining 36 species come from the literature. Black bars are the rhodopsins from 219 single pigment species, green bars the rhodopsins from species with more than one visual pigment, and red bars the porphyropsins in these species.

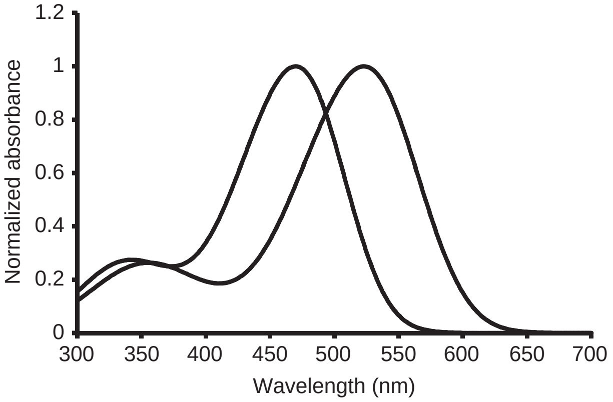

Figure 22 Two rhodopsin visual pigments isolated by partial bleaching of *Benthalbella elongata* retinal extracts ($\lambda_{\max}$ 470 and 523 nm). The retina of the closely related *B. macropinna* also contains two rhodopsins ($\lambda_{\max}$ 453 and 482 nm).

vertebrate photoreceptors might have the potential for such photosensitization.

Given the huge selective advantage such a 'private wavelength' would give stomiids, it is perhaps not surprising that myctophids, which form a significant part of the diet of most dragonfish, may also be more long-wave sensitive than other deep-sea fish, despite not producing long-wave bioluminescence. *Myctophum nitidulum*, for example, posses two visual pigments, the most long-wave sensitive of which ($\lambda_{\max}$ 522 nm) makes these animals significantly more red sensitive than other, non-stomiid deep-sea fish (**Figure 21**) and modeling suggests that *Myctophum nitidulum* could detect stomiid bioluminescence up to a distance of 1 m. Preliminary data suggest a second myctophid, *Bolinichthys longipes*, like *Malacosteus*, posses a bacteriochlorophyll-like substance in its retina (**Figure 26**), which might theoretically allow the detection of stomiid bioluminescence up to a distance of 7 m. It appears as if the dragonfish and myctophids may be involved in a sensory arms race within the deep sea involving sensitivity to far-red light.

Effect of Ambient Pressure on Visual Pigments

The literature relating the absorption spectra of deep-sea visual pigments to their environment is potentially subject to a serious artifact: all visual pigment analyses have been done at atmospheric pressure (0.1 MPa). However, at the average depth of the ocean (4000 m)

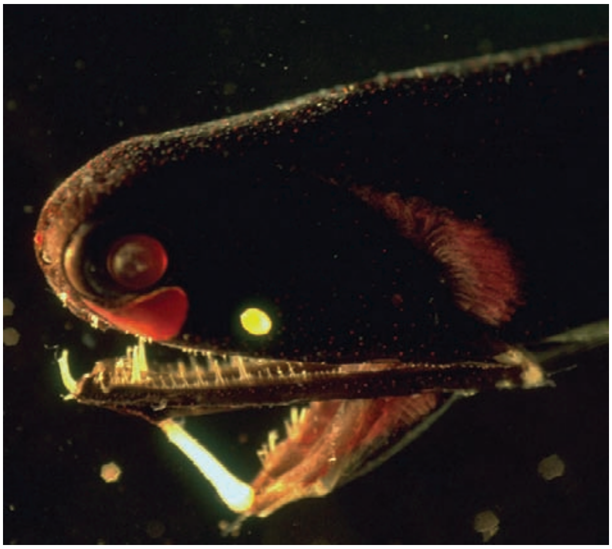

Figure 23 Stomiid losejaw dragonfish *Malacosteus niger* showing the teardrop-shaped suborbital photophore that produces long-wave bioluminescence and the postorbital photophore that emits conventional short-wave bioluminescence. Photo courtesy of T. Frank.

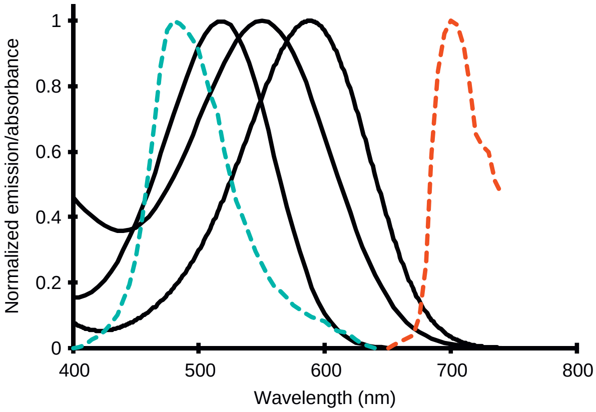

Figure 24 Three visual pigments isolated from the retina of *Aristostomias tittmanni* by both whole-mount spectroscopy of fresh retinae and microspectrophotometry (black lines). The two short-wave-sensitive pigments (λ_{max} 520 and 551 nm) form a rhodopsin/porphyropsin pair. The most long-wave-sensitive pigment is best described by the template for a rhodopsin pigment with λ_{max} 588 m. The dotted lines represent the emission spectra of the postorbital (blue) and suborbital (red) photophores, respectively.

animals will be subjected to 400 times the pressure experienced at the water surface. Because the absorption characteristics of a visual pigment are partially determined by the complex tertiary structure of its opsin protein, it is possible that the absorption characteristics of the visual pigments at depth may be different to those measured at atmospheric pressure. Luckily, however, when visual pigment solutions are subjected to such

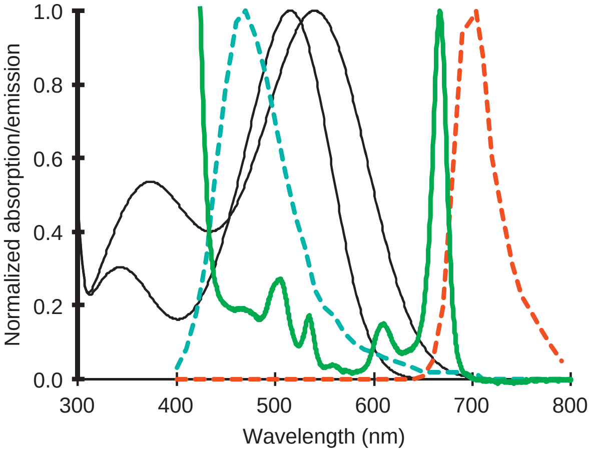

Figure 25 Two visual pigments isolated from the retina of *Malacosteus niger* by detergent extract, microspectrophotometry, and spectroscopy of outer segment suspensions (black lines). These represent a rhodopsin/porphyropsin pigment pair (λ_{max} 515 and 540 nm). The photoreceptor outer segments of this species also contain a form of bacteriochlorophyll (green curve) which acts as a 'photosensitizer', absorbing the red bioluminescence (red dotted curve) emitted by its suborbital photophore and activating the visual pigments. The bioluminescence emitted by the postorbital photophore is shown in blue. Modified from Douglas RH, Partridge JC, Dulai KS, *et al*. (1999) Enhanced retinal longwave sensitivity using a chlorophyll-derived photosensitiser in *Malacosteus niger*, a deep-sea dragon fish with far red bioluminescence. *Vision Research* 39: 2817–2832.

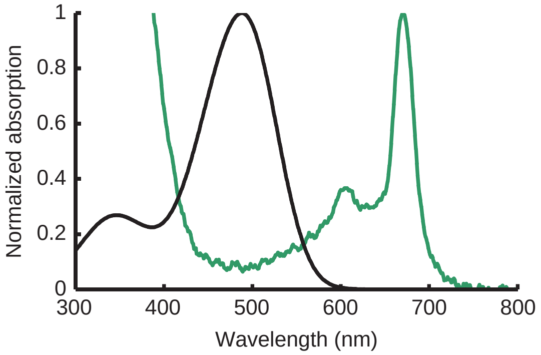

Figure 26 Partial bleaching of retinal extracts reveals only a single visual pigment in *Bollinichthys longipes* (black line). However, these extracts also contain a photostable substance (shown in green and represented by the absorption spectrum of a bleached extract) whose spectrum is very similar to the bacteriochlorophyll-derived photosensitizer of *Malacosteus niger*.

pressures in the laboratory their absorption spectra are little changed. It would be interesting to see if visual pigments in cell membranes, or their rates of regeneration, as well as bioluminescence emission spectra, are similarly unaffected by pressure.

Olfaction and olfactory Refers to the sense of smell.

Pheromones Odorants that are secreted by animals that have a specific function to influence the development or behavior of conspecifics.

Receptor A signal transduction molecule that is activated by a hormone.

Tastants Chemicals in the water that stimulate the gustatory receptors.

The last decade saw important advances in our understanding of the functions of the chemosensory systems. The function of chemical senses, or chemoreception, is the most ancient of sensory systems, having evolved 500 million years ago. They mediate the animals' functions most basic to the survival of the individuals and species: feeding and reproduction. Fish live in the aquatic environment, and their sensory systems are in continuous interactions with their physical and chemical perturbations in the surrounding water. The aquatic environment is similar to the terrestrial, in that it contains a multitude of chemical mixtures. However, the aquatic environment differs from the terrestrial one in the ways that chemical substances can be distributed: (1) molecules of chemical substances need to be in solutions rather than in the gaseous phase to be transported, and (2) water is a much slower carrier medium, both in terms of diffusion and convection or currents. Thus, solubility, rather than volatility, of chemical compounds determines their capacity as chemical cues. Consequently, nonvolatile compounds with relatively low molecular weights are superior substances for fish chemoreception and have been implicated in various behavioral roles.

Fish, like all other vertebrates, detect chemical stimuli through olfaction, gustation, and less well-defined senses represented by the general chemical senses and the solitary chemosensory cell. The two major channels of chemoreception – and gustation (or taste) – are discussed elsewhere in this encyclopedia. In terrestrial vertebrates, olfaction is normally distinguished as a distance chemical sense with high sensitivity and specificity, and gustation is primarily a contact or close-range sense with moderate sensitivity. In water, in contrast, these senses both act as distance receptors, detecting stimuli located remote from receptors, similar to hearing and vision, and act as contact receptors, detecting stimuli that are in direct contact with body surface, similar to touch and pain receptors. Thus, the aquatic environment surrounding fishes makes their chemical senses unique, and distinction between these two sensory modalities is not always as clear as in terrestrial organisms. In air or water, however, all chemoreception ultimately is an aquatic phenomenon, because the receptors are covered with fluid materials where the initial sensory transduction process takes place. Although chemo-sensitivities of the solitary chemosensory cell, the trigeminal system, and the lateral line system have been suggested, their biological relevancy has not been demonstrated, and therefore will not be addressed here. All the sensory systems are innately stimulated by chemical substances, whether specific or nonspecific, and all are prone to mechanical stimulation.

Fish, constituting more than half of the total number of *c.* 50 000 recognized living vertebrate species, are a pivotal group that has served as a model for the study of the vertebrate chemosensory system. The fishes often possess specific, sensitive, and readily accessible chemosensory organs. The ability to define specificity and sensitivity has permitted a critical evaluation of the several transduction sequences that follow the initial receptor-binding step. Unfortunately, however, little is known about the chemical senses of the majority of fish species that most likely have diverse behavioral ecology and taxonomy; consequently, elsewhere in this encyclopedia, discussion focuses on the fish species cyprinids (carp, goldfish), ictalurids (catfishes), zebrafish, and salmonids. Historically, the existence of the sense of smell in fish has long been controversial. The earliest description of the olfactory system in fish is probably the one by Monro in 1785: he wrote "... In all fishes, external openings or nostrils for smell are very evident, generally two on each side in the osseous fishes (a), which, on each side of the head (b), lead to a complex organ, the surface of which is of considerable extent; and upon them a pair of large or olfactory nerves terminates, with the addition of some branches from nerves resembling our fifth pair (c). In some fishes, as in the head and nose, passes through a cineritious ball (d), resembling the cineritious matter connected in our body to the olfactory nerve within the cranium. There can, therefore, be no doubt that they enjoy the sense of smelling; nay, there is great reason to believe that, suited to their surrounding element, they are much more sensible of odorous bodies dissolved in water, and applied by its medium, than we should be, if the application of the object was to be made to our organ of smell by the same medium."

What seemed to be the first paper dedicated exclusively to the olfactory sense of fishes was by Duméril in 1807, and by the 1850s the existence of three types of cells: sensory, supporting, and basal cells in the olfactory epithelium were recognized. Also, the connection of nerve fibers to the cells characterized as sensory cells was established for the first time. Nevertheless, Nagel in 1894, for instance, denied the existence of true olfactory sense in aquatic animals, suggesting that the organ of smell can be stimulated only by gaseous substances, implying that chemical stimulation in aquatic animals could only be mediated by taste. Taste buds, constituting the structural basis of the peripheral gustatory organ, were first described in fish as terminal buds (also termed as end buds or cutaneous buds) in the early 1800s before their function as organs of taste became firmly established. The most convincing evidence indicating that distinct olfactory and gustatory functions exist in fish was obtained by Strieck in 1924. Although the peripheral and central organization of the gustatory pathways in fishes was only described at the beginning of the twentieth century, similar studies in mammalian systems came much later.

As in other biological fields, experimental approaches to the functional aspects of chemoreception lagged far behind general morphological, anatomical, and histological studies. In particular, application of electrophysiological work to clarify the function and interrelationships of sensory mechanisms is very recent, and had to await progress in the physical sciences and its instrumentation. With respect to the fish system, it came as recently as 1938, when Adrian and Ludwig recorded an electrical discharge in the olfactory organs of catfish *(Ameiurus melas)*, carp *(Cyprinus carpio)*, and tench *(Tinca tinca)* in response to stimulation of the olfactory epithelium with fluid from decaying animal tissue. In fact, this marked the first study of the vertebrate olfactory system using an electrophysiological technique. The application of olfactory epithelium response (electro-olfactogram) and bulb recording techniques developed by Ottoson to the research on fishes greatly expanded progress in contemporaneous works.

One of the most characteristic features of the chemical senses, olfactory in particular, is that olfactory receptor neurons are the certified neurons belonging to the brain but miles away out in the open water, nosing around the world, whose axons carry external information directly to the brain. Unlike any other neurons of the vertebrate central nervous system, olfactory neurons are replaced every few weeks. Furthermore, chemoreceptive membranes are directly exposed to the aquatic environment and are not protected by external barriers or internal detoxifying system. Therefore, the physiological importance, chemical reactivity, structural complexity, and exposed location of chemosensory membranes combine to make them prime targets for interactions with aquatic contaminants.

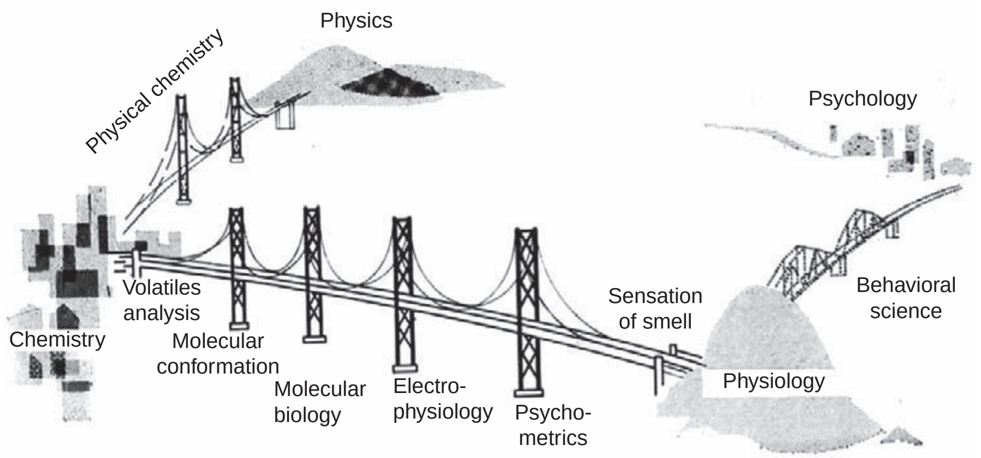

Figure 1 The Bay Bridge analogy for odor research. Modified from Amoore JE (1970) *Molecular Basis of Odor*, 200pp. Springfield, IL: Charles C. Thomas.

The last span between chemistry and physiology, a San Francisco Bay Bridge Analogy used by Amoore (**Figure 1**) some 40 years ago, has now been bridged by the discovery of a large multigene family of G-protein-coupled olfactory receptor genes first in rodents, and has opened a new era in olfaction as well as gustation research. Amoore had proposed that selective deficiencies in the ability to smell certain odors (specific anosmias) derive from genetic variations in genes encoding specific odorant receptor proteins. Direct evidence for the existence of such receptors was subsequently provided by studies in which radioactive odorants (amino acids) specifically bind to membrane fractions collected from olfactory cilia of salmonid fishes. The Nobel prize-winning work by Buck and Axel illuminates the logic of the most enigmatic of sensory systems, and homologous families of olfactory receptor genes have now been identified in a variety of vertebrate species, including fishes. The multigene family is a set of similar but not identical genes that encode the different members of a family of related proteins, and presumed to have arisen by duplication and divergence of an ancestral gene. Phylogenetic analyses of olfactory receptor genes suggest that the most recent common ancestor between fishes and tetrapods had at least nine ancestral olfactory receptor genes, and all olfactory receptor genes identified are classified into nine groups, each of which originated from one ancestral gene. The sizes of the receptor repertoires of vertebrate species are extremely large and are estimated to contain as many as 1000 individual genes. These observations suggest that approximately 1% of all genes are devoted to the detection of odors, making this the largest gene family thus far identified in vertebrates. Such an enormous amount of genetic information devoted to smell perhaps reflects the significance of this sensory system for the survival of most vertebrate species. Although many olfactory, pheromone, and gustatory receptors have been partially cloned or identified through genome sequencings, the identification of the ligands or odorants, or tastants, which activate individual receptors (deorphanization), has proved to be difficult. One of the few examples of deorphanized receptors is the 5.24-amino-acid receptor identified in the goldfish olfactory epithelium by Speca *et al.* in 1999. Here, again, fish have been proved to serve as important leading models for understanding the basic physiology of the chemosensory systems.

The gustatory system in fish, on the other hand, has evolved differently, reflecting their diverse modes of lives in the aquatic environment. Hypertrophy of the system has occurred independently in several groups, notably in the siluroids and the cyprinids. Traditionally, the gustatory system has been thought to be the primary channel for the detection of chemical cues for feeding. However, recent studies demonstrate that in many fish species feeding is triggered primarily through olfaction, complemented by gustation, and there is growing evidence suggesting that the CO_2 sensitivity of gustatory receptors might be involved in the ventilatory/respiratory regulation in fishes (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior and Neurophysiology of Olfaction). Therefore, the statement such as, "Where studied, gustation in fish appears to be exclusively associated with feeding" may no longer be valid. Analyses of genomic sequences encoding proteins homologous to mammalian gustatory receptors identify two families of candidate fish gustatory receptors in pufferfish, medaka, and zebrafish, suggesting that vertebrates commonly possess gustatory receptors of the G-protein-coupled and signaling pathways. Identification of olfactory and gustatory receptors during the last couple of decades has provided extraordinary insight into the strategies for information coding used by the chemosensory systems. Moreover, the integration of molecular, physiological, and morphological approaches has peeled away some mysteries in these sensory systems. The articles such as **Smell, Taste, and Chemical Sensing**: Chemosensory Behavior, Morphology of the Gustatory (Taste) System in Fishes, Morphology of the Olfactory (Smell) System in Fishes, Neurophysiology of Gustation, and Neurophysiology of Olfaction describe fundamental features of organization and function of both the olfactory and gustatory systems of fishes, with occasional comparison with those of terrestrial vertebrates, and provide up-to-date information on their roles in behaviors. The discussion will be centered on the chemosensory systems of limited fish groups, namely salmonids, goldfish, and catfishes, which have served as important models for extensive studies. However, no attempt has been made to be all inclusive; the reader is referred to the review listed in the Further Reading section (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior, Morphology of the Gustatory (Taste) System in Fishes, Morphology of the Olfactory (Smell) System in Fishes, Neurophysiology of Gustation, and Neurophysiology of Olfaction). Of course, two classical works, one by Herrick in 1905 and the other by Sheldon in 1912, are still very alive one hundred years after their publication; the former celebrated its centenary 2 years back, and the latter will do the same in a couple of years.

Glossary

Desmosome A plaque-like structure on the surface of the cell that functions in adhesion with adjacent cells.

Perigemmal Surrounding a budlike or bulblike body; denoting a mode of nerve termination by fibrils surrounding an end bulb.

Peripheral Gustatory System

Taste Buds

Distribution

Taste buds, also termed terminal buds, end buds, or cutaneous buds, constitute the structural basis of the peripheral gustatory organ. The term gustatory system is used to designate these organs, together with their nervous pathways toward and within the brain. In teleosts, taste buds are distributed in five subpopulations, to varying degrees: (1) oral, (2) palatal and laryngeal, (3) branchial (gills), (4) cutaneous, and (5) barbels (**Figure 1**).

The taste bud distribution patterns reflect feeding habits, strategies, and habitats of fishes. Most teleosts lack external taste buds, although some have independently evolved external taste buds on specialized parts of the body, such as barbels, elongated fin rays, and the lips of the mouth. Catfishes and goatfish (*Parupeneus* sp.) are a notable exception to the general condition among teleosts, as they have evolved thousands of external taste buds distributed over the barbels and the entire body surface. Yellow bullhead catfish (*Ictalurus natalis*), for example, have more than 175 000 taste buds on the entire body surface alone. In goatfish, the entire surface of the barbels is distributed with taste buds, with the densities of 150 to 250 mm^{-2}. Carp (*Cyprinus carpio*) and goldfish (*Carassius auratus*) have evolved a highly sophisticated food separation system on the roof of the mouth (palatal organ) that is studded with thousands of taste buds. In rainbow trout (*Oncorhynchus mykiss*), a visual feeder, taste buds are restricted to the lips, the palates, and gill rakers with the highest density of 30 per mm^2 totaling 3000–4000. In amago salmon (*Oncorhynchus rhodurus*), the number of taste buds in the oral cavity increases during the first 60 days post-hatching, then sharply increases over the next 300 days, reaching a total number of more than 15 000, at which time smolt transformation takes place. Freshwater species generally have well-developed taste buds in the oropharyngeal cavity and gill arches/rakers, which is thought to be an adaptation to freshwater habitats where a wider range of physical and chemical changes exist than in sea water.

Structure

Most taste buds are bulbiform or flask-shaped, which vary in size (45–75 μm in length and 30–50 μm in width) depending on the thickness of the epithelial layer, and are oriented perpendicular to the skin surface (**Figure 2**). The sensory area, or taste bud pore, is about 10 μm in diameter. A taste bud is buried in the epithelial layers or sits on a dermal papilla without being partitioned by membranes or any other tissues from the surrounding epithelial cells. Generally, three gustatory cell types constitute a fish taste bud: (1) those ending with a rod-shaped apical protrusion or cilia (0.5 μm thick and 1.5–3.0 μm long; rod cell or light cell); (2) those ending with microvilli (0.1–0.2 μm in diameter and 0.5–1.0 μm in length; microvillar cell or dark cell); and (3) basal cell. The total number of gustatory cells in a taste bud varies greatly; for example, 5 cells in *Pomatoschistus*, 67 in *Corydoras*, and as many as 100 in *Ciliata mustela* (60 rod cells and 49 microvillar cells). It is believed that the taste bud evolved while fish took possession of their own distinct ecological niche, thus resulting in considerable variation in their micromorphology. Some believe that taste buds are species specific, and no common type of taste bud exists in fish. Furthermore, in channel catfish (*Ictalurus punctatus*), taste buds innervated by the facial nerve contain significantly more cells than those innervated by the vagal nerve (216.3 ± 34.6 vs. 135.0 ± 19.2), and show heterogeneous distribution patterns of immunoreactivities for metabolites, notably more γ-aminobutyric acid (GABA) positive cells (microvillar cells) exist in the vagal innervated taste buds.

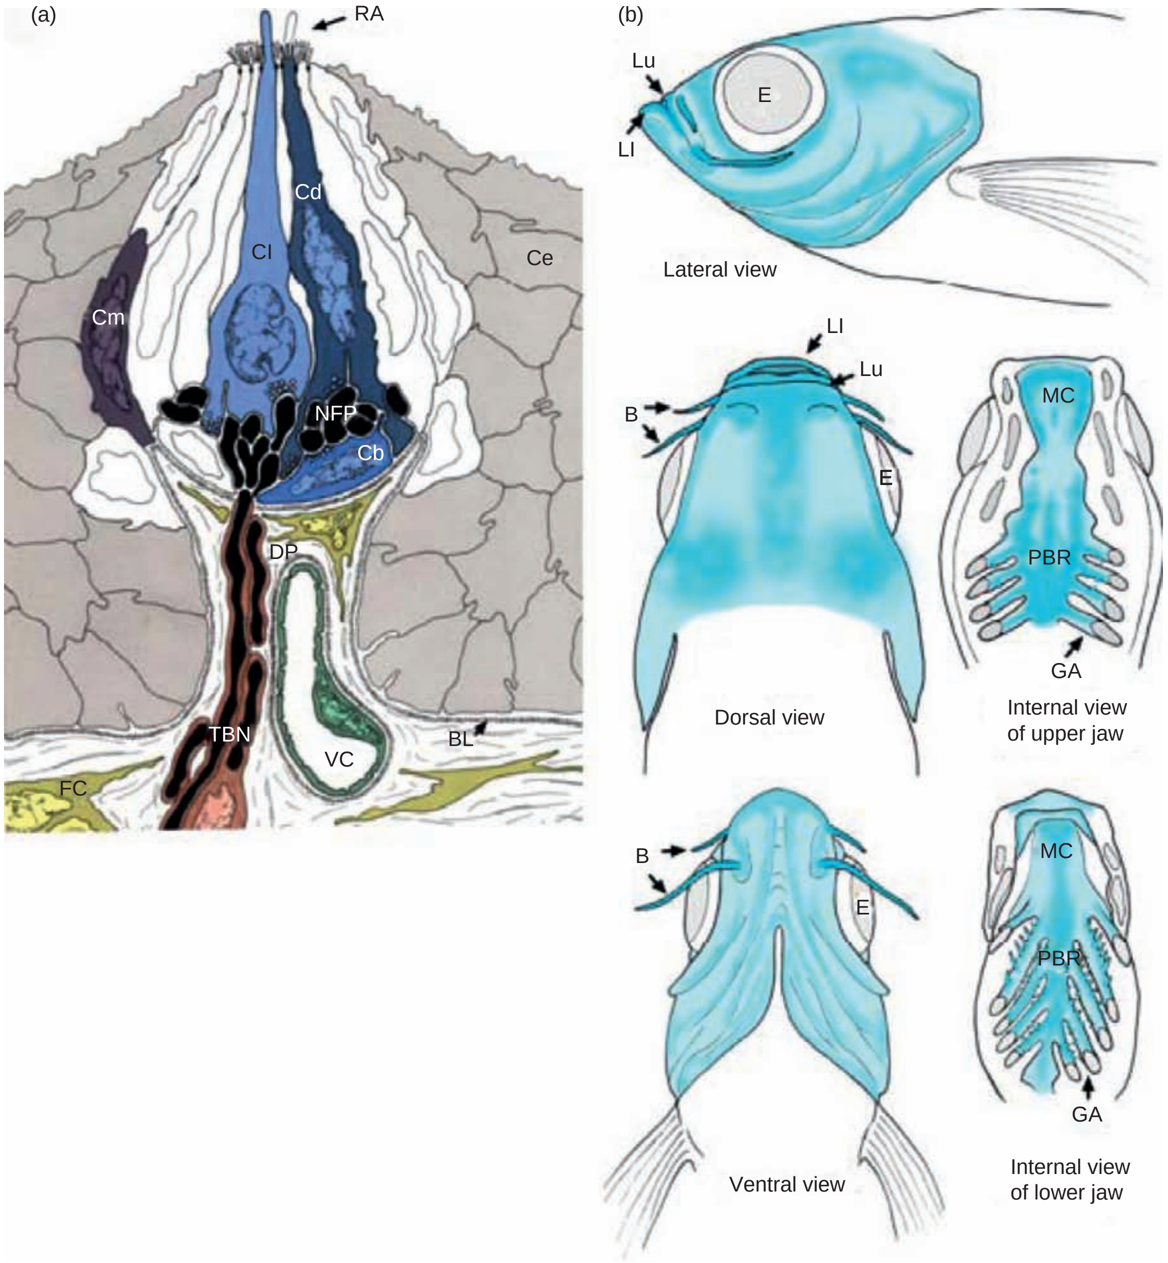

Figure 1 (a) Schematic drawing of a taste bud (TB) typical of teleosts. Dark cells (Cd) with microvilli, light cells (Cl) with a single rod-like protrusion, and basal cells (Cb) constitute a pear- or onion-shaped TB sitting on a dermal papilla (DP). Marginal cells (Cm), not belonging to the TB proper, form the interface between the TB and the epithelial cells (Ce). The TB nerve (TBN) reaches into the TB to form the nerve fiber plexus (NFP). (b) Distribution of TBs in juvenile and adult zebrafish (*Danio rerio*). High-density distribution of TBs is marked by darker shades of color. B, barbels; BL, basal lamina; E, eye; GA, gill arches; Ll, lower lip; Lu, upper lip; MC, mouth cavity; PBR, pharyngo-branchial region; and RA, receptive area. Modified from Hansen A, Reutter K, and Zeiske E (2002) Taste development in Zebrafish, *Danio rerio. Developmental Dynamics* 223: 483–496.

The rod cell, most likely a receptor cell, is cylindrical to spindle shaped. Its supranuclear cytoplasm contains numerous electron-dense tubules (0.4 − 0.6 μm), and the infranuclear portion is characterized by the presence of abundant vesicles (50–70 nm in diameter). Microvillar cells, often believed to be a supporting cell, but, could well be a receptor cell, are characterized by numerous fine filaments (*c.* 50 nm in diameter), running through the entire cytoplasm either diffuse or in bundles. Junctional complexes exist between microvillar cells and between the rod and microvillar cells.

The basal cells, typically one to five per taste bud, are situated at the bottom of the taste bud in depressions of the basal lamina, perpendicular to its longitudinal axis. They attach to both receptor and supporting cells by desmosomes. The basal cells contain many lucent vesicles

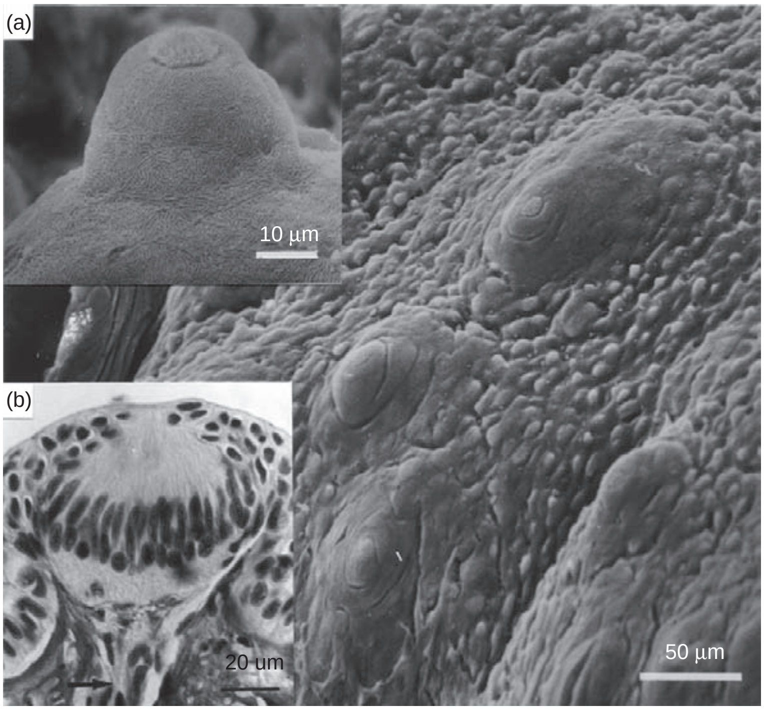

Figure 2 Morphology and distribution of taste buds on the palate of rainbow trout *Oncorhynchus mykiss*. (a) Scanning electron micrograph of a single taste bud located on an elevated papilla. (b) Light micrograph of a longitudinal section through a taste bud on the palate. Adapted from Hara TJ (2005) Olfactory responses to amino acids in rainbow trout: Revisited. In: Reutter K and Kapoor BG (eds.) *Fish Chemosenses*, pp. 31–64. Enfield: Science Publishers.

(40–50 nm in diameter), rich in serotonin (5-HT), and possess synaptic connections with both cell types as well as with nerve fibers, suggesting that they might act as modulators of gustatory activity. Unlike those of mammalian taste bud, the basal cells of fish are not the precursors of other cell types within the taste buds.

Taste buds are innervated by bundles of unmyelinated nerve fibers that enter from below into their basal portion passing by the side of the basal cells. Generally, one to three nerve bundles supply each taste bud, but the number and pattern of the supply vary among species and locations, even within the same species. Upon entering a taste bud, they further branch out and make an intricate intragemmal nerve plexus, some components of which make synaptic contacts either with the rod cells or with the microvillar cells. However, the synaptic specialization at these nerve-ending receptor junctions is not always clear such as those found in the central nervous system. Even in the mammalian taste buds, synaptic contacts between gustatory cells and nerve endings are not all clear-cut. Synapses are clustered with vesicles (40–70 nm) within the cell cytoplasm adjacent to the presynaptic membrane. In mammals, adenosine-5′-triphosphate (ATP), and not 5-HT, is suggested to serve as a key neurotransmitter linking taste buds to sensory nerve fibers. Mice with genetically knockout ionotropic purinergic receptors (P2Xs) either reduce or eliminate gustatory nerve and behavioral responses to sweeteners, glutamate, and bitter substances, leaving the responsiveness to touch and temperature intact, while 5-HT knockout mice reduce the behavioral responsiveness to pain, leaving the chemical sensitivity intact.

Development

Gustatory cells of vertebrates, unlike all other sensory receptor cells and neurons, are unique in that they originate from local epithelial tissue elements of primary endoderm, and not from neurogenic ectoderm (neural tube, neural crest, or ectodermal placodes). Nevertheless, gustatory cells form synapses and are capable of generating receptor potentials, and like epithelial cells they have a limited life span and regularly replace themselves.

Ontogenetically, taste buds generally develop later than their counterpart olfactory system. For example, in rainbow trout the earliest taste buds are seen only in larvae 8 days post-hatching. Taste bud primordia appear first around the mouth and within the oropharyngial regions a few days prior to hatching, far ahead of those in the head region, in zebrafish (*Danio rerio*) and channel catfish (*Ictalurus punctatus*). The primordial cells accumulated beneath the single layer of epithelial cells begin to elongate from the basal lamina to the epithelial surface by 4 days post-fertilization. By 10 days post-fertilization, the primordia begin to erupt as mature taste buds, at which time basal cells and nerve fibers are clearly seen and the dermal papillae begin to form beneath the basal cells. Although details of the development of the innervation of taste buds are still unknown, taste buds are believed to arise from within the specified epithelium (early specification) rather than being induced (nerve induction) by peripheral nerves. Thus, the taste bud, while maintaining its entity, is a constituent of the epithelium without partition from the surrounding epithelial cells. The average life span of taste bud cells on the channel catfish barbel is 12–42 days. Unlike the olfactory epithelium, in which the basal cells function as progenitors for the receptor neurons, epithelial cells surrounding the taste buds divide and some of their daughter cells migrate into taste buds to form gustatory cells.

Central Gustatory Pathways

Primary Gustatory Centers

The gustatory system is the only vertebrate sensory system in which three cranial nerves carry all peripheral gustatory information. Depending upon the location of the taste buds, either the facial (cranial nerve VII), glossopharyngeal (IX), or vagal (X) gustatory nerves innervate the gustatory cells. Generally, all cutaneous taste buds on the body surface and rostral oral regions are innervated by the facial nerve, while taste buds within the posterior oral cavity and pharyngo-branchial region are innervated by the glossopharyngeal and vagal nerves. Somatotopic organization generally exists in the termination of axons in the primary gustatory nucleus (PGN), the mammalian equivalent of the nucleus of the solitary tract (NST). The gustatory nerves from the different regions of the body thus enter the nucleus in approximately the same order as they are located in the body, that is, axons from more rostral regions of the mouth (or body) enter the more rostral portions of the nucleus (**Figure 3(a)**).

Both the vagal and facial lobes have two main types of secondary neurons: (1) large specialized neurons superficially arranged over the lobes – the chief secondary gustatory neurons and (2) small intrinsic neurons, filling the interior of the lobe. The chief gustatory neurons, directly receiving the peripheral gustatory terminals of the first order, give rise to the long paths of the secondary connection primarily to the superior secondary gustatory nucleus (SGN) in the isthmus, while the intrinsic neurons function as interneurons within the lobe.

Secondary and Tertiary Gustatory Nuclei (SGN and TGN)

The major efferent projections of the primary gustatory center ascend via two pathways (**Figure 4**). Typically, the primary centers project to the superior SGN in the pons (or isthmus), to the tertiary gustatory relay nucleus in the caudal diencephalon, and then to the telencephalic gustatory area. The SGN neurons also project to the hypothalamic inferior lobe (IL) and to a posterior thalamic nucleus. The caudal part of the diencephalon is called the preglomerular nuclear complex. In the rainbow trout, neurons of the preoptic nucleus project to the SGN, suggesting that preoptic SGN and/or preoptic primary gustatory column projections may be important neuroregulatory circuits in fishes. The IL is a large and highly differentiated brain part in teleosts comparable to other major brain parts such as cerebellum, optic tectum, or telencephalon, and is believed to represent a multisensory integration center. Thus, the ascending gustatory connection pattern is shared by all teleosts and seems to represent the ancestral patterns for teleosts. The SGN is the homolog of the parabranchial nucleus, that is, the pontine taste area of mammals.

Telencephalic Gustatory Areas

Telencephalic projections of the secondary and tertiary gustatory neurons have been demonstrated in carp, channel catfish, goldfish, and rainbow trout. Generally, gustatory

nuclei in the telencephalic region include medial and central portions of area dorsalis, which receive projections from the pTGN. In tilapia (*Oreochromis niloticus*), for example, preglomerular TGN (pTGN) projects to the dorsal region of area dorsalis pars medialis (dMm), while in rainbow trout, it projects to the medial region of the dorsal telencephalic area (Dm) and the ventral telencephalon. In addition, in tilapia, the SGN projects to area ventralis pars intermedia (Vi) and area dorsalis pars posterior (Dp). Note that the Vi and the Dp of tilapia and Dm and the ventral telencephalon in salmonids receive direct projections from the olfactory bulb. As Herrick pointed out with regard to the major importance of the relation of gustation and olfaction, the secondary center is the area olfactoria of the forebrain, whose commissure bears the same relation to the secondary tracts as do those of the secondary gustatory nuclei. The main tertiary tract passes to the inferior lobe, which is, in fishes, the central correlation station for all sensory impression. The olfactory and gustatory tertiary tracts end together throughout the inferior lobe and they have a common descending conduction path, the tractus lobobulbaris (**Figure 4**).

The ascending fiber connections of the central gustatory system in teleosts are essentially similar to those of mammals. The mammalian SGN projects directly to the amygdala, which receives direct projections from the olfactory bulb. Phylogenetically, the Vi and Dp are respectively considered as a part of the amygdala and the lateral pallium.

Descending Projections to Facial and Vagal Lobes

The inferior lobe and lobobulbar lobe develop extensive descending fiber projections to the primary gustatory centers in the facial (cyprinids) and vagal (catfishes) lobes as well as in the viscerosensory column (trout). The vagal lobe, as described, projects to motoneurons that innervate the oropharyngeal musculature, which controls swallowing or intraoral food handling in cyprinids (**Figure 5**). By contrast, the facial lobe of catfishes projects to somatosensory nuclei in the caudal medulla, which may provide a means to correlate gustatory and somatosensory inputs from a single locus on the body surface. Furthermore, the return path for all sensory activities of the inferior lobe is the tractus lobobulbaris passing into the oblongata, through which the descending neurons of the inferior lobe communicate with the peripheral motoneurons of the oblongata, and probably also of the spinal cord, thus providing for the most complex reflexes that a fish can achieve.

Palatal Organs and Barbels

Although the gustatory system is generally well developed throughout fishes, two groups of fishes, cyprinids and ictalurids, as well as goatfishes, have become highly specialized for the use of sophisticated food-handling apparatus, the palatal organ and the barbel, and therefore, deserves special attention here. Along with the expansive taste buds, they have developed the most complex neural organization seen in any fish central nervous system. Both groups of fishes are bottom feeders, and have evolved highly sophisticated mechanisms of food detection and separation. In goldfishes and carps, the palatal organ, which is a muscular structure attached to the roof of the mouth and studded with numerous taste buds, combined with the surface of the gill arches, manipulate to separate palatable food materials from the

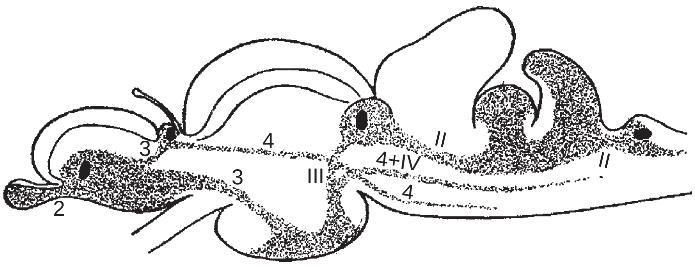

Figure 5 Diagram showing the relations of the gustatory and olfactory centers in teleosts, as represented by the shaded areas. The black spots represent the position of commissures of secondary or tertiary fibers. Numbers 2, 3, and 4 represent the olfactory conduction paths of the second, third, and fourth orders, respectively, and II, III, and IV represent the gustatory conduction paths of the second, third, and fourth orders, respectively. From Herrick CJ (1905) The central gustatory paths in the brains of bony fishes. *Journal of Comparative Neurology and Psychology* 15: 375–456.

unpalatable. The vagal nerve terminates in the gustatory nucleus as in other fishes, but the gustatory nuclei in these fishes have largely bulged out to form a prominent vagal lobe (cf. **Figure 3(b)**). The internal structure of the vagal lobe is topographically organized, that is, the entire structural feature of the oropharyngeal cavity is mapped onto the vagal lobe, so that the anterior end of the palatal organ is represented anteriorly in the lobe and progressing posteriorly. The vagal lobe consists of a series of nine layers of neurons with a complex organization. In addition to a topographical organization of mouth structure in the vagal lobe, gustatory nerves from each of the oropharyngeal structures terminate in specific layers of the lobe, that is, nerves innervating taste buds of the palatal organ project to layer 6, those innervating the gill arches project to layers 2 and 4, and so on. In parallel with the sensory neuron inputs, the outputs of the motor neurons innervating musculatures of the palatal organ and gill arches, occupying the deepest layer of the lobe, are also organized in a topographic fashion (**Figure 6**).

In catfishes, the facial lobe is large, lying rostro-medial to the vagal lobes (cf. **Figure 3(c)**). The facial lobe is organized into six longitudinal columns or lobules extending rostrocaudally and arranged alongside each other, and receives the gustatory axons of the ventrolateral facial nerve. Each lobule receives segregated input from discrete portions of the body surface. The three medial lobes in channel catfish respectively receive input from the medial and lateral mandibular barbels and the maxillary barbels. The two ventral lobules receive inputs from the nasal barbel and pectoral fin and a large dorsolateral lobule from the face and trunk. Thus, the entire extraoral surface of the body is mapped somatotopically onto the facial lobe in a well-defined manner.

In goatfish, taste buds are evenly distributed on a single pair of barbels extending vertically from the lower jaw. Unlike the palatal organs in cyprinids, no muscular structure exists within the barbels. Longitudinally running nerve branch originating from the main nerve trunk of the facial nerve sends a pair of circumferential branches medially and laterally around the margins of a barbel which innervate four taste bud clusters, each containing 14 taste buds, at each proximal–distal level. Thus, each longitudinal nerve, consisting approximately 90 fibers, innervate a total of 56 taste buds, forming a functional unit.

Alliance with the Trigeminal Nerve

The complex gustatory system as has been described makes itself even more complex by the fact that the facial nerve is closely allied with the trigeminal nerve, and strong tactile component exists in the gustatory sensory signal. In vertebrates, the trigeminal nerve generally carries the sensory nerves including pain, temperature, touch, and proprioception from the jaws and head as well as the motor neurons controlling the jaw muscles. Catfish barbells are heavily innervated both by trigeminal and facial nerves, both of which project to the facial lobe by three branches – ophthalmic, maxillary, and mandibular. The trigeminal fibers terminate not only in the principal and spinal trigeminal nuclei but also throughout the facial lobe, with the exception of the lateral-most lobule which contains a representation of taste buds innervated by the recurrent branch of the facial nerve. The trigeminal fibers are coarser than those of the facial which terminate within the same structural loci, and its input to the primary gustatory complex is restricted to those portions of the nucleus receiving sensory inputs from the face and barbels.

Contrary to its central projections, virtually nothing is known about the peripheral termination of the trigeminal nerve, except for the observations that in sea catfish and goatfish some nerve fibers terminate inside taste buds perigemmally without ending on gustatory cells. It thus appears as if the trigeminal fibers have failed to locate their target cells, that is, they become orphaned gustatory nerves. Thus, the relationship between gustatory and tactile sensibility is well recognized but its implications are not fully understood. It seems there may be no pure gustatory area at any level of the gustatory neuraxis.

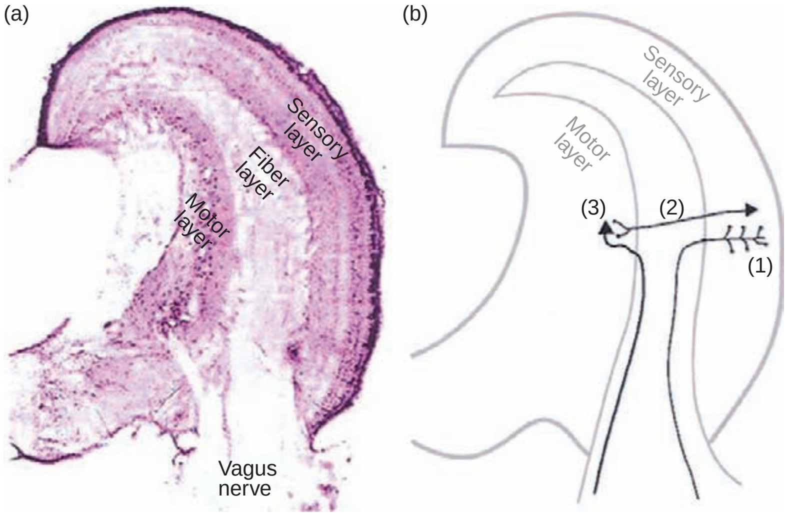

Figure 6 (a) Micrograph of the vagal lobe showing the overall laminar organization. The sensory fibers terminate superficially in the sensory layer; the motor output to the palate originates from motoneurons of the motor layer. (b) Hypothesized reflex circuit utilized in food sorting. Sensory information from a particular point in the oral cavity will terminate in a limited portion of the sensory layer (1) where it activates local interneurons (2). These interneurons have axons that traverse the fiber layer to terminate on the underlying motoneurons (3). The motoneurons that receive the reflex connection innervate muscles in the same local region of the palate from which the sensory input arises. Adapted from Finger TE (2008) Sorting food from stones: The vagal taste system in goldfish, *Carassius auratus*. *Journal of Comparative Physiology A* 194: 135–143.

Concluding Remarks

A great deal of effort has been expended to work out, at the peripheral end, the details of the structure of taste buds including distribution on the body surface, fins, lips, and in the mouth, which provide fishes with a highly detailed gustatory map, chemical or tactile, of the environment as well as the means to detect food and reject noxious objects. Centrally, details of the extremely well-developed vagal/facial lobe system in cyprinids, silurids, and goatfish have enhanced our understanding of the way gustatory information is processed in the central nervous system in vertebrates in general. Despite these exciting advances, two of the major aspects of the peripheral gustatory system still remain unexplored: (1) characterizing homo- or heterogeneity of receptor cells, whether it be the light or dark, or rod or microvillar cells, within a taste bud and synaptic contacts with innervating gustatory nerves and (2) identifying gustatory cells that have the high percentage of the chemical, or tactile, sensitivity.

Glossary

Anlage In embryology, an embryonic area capable of forming a structure: the primordium or bud.

Desmosome A plaque-like structure on the surface of a cell that functions in adhesion with adjacent cells.

Placodes Plate-like thickenings of embryonic ectoderm from which definitive structures develop.

Stroma Refers to the supporting framework of an animal organ typically consisting of connective tissue.

Peripheral Olfactory Organ

Development of the Olfactory Organ

Ontogenetically, the peripheral olfactory organ is the first chemosensory organ to develop in fish, preceding the gustatory. It originates from an anlage formed by the ectoderm and remains ectodermal throughout its development. In rainbow trout (*Oncorhynchus mykiss*), the anlage appears on the ventrolateral part of the head just in front of the rudimentary eyes as early as 11 days postfertilization, and 5–8 mm in length (**Figure 1**). Separate ventrolateral olfactory placodes emerge from the thickened ectoderm, built by cells that separate from the anterior neural plate. The homogeneous population of the olfactory placodal cells then differentiates into the olfactory organ. On 12–16 days postfertilization, the embryos rapidly elongate, primordial organ systems become visible, and the olfactory placodes thicken and begin to form a central depression. At hatching, the olfactory pits, now rectangular-shaped grooves, migrate to a dorsolateral position on the head. In embryos, 15–20 mm in length, the median portion of the external lip of the elongating olfactory pit expands toward the internal lip, resulting in the formation of distinct anterior and posterior nares. The salmonid type of nasal formation is widespread among teleosts, and is phylogenetically considered to be archetypical.

There is considerable variation in size, structure, and degree of development of the olfactory organs. The paired olfactory pits are usually located on the dorsal side of the head. Eels and morays have large and elongated olfactory pits, extending from the tip of the snout to the orbit of the eye. Certain puffers (Tetrodontidae), in contrast, have completely lost the nasal sac. However, in most teleost species, the olfactory organ lies somewhere between these two extremes. In few cases, there are differences between sexes of the same species, for example, bathypelagic anglerfishes.

Each nasal pit generally has two openings, anterior inlet and posterior outlet, which are separated by a nasal flap or bridge. A current of water enters the anterior and leaves through the posterior opening, either passively through the locomotion of the fish in water, or actively by ciliary action within the pits or by the pumping action of the nasal sac. In some teleosts, two accessory nasal sacs, the ethmoid and the lacrimal sac, a single nasal sac, or a fused nasal sac assist in ventilating unidirectional water flow through the nasal cavity. The occurrence of these nasal sacs has long been associated with the need to regulate water flow in sedentary bottom-dwelling fish, but this is questionable in many cases (**Table 1**).

Olfactory Epithelium

The olfactory epithelium lines the olfactory cavity and is generally raised from the floor of the organ into a complicated series of folds or lamellae to make rosette-like arrangements. The arrangement, shape, and degree of development of the lamellae in the olfactory rosette of teleosts vary considerably among species. The largest number of lamellae (over 200) occurs in Anguilliformes, while few or no lamella exists in some Atheriniformes and Tetrodontiformes. Normally, a central ridge is formed rostro-caudally on the bottom of the olfactory chamber from which a varying number of transverse lamellae radiate. In some teleosts, a series of parallel lamellae occur in the absence of the ridge. A new lamella develops caudad and progresses rostrad, so that the oldest and largest lamella is located most posteriorly. The number of the lamellae increases to some extent with growth of

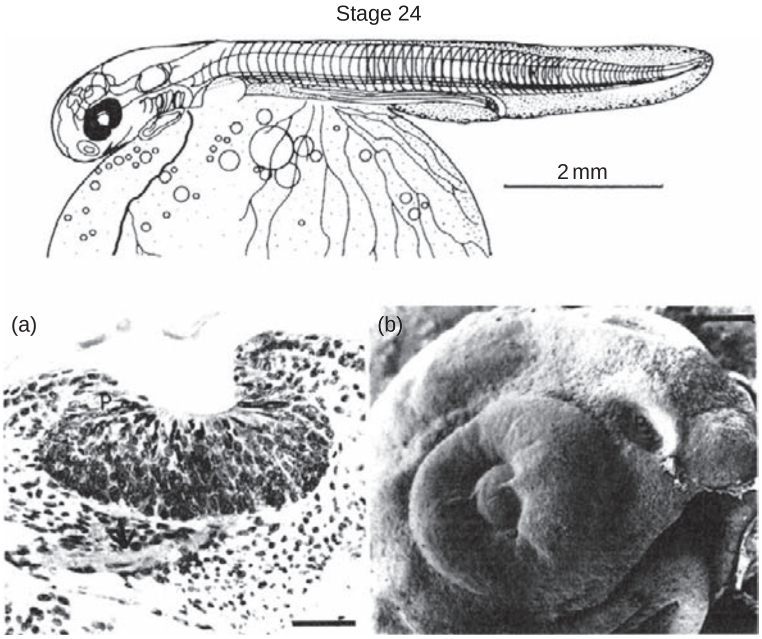

Figure 1 Formation of the olfactory placode and development of the olfactory neuron in rainbow trout embryo. (a) Histologically identifiable olfactory nerve (arrow) extending from the placode (P) to the brain; bar = 200 μm. (b) Scanning electron micrograph of the olfactory placode (P); Scale = 50 μm. Adapted from Hara and Zielinski (1989) Structural and functional development of the olfactory organ in teleosts. *Transactions of the American Fisheries Society* 118: 183–194.

individuals, but remains constant after the fish reaches a certain stage in growth. Secondary folding of the lamella occurs in some species. Most notable are salmonids; there are 5–10 secondary folds per lamella in adults, but none in the parr and younger stages (**Figure 2**).

The olfactory lamella is composed of two layers of epithelium enclosing a thin stromal sheet. The epithelium, columnar pseudo-stratified (65–85 μm in thickness), is separated into two regions: sensory and nonsensory (**Figure 3**). The sensory epithelium shows various distribution patterns: (1) continuous except for the lamella margin (*Anguilla*, *Ictalurus*), (2) separated regularly by the nonsensory epithelium (Salmoniformes), (3) interspersed irregularly with the nonsensory epithelium (*Gasterosteus*, *Thunnus*), and (4) scattered in islets (*Phoxinus*, *Cyprinus*, *and Carassius*). The sensory epithelium consists of three main cell types: (1) receptor cells (olfactory receptor (OR) neurons), (2) supporting cells, and (3) basal cells. The nonsensory epithelium is of a stratified squamous type, usually thinner than the sensory epithelium. It consists of epidermal cells, ciliated nonsensory cells, and basal cells. Mucus cells (goblet cells) usually occur only within the nonsensory epithelium. The stromal sheet which is separated by a basal lamina from the epithelium is filled with loose fibers and cell bodies of the connective tissue. It also contains blood capillaries and bundles of axons arising from the bottom of the receptor neurons. In addition to the olfactory axons, free nerve endings are generally present, some of which are identified as sensory fibers of the trigeminal nerves.

Olfactory Receptor Neurons

Traditionally, two morphologically and ontogenetically distinct receptor neuron types have been recognized in teleosts: ciliated and microvillar (**Figure 4**). This situation contrasts with those of terrestrial vertebrates including humans, where the olfactory neurons are segregated into two separate compartments: (1) ciliated neurons populate the main olfactory epithelium, and (2) microvillar neurons lie in the vomeronasal organ. In rainbow trout embryos, the ciliated form precedes the microvillar form; the former appears when the olfactory placode is folded to form a groove-like structure rostrad to the eye, and predominate until immature microvillar receptor neurons develop at about 28 days postfertilization. A third neuron type, crypt cells have recently been added to the list of receptor neurons. The crypt cell type is widely distributed in teleost fishes, but has not yet been reported in salmonids. The scarcity, however, makes them difficult to find in ordinary electron-microscopic preparations, despite the fact that they line up in a queue in some species. Elasmobranchs and Australian lungfish (*Neoceratodus forsteri*) have only microvillar-type neurons, while river lamprey (*Lampetra fluviatilis*) has only the ciliated. There is currently no evidence to suggest that different neuron types mediate responses to different odorants.

The bipolar olfactory neuron has a cylindrical dendrite that terminates at the free surface of the epithelium. The distal end of the dendrite forms a swelling (olfactory

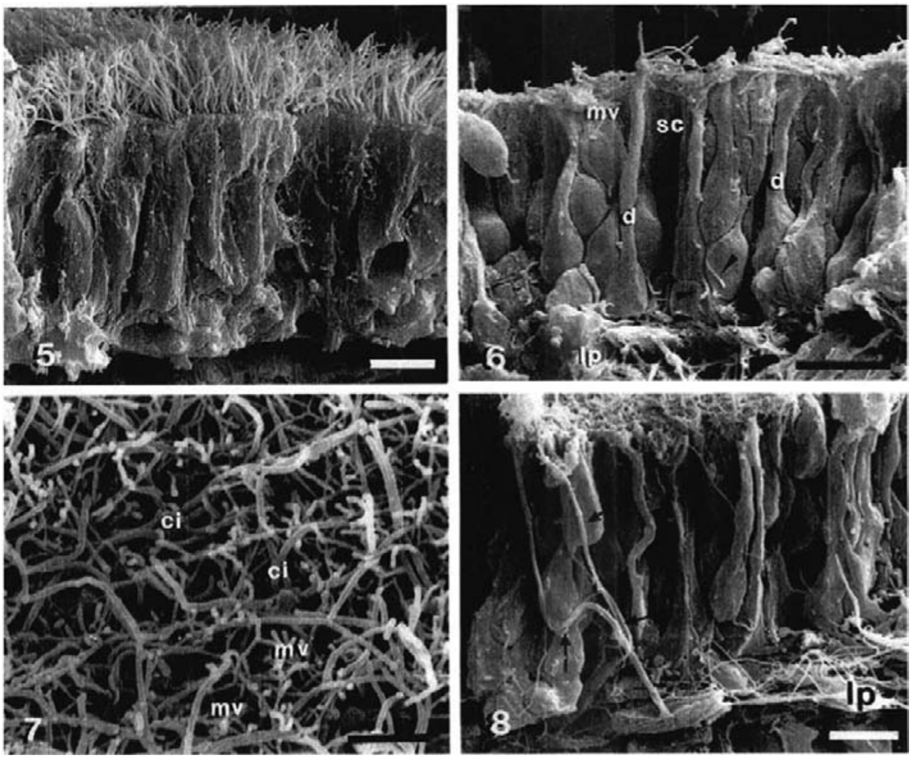

Figure 3 Scanning electron micrographs of fractions of nonsensory (a), sensory (b, d), and the surface of the sensory epithelium of zebrafish. Scale = 5 μm (a, b, d) and 2 μm (c). Adapted from Hansen and Zeiske (1998).

knob or olfactory vesicle), and protrudes slightly (about 1 μm) above the epithelial surface. Each dendrite, 1.5–2.5 μm in diameter, is enclosed entirely by supporting cells with tight junctions near the epithelial surface. The proximal part of the perikaryon (the cell body containing the nucleus) tapers to form an axon. The ciliated neuron has four to eight cilia radiating from an olfactory knob. Each cilium measures 2–7 μm in length and 0.2–0.3 μm in diameter. The cilia show the 9 + 2 arrangement of microtubules, which is identical with that of common kinocilia. The microvillar neuron bears from 30–80 microvilli (2–5 μm long and about 0.1 μm wide) depending upon species. The crypt neurons with ovoid to oval cell bodies (2–3 times the diameters of the other two types) are located in the upper third of the olfactory epithelium. Their axons travel toward the basal lamina and join the axons bundles of other neurons (olfactory nerve; cranial nerve I). The most striking feature is the

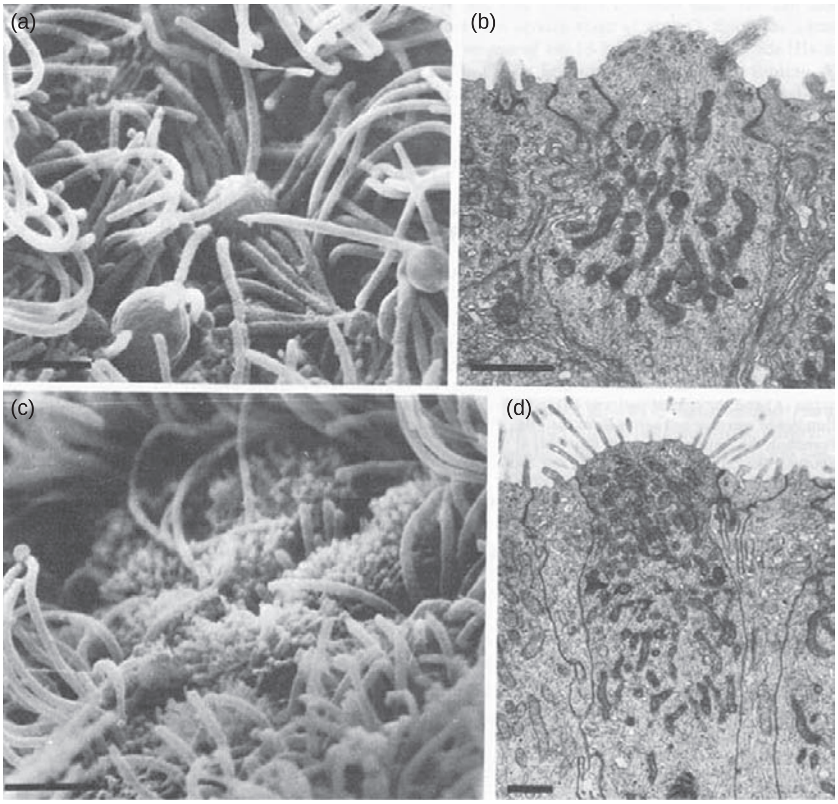

Figure 4 Scanning (a, c) and transmission (b, d) electron micrographs of ciliated and microvillar olfactory neurons of rainbow trout. Scale = 3, 4, 0.3, and 1 μm in (a), (b), (c), and (d), respectively. Adapted from Zielinski and Hara (1989).

apical invagination bordered by microvilli, forming a crypt. They bear cilia as well as microvilli. These cilia do not extend above the surface of the olfactory epithelium, and microvilli encircle the apical rim of the neurons. Thus, the crypt neurons have characteristics of both ciliated and microvillar neurons, assuming an aspect of a compound receptor neuron (**Figure 5**). This limited exposure to the environment could pose a serious problem in accessing to stimulant molecules.

Approximately 5–10 million olfactory neurons comprise the sensory epithelium on each side of the nose in an average teleost. A correlation exists between the receptor neuron morphology, the type of odorant receptor, and G-proteins expressed. An odorant receptor specific G-protein, $G\alpha_{olf}$ is expressed in ciliated olfactory neurons distributed homogeneously across the entire sensory epithelium of several fishes including goldfish. In contrast, microvillar neurons express $G\alpha_o$, $G\alpha_q$, or $G\alpha_{i\text{-}3}$, and, not surprisingly, crypt neurons express both $G\alpha_o$ and $G\alpha_q$ (**Figure 6**). Double-transgenic zebrafish show that the ciliated neurons project axons mostly to the dorsal and medial olfactory bulb regions, whereas the microvillar neurons project to the lateral region, which is established in very early embryonic stages (**Figure 7**).

Olfactory (Odorant) Receptors (ORs)

The initial step in olfaction requires the interaction of odorant molecules with specific receptors on OR neurons. This sensory information is then transmitted to the brain where it is decoded (**see also Smell, Taste, and Chemical Sensing**: Neurophysiology of Olfaction). A large multigene family that encodes ORs on olfactory neurons was first identified in rodents. Subsequent studies identified homologous gene families in a variety of vertebrate species, including fishes: catfish, zebrafish, goldfish, medaka, loaches, and salmon. These genes belong to the superfamily encoding G-protein-coupled receptors (GPCRs), whose protein products exhibit a seven-transmembrane domain structure. The repertoire of OR genes is extremely large, numbering around 100 in fish to as many as 1000 for some mammals. Whole genome analysis reveals the complete set of 143 OR genes in zebrafish, 44 in fugu, and 42 in *Tetrodon.* Interestingly, the OR gene family identified in fishes is smaller in number but much more diverse than in mammals, and the gene groups found in mammals are nearly absent in fishes. Fish ORs belong to one of three families of GPCRs, the family C (or 3) GPCRs, along with those for glutamate and γ-aminobutyric acid, for Ca^{2+}, for sweet and amino acid taste compounds, and for some mammalian

pheromone molecules (**Figure 8**). One of the most important characteristic features of these ORs is the possession of a large extracellular domain that is responsible for ligand recognition, and is structurally similar to the metabotropic glutamate receptor.

In situ hybridization experiments with channel catfish provide strong evidence that individual olfactory neurons express a limited subset of ORs. Assuming that the catfish genome encodes as few as 100 OR genes, each neuron expresses one or a few ORs. Furthermore, neurons expressing specific ORs appear to be randomly distributed within the olfactory epithelium (**Figure 9**). These data are consistent with a model in which randomly dispersed olfactory neurons with common receptor specificities project to common glomeruli in the olfactory bulb.

Nonreceptor Cells

The supporting cells are columnar epithelial cells extending vertically from the epithelial surface to the basal lamina, forming a mosaic interspersed with receptor neurons. The free surface is flat, with a few microvilli. Supporting cells adjoin receptor neurons, ciliated nonreceptor cells, and other supporting cells at the free surface by an apical tight junction. Small vesicles in various sizes accumulate in the apical cytoplasm. The function of the supporting cells in fish olfaction is not defined, but in higher vertebrates they may have a role in the binding of odor molecules as they dissociate from OR sites. Crypt neurons are surrounded by special type of supporting cells that have numerous microvilli at their apical rim, and wrap around a crypt neuron. Crypt supporting and regular supporting cells are connected by numerous desmosomes.

The basal cells are small and oval-shaped, forming a discontinuous layer just above the basal lamina, interspersed by the bases of supporting cells in the sensory epithelium. They have numerous projections enclosing a bundle of receptor neuron axons. The basal cells in the sensory epithelium are assumed to be the progenitors of the receptor neurons and supporting cells. Increased mitotic figures are seen in the basal region in the reconstituting epithelium after degeneration.

Ciliated nonsensory cells are typical columnar cells with a wide flat surface, from which long kinocilia (20–30 μm), showing the 9 + 2 axial pattern of microtubules, extend. These cilia move water over the olfactory lamellae, presumably assisting in the transport of stimulant molecules within the olfactory organ.

Epidermal cells fill the nonciliated part of the nonsensory epithelium and are structurally identical with those of the fish epidermis. They are usually flattened in the

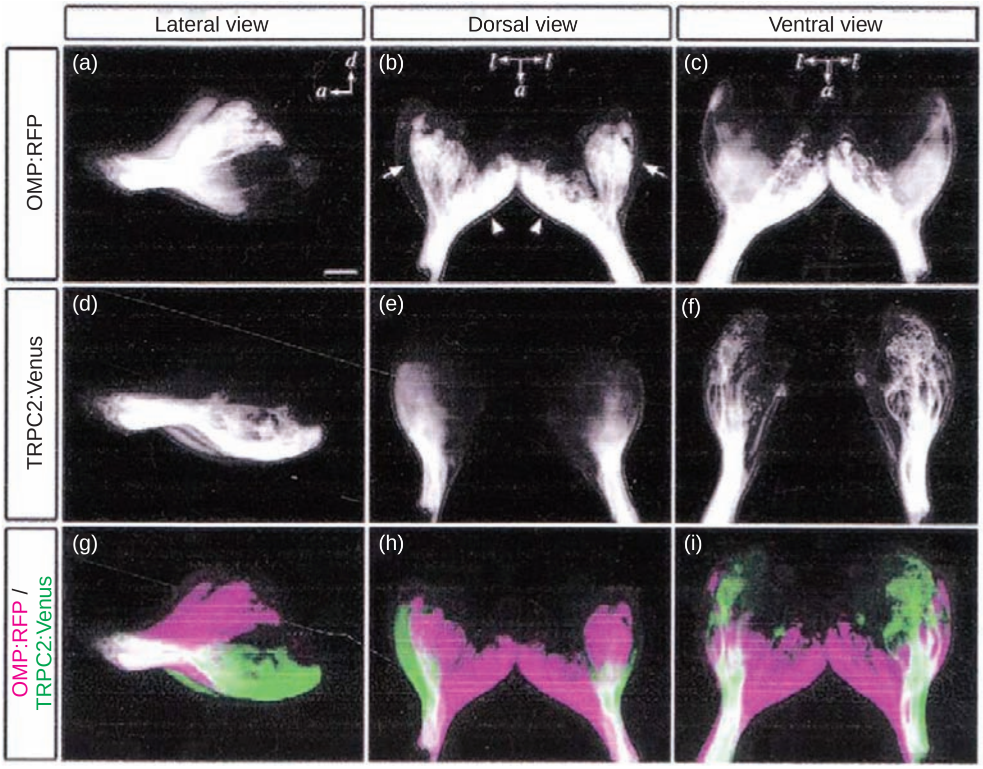

Figure 7 Differential projections of two types of olfactory neuron (ON) in zebrafish, ciliated ONs (magenta) project their axons to almost entire dorsal and the ventromedial regions of the olfactory bulb, whereas microvillar ONs (green) project their axons exclusively to the ventrolateral region. Adapted from Sato *et al*. (2005) Mutually exclusive glomerular innervation by two distinct types of olfactory sensory neurons revealed in transgenic zebrafish. *Journal of Neuroscience* 25: 4889–4897.

surface layer of the epithelium, and shows a prominent microridge arranged in fingerprint-like patterns in the free surface on the cell.

Mucus cells (goblet cells) contain many secretory granules in the cytoplasm with various electron densities, which are secreted between adjacent cells and are the major component of the mucus layer that covers the olfactory epithelium. In salmonids, additional mucus cells are present in the nonsensory epithelia on the ridges of the secondary folds and in the neuroepithelium.

In addition, in rainbow trout, magneto-receptor cells are present in the lamina propria of the olfactory epithelium, which is linked to the brain through the superficial ophthalmic branch of the trigeminal nerve. The cells contain magnetite crystals and respond to changes in the intensity of an imposed magnetic field, which is implicated in the magnetic orientation in salmonids navigation (**see also Sensory Systems, Perception, and Learning**: Magnetic Sense in Fishes).

Regeneration of OR Neurons after Degeneration

As mentioned, the OR neurons have a wonderful property described by Thomas as “this population of brain cells, unlike any other neurons of the vertebrate central nervous system, turn over every few weeks; cells wear out, die, and are replaced by brand-new cells rewired to the same deep centers miles back in the brain, sensing and remembering the same wonderful smells.”

Severance of the olfactory axons results in complete degeneration of all existing mature neurons, followed by reconstitution of new receptors from stem cells in the neuroepithelium of adult animals. The time course of degeneration and regeneration varies for different species. In rainbow trout, massive degeneration of receptor neurons takes place between 14 and 28 days following nerve section. The declining populations of neurons observed histologically are supported by the gradual decline in their activities when monitored by electro-olfactogram (EOG) responses and biochemical binding (**see also Smell, Taste, and Chemical Sensing**: Neurophysiology of Olfaction). The supporting cells remain unaffected during the process. Reconstitution of the neuroepithelium is initiated by an outburst of mitosis in the basal cells. The numbers of newly differentiated receptor neurons returns to normal in 84 days. Following either olfactory nerve transection or the removal of the olfactory bulb in goldfish, the OR neurons show similar degeneration and subsequent neuron death. However, the time course of the renewal of neurons is different, with more rapid and complete renewal in axotomized fish.

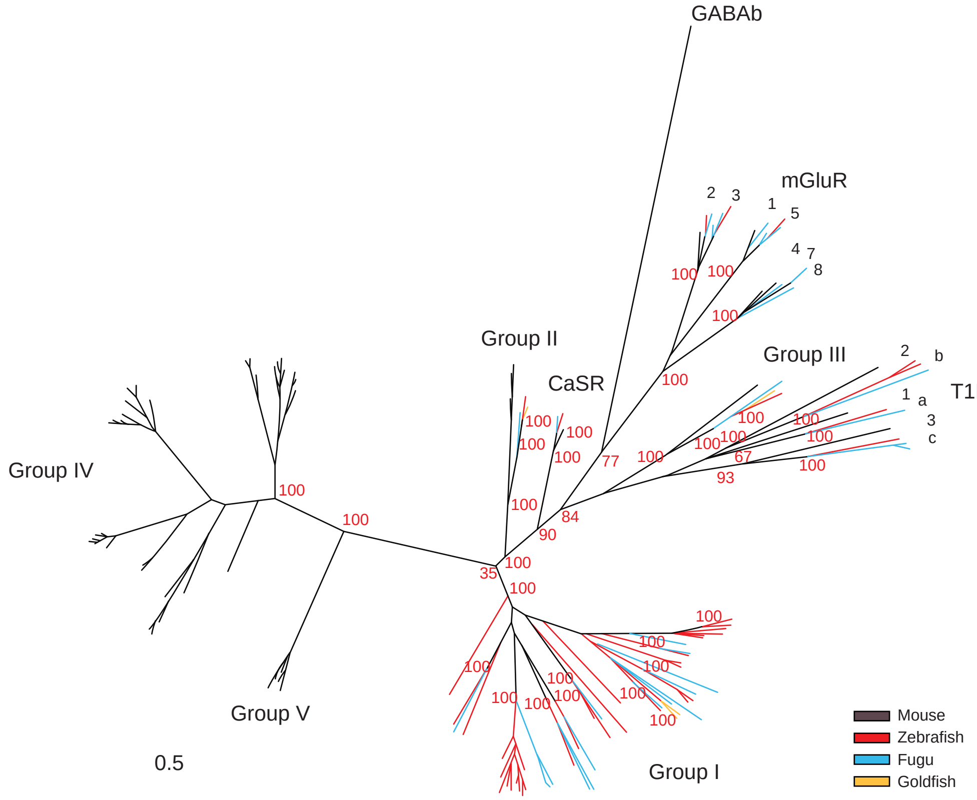

Figure 8 Phylogeny of C family GPCRs from zebrafish, fugu, goldfish, and mouse. Most of the fish receptors form a clade (group I) distinct from the mouse receptors (groups II, IV, and V). Group II contains both fish receptor and mouse sequences. Note that goldfish 5.24 belongs to group III. Adapted from Alioto and Ngai (2006).

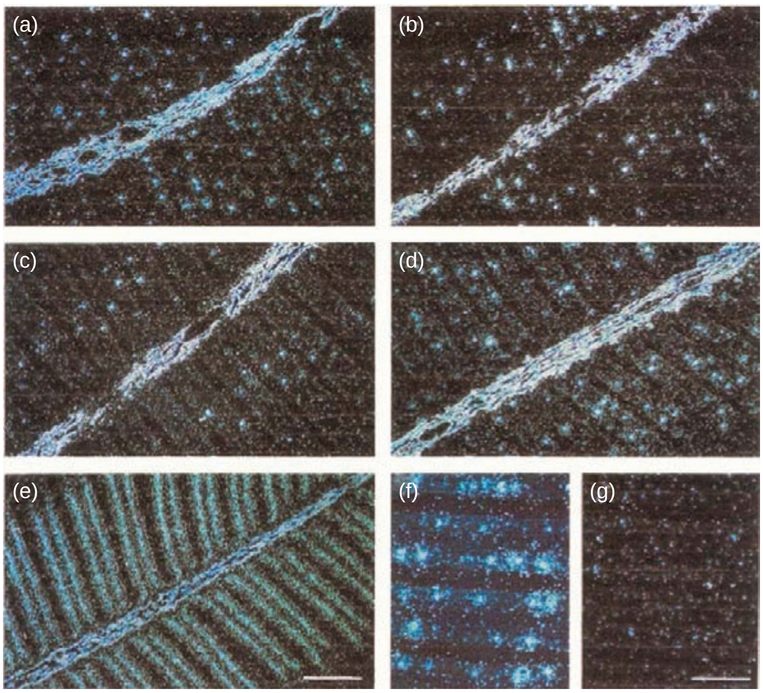

Figure 9 *In situ* hybridization experiments in channel catfish demonstrating that the four receptor subfamilies are expressed in different and largely nonoverlapping subsets of neurons, suggesting that each neuron expresses one or a few receptors. Adapted from Ngai *et al.* (1993).

Olfactory Bulb and Central Projections

The Olfactory Nerve

The axons of the olfactory neuron are unmyelinated, pass through the lamellae, and form the olfactory nerve, fila olfactoria (cranial nerve 1). They are centrally directed axons of the receptor neurons, arise in the nasal mucosa, where they make synaptic contact and terminate in the olfactory bulb. In carp (*Cyprinus carpio*), the olfactory nerve consists of two main bundles, medial and lateral. The medial bundle is derived from the more rostral lamellae, while the lateral from more caudal lamellae. The fibers of the two bundles often cross before they reach the olfactory bulb so that fibers from each reach all parts of the bulb. A number of large scattered ganglion cells lie between the two olfactory nerve bundles, forming the ganglion of the nervus terminalis, or terminal nerve (TN). Dendrites from these cells run mesad to form a bundle of fibers on the mesad aspect of each olfactory bulb. In rainbow trout, subsets of receptor neurons enter the bulb segregated and project to specific regions of the glomerular layer. The olfactory fibers are extremely small (~0.14 μm), and do not branch until they terminate. The length of the nerves varies depending upon the relative positions of the olfactory bulb in different species. The olfactory nerves do not increase in number by mitosis in the post-embryonic stage. However, they do regenerate after degeneration of the olfactory epithelium or nerve. Generally, there are two types of position: (1) the olfactory bulbs are located close to the noses, the olfactory nerves are very short, and long olfactory tracts are present (cyprinids, ictalurids, and silurids) and (2) the bulbs are close to the hemispheres of the forebrain so that long olfactory nerves are present (eels, salmonids, and majority of teleosts).

The Olfactory Bulb

The olfactory bulb is the first relay station receiving the primary olfactory nerve inputs and sending its output signals to target areas in the telencephalon and diencephalon. The organization of the teleost olfactory bulb is basically similar to that of other vertebrates, with variations in differentiation of neuronal elements and development of intra-bulbar local circuitry. Thus, evolutionarily, the olfactory bulb may be one of the most conserved regions of the vertebrate central nervous system. As in all vertebrates, the fish olfactory bulb shows a concentrically laminated structure. Generally, four layers are recognized from superficial to deep: (1) olfactory nerve layer, (2) glomerular layer, (3) mitral cell layer, and (4) internal or granule cell layer. Bundles of olfactory nerve fibers are interwoven in the outermost layer of the bulb. However, the individual nerve fibers do not branch before entering the glomeruli, which are regular in size and shape. The glomeruli, well-defined spherical bodies, may be the most distinctive feature of the olfactory bulb. Important synaptic interactions between the primary and secondary olfactory neurons, mitral cells, take place in the glomeruli, suggesting physiological significance. As mentioned above, the incoming olfactory nerve fibers do not divide before entering the glomeruli, although they branch freely within them. Hence, the axon of a receptor neuron does not terminate in more than one glomerulus, and each glomerulus receives impulses from a segregated and independent collection of ORs, indicating that glomeruli are discrete functional units. This indicates that point-to-point connections like those seen in the visual system (the retinal–tectal projection) do not exist in the epithelium bulb projection.

Fish mitral cells, though comparable in every respect with those of other vertebrates, have several main dendrites reaching out to branch in two or more glomeruli and can also contact diffuse olfactory neuronal terminal fields. Recent study shows that the majority of zebrafish mitral cells innervate a single glomerulus rather than multiple glomeruli, a feature similar to mammalian mitral cell system. Mitral cell dendrites receive numerous synaptic inputs from the olfactory nerve, where they form excitatory synapses, and at the same time they make numerous dendro-dendritic reciprocal synapses (excitatory to and inhibitory from) with the granule cells. Another cell type, ruffed cells, also occurs in some teleosts; they make synaptic contacts with other cell types including the primary olfactory neurons, suggesting a distinct function. Unlike higher vertebrates, the mitral cells of fish can also contact diffuse olfactory neurons terminal fields. These aglomerular plexii seem to be unique to fish.

In higher vertebrates, the accessory olfactory bulb is clearly separable from the main bulbar formation. It forms its own eminence on the lateral surface of the forebrain between the bulb and the hemisphere but of variable size according to the degree of development of the vomeronasal formation. Microscopically, it resembles the main olfactory bulb, except that the mitral cells are more scattered in the accessory bulb and a definite inner plexiform layer is lacking. Like in the fish olfactory bulb, each mitral cell has two, three, or more dendrites ending in the glomeruli. *In situ* hybridization and Northern blot analyses show that the vomeronasal sensory neurons express a transduction cascade distinct from that in the olfactory epithelium. Some consider that the fish pattern of mitral cell glomerular innervation is reminiscent of the mammalian accessory olfactory bulb.

The fact that the architecture of the glomerular population in vertebrates is highly stereotyped is an important aspect of information processing in olfaction. The number of glomeruli per olfactory bulb in teleosts ranges from

80 to several hundreds. The zebrafish olfactory bulb has about 80 glomeruli, of which 22 are identifiable individually by their characteristic position and morphology. Although the goldfish olfactory bulb contains many more glomeruli, their distribution pattern is essentially bilaterally symmetrical. In rainbow trout, subsets of olfactory neurons that are widely distributed and intermingled with the other receptor neurons in the olfactory epithelium and nerve segregate as they enter the olfactory bulb, where most axons terminate in nine discrete terminal fields in the glomerular layer, except a few that project into the ventral medial telencephalon. Recent *in situ* hybridization studies in channel catfish (*Ictalurus punctatus*) also show that a specific OR neuron is distributed evenly all over the epithelium. If this is the general case, a particular olfactory glomerulus would process olfactory information derived from only very few or one receptor types.

Olfactory Tract and Central Projections

The secondary olfactory projections originate in the large mitral cells of the olfactory bulb and generally run in the lateral and medial olfactory tract. Almost 100 years ago, Sheldon (**Figure 10**) described that in carp the lateral olfactory tract is mainly formed by projection fibers from the lateral part of the olfactory bulb, while the medial olfactory tract carries most fibers from the medial olfactory bulb (cf. **Figure 8**). In goldfish, the lateral tract consists of 10–14 fasciculi, in which myelinated fibers (mean diameter 0.7 μm) are prominent, whereas the medial tract contains two large fasciculi containing numerous unmyelinated nerve fibers (mean diameter 0.17 μm) as well as myelinated fibers.

Generally, the lateral olfactory tract projects to the dorsal part of the posterior telencephalon, with a small branch running ventrally in the telencephalon. The medial olfactory tract has two major branches, the dorsolateral and ventromedial bundles. The latter exclusively innervates the ventral telencephalon, preoptic area, and the diencephalon. The dorsolateral bundles terminate in various areas of the dorsal and ventral telencephalon as well as the preoptic area and the diencephalon. A significant portion of the olfactory tract fibers projects contralaterally through different commissures. The contralateral bulb and the anterior commissure also receive an input from the olfactory bulb. Centrifugal connections from the telencephalon to the olfactory bulb also run in the medial part of the medial olfactory tract. In goldfish, electrical stimulation of the opposite olfactory bulb or the anterior

commissure depresses both intrinsic and afferent-evoked olfactory bulbar activities, while sectioning of the olfactory tract results in augmentation of the bulbar activities evoked by chemical stimulation. All of these results suggest that olfactory bulbar responses to the normal afferent stimuli can be modulated by influence from the other bulb and from more posterior parts of the brain.

Little has been established about the central neural pathways of the fish olfactory system. The third-order neurons in the olfactory bulb have not been clearly identified in any fish species. However, one thing is certain, the central olfactory pathways of fishes are believed to be quite different from mammals. This is primarily because the teleostean telencephalon is dominated by eversion of pallial masses, instead of evagination as in other vertebrates, making the identification of major pallial and subpallial division difficult. However, there is growing evidence supporting the hypothesis that the teleostean dorsal telencephalic area, homologous to olfactory cortex, represents the pallium, whereas the ventral telencephalic area represents the subpallium. The latter is connected reciprocally to the hypothalamus, suggesting its involvement in the control of reproductive physiology and behavior. In channel catfish, a simple odotopy, the spatial mapping of different odorants, is maintained above the level of the olfactory bulb, in which feeding cues, amino acid responses are represented in the lateral pallial, whereas bile acid signals are represented in the medial forebrain centers, homologous to portions of amygdala. Recent genetic labeling studies in zebrafish, however, show that the topographic odor map in the olfactory bulb is not maintained intact, but reorganized in higher olfactory centers. Individual mitral cells project axons to multiple target regions in the forebrain, and those innervating the same glomerulus do not necessarily display the same axon trajectory.

Extrabulbar Projections of Olfactory Nerves

The olfactory system is not uniform; not all olfactory neuronal axons terminate in the olfactory bulb. In many fish species, a small subset of these neurons project directly to the forebrain bypassing the bulb and enter the ventromedial telencephalon. An electron microscopic study shows that the medial olfactory tract of carp contains numerous fine unmyelinated nerve fibers. Extrabulbar olfactory fibers of brown trout run in the medial olfactory tract and project to the ventral and commissural nuclei of the area ventralis telencephali, the periventricular preoptic region, the organum vasculosum laminae, and the postoptic hypothalamus. These studies strongly suggest that these extrabulbar fibers, and not the TN, are the primary mediators of neuroendocrine responses to pheromones. In support of this, a population of chemosensory cells responsive to a putative pheromone is located in the ventromedial area that links the olfactory bulb to the telencephalon. The existence of the extrabulbar olfactory fibers is consistent with earlier findings that olfactory stimulation directly activates hypothalamic neurosecretory cells in goldfish (**see also Smell, Taste, and Chemical Sensing**: Morphology of the Gustatory (Taste) System in Fishes). The olfactory–endocrine neuronal pathway seen in fishes may possibly be a ascendant of the olfactory afferent-GnRH (LHRH) neuronal system recently described in mice, in which a small population of olfactory sensory neurons located in a medial zone of the olfactory mucosa is the major conduit of pheromonal cues that regulate GnRH synthesis and release.

Concluding Remarks

Although the basic plan of the olfactory organ of fishes is consistent throughout all fishes, its developmental and molecular anatomical characteristics exhibit great diversity. OR neurons are the only neurons that transmit information from the outside world directly onto the brain, and yet they turn over considerably, unlike any other vertebrate neurons. The fish olfactory system, unlike in mammals, does not possess the vomeronasal system, but instead has three types of receptor neurons, ciliated, microvillar, and crypt. Crypt cells are a common feature of actinopterigian fishes. Cilia and microvilli cells both surround the apical surfaces, which are not directly open to the outside lumen. There is little evidence to suggest that fish microvillar cells are homologous to tetrapod vomeronasal cells, or that the fish ciliated cells are homologous to tetrapod olfactory neurons.

The axons of olfactory neurons project to the ipsilateral olfactory bulb, where they form synapses with mitral cells within glomeruli, forming a discrete functional unit. The olfactory bulb also receives centrifugal fiber inputs from the contralateral bulb as well as from higher brain structures. In addition, a subset of olfactory primary neurons projects directly to the forebrain bypassing the bulb, creating two olfactory subsystems. Thus, olfactory bulb-derived signals may ultimately reach multiple brain regions, including the cortex, the presumed location of conscious perception of odors leading to behaviors such as feeding, whereas extrabulbar signals are targeted to hypothalamic structures that are implicated in reproductive physiology and behavior.

Molecular biological findings suggest that fish olfactory C-family GPCRs have evolved to detect and discriminate a spectrum of amino acids, and have diverged significantly from a common ancestral gene with mammals. Current research is actively pursuing the molecular identities and cellular mechanisms that underlie amino acid sensing. Binding of amino acids with ORs depends on highly conserved residues in the N-terminal domains that bind the α-amino and α-carboxylate functional groups.

The development of conditioned knockout fish GPCRs, for example, the goldfish 5.24 that selectively lacks amino acid sensitivity will allow the systematic analysis of the key physiological issues in fish olfaction.

Glossary

Amino acids Molecules with an amine group, a carboxylic group, and one of 20 R groups that are the building blocks of proteins.

Bile acids Steroid acids found predominantly in the bile of vertebrates. The two major bile acids are cholic acid and chenodeoxycholic acid.

Epitope Any site on an antigen molecule at which an antibody can bind.

Heterologous expression Expression of a gene in a cell that normally does not express that gene.

Kynurenine An amino acid that is a metabolite of another amino acid, tryptophan.

Odorant A chemical that binds to and stimulates an olfactory receptor.

PGFs Specific types of prostaglandins that act as odorants.

Prostaglandins Any of various oxygenated fatty acids of animals that are formed as cyclooxygenase metabolites, especially from unsaturated fatty acids composed of a chain of 20 carbon atoms, and that perform a variety of hormone-like actions.

Tuned The extent to which a receptor is specialized to respond to a specific chemical stimulus. Broadly tuned receptors respond to a variety of chemical stimuli.

Zwitter ion An ion with both a positive and a negative charge.

Olfactory Signal Transduction

The initial event of olfaction is binding of an odorant molecule with a specific membrane receptor located in the cilia or microvilli of the olfactory receptor neuron. The molecular era of research into olfaction and gustation came of age in 1991 with the discovery of a large multigene family encoding odorant receptors (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction and Morphology of the Olfactory (Smell) System in Fishes). The olfactory receptor gene families are extremely large; in mammals they appear to contain 500–1000 genes, whereas the gene family of fish contains about 100 genes. Each neuron expresses only a single receptor gene. Transgenic and *in situ* hybridization studies in fish have identified mammalian and nonmammalian types of receptor genes in several fish species. A direct demonstration that one member of these gene families could initiate a physiological response to odorants was achieved by expression in heterologous cells (i.e., cells that normally do not express olfactory genes) in goldfish (*Carassius auratus*).

The molecular olfactory receptors thus expressed are G-protein-coupled seven transmembrane proteins, which exhibit seven hydrophobic domains that are likely to serve as membrane-spanning α-helices (**Figure 1**). The transmembrane domains that show exceptional diversity are believed to be involved in ligand binding. The binding of odorant molecules to receptors induces a transduction cascade that ultimately leads to depolarization of the neuron and action potential generation in the olfactory axon. A variety of receptor-mediated transduction events are known. Fish use at least two processes: one that alters the concentration of second messengers, mediated most probably by guanosine 5′-triphosphate-binding proteins (G-proteins), and another that affects intracellular ionic activity via stimulus-gated ion channels. Odorant binding to receptor in the membrane activates G-proteins that stimulate the activity of adenylcyclase (AC) in olfactory cilia. AC generates cyclic AMP (cAMP) from ATP, which directly gates an ion channel in the membrane, allowing influx of Na and Ca ions (**Figure 1**). This leads to change in membrane potential which results in action potential generation in the axons. This transduction scheme is

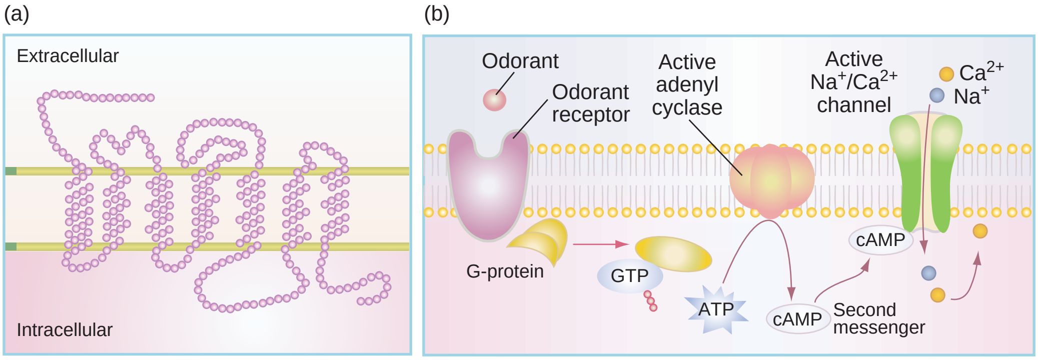

Figure 1 Diagrams representing seven transmembrane domain structure of an olfactory receptor (a), and olfactory signal transduction pathway in vertebrates (b). An odorant interacts with an odorant receptor, resulting in G-protein activation, stimulation of adenyl cyclase activity, opening of a cyclic-nucleotide gated channel by elevated cAMP levels, influx of cations and depolarization. widely distributed among vertebrates. In teleosts, two other second messengers, inositol triphosphate (IP_3) and diacylglycerol (DAG), are also involved in transduction. However, the particular transduction pathways associated with specific odorants are largely unknown.

Potency and Specificity of Olfactory Stimuli

To date, four main classes of chemical compounds have been identified as specific olfactory stimuli (odorants/pheromones) for fish and their stimulatory effectiveness characterized: amino acids, bile acids, sex steroids, and prostaglandins (PGs). These four odorant classes, detected by separate receptor types, are typically nonodorous to humans. Of these, amino acids are by far the most widely studied chemicals in fish olfaction. Their high sensitivity and specificity for the fish olfactory system have been shown in more than 20 fish species. Two less well-characterized chemical groups are nucleotides and polyamines. For the ultimate understanding of the molecular basis of the physiological responses, it is essential to rigorously characterize the receptor–response systems *in vivo*.

Amino Acids

At physiological pH values, amino acids exist naturally in a zwitterion state, with the carboxylic acid moiety ionized and the basic amino group protonated. The entire class of amino acids has a common backbone of an organic carboxylic acid group and an amino group attached to a saturated carbon atom. The simplest is glycine, in which the saturated carbon atom is unsubstituted, rendering it optically inactive. The rest of the 20 most common amino acids are optically active and exist as both D- and L-stereoisomers. Naturally occurring amino acids are, for the most part, the L-isomers. Amino acid side chains are polar, nonpolar, or practically neutral.

Electrophysiological and optical imaging studies in salmonids, channel catfish (*Ictalurus punctatus*), and zebrafish (*Danio rerio*) show that: (1) only α-amino acids are stimulatory at biologically relevant concentrations, (2) the natural L-isomer of an amino acid is significantly more stimulatory than its D-isomer, (3) ionized α-amino and α-carboxyl groups are required, (4) the α-hydrogen of an amino acid must be free, and (5) the size and polar nature of the fourth α-moiety are important factors for stimulatory effectiveness (**Figure 2**). The amino acids effective as odorants are thus characterized by being simple, short, and straight chained, with only certain substituent groups.

The olfactory spectrum of amino acids is generally similar across all fish species examined. An amino acid receptor model involving two charged subsites, one anionic and the other cationic, capable of interacting with ionized amino and carboxylic groups of stimulant amino acid molecule is hypothesized. Biochemical evidence for the existence of such binding sites came from studies on binding experiments using radioactively labeled amino acids on an isolated olfactory preparation from trout. Physical parameters such as saturability, reversibility, affinity, and quantity of binding sites are reasonably consistent with receptor criteria. In addition, good agreement between the rank order of binding and electrophysiological potency further supports the conclusion that binding data reflect the interaction of amino acids with physiologically relevant receptors. Amino acids assert their activities through multiple receptor systems; note, for example, that in **Figure 2** cysteine, glutamate, and arginine evoke different maximal effect, suggesting the involvement of different receptor-mediated physiological functions.

All lines of experimental evidence indicate that in channel catfish, Arctic char (*Salvelinus alpinus*), and rainbow trout (*Onchorynchus mykiss*) at least three receptor types

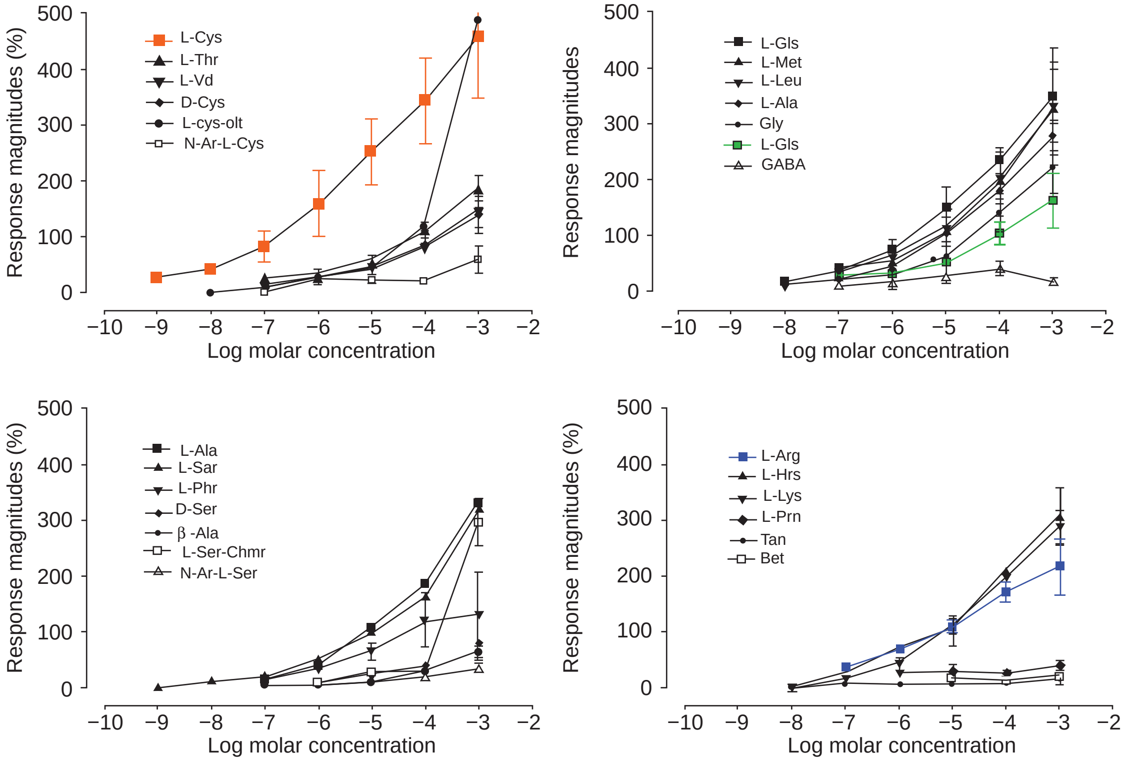

Figure 2 Concentration–response (*C–R*) relationships of EOG responses of rainbow trout to amino acids and related chemicals (arbitrarily grouped). Note that neutral amino acids (represented by cysteine; red), glutamate (green), and arginine (blue) evoke different maximal responses. L-Cys-OMe, L-cysteine methyl ester; N-Ac-L-Cys, *N*-acetyl-L-cysteine; GABA, γ-aminobutyric acid; Tau, taurine; Bet, betaine. Modified from Hara (2005) Olfactory responses to amino acids in rainbow trout: Revisited. In: Reutter K and Kapoor BG (eds.) *Fish Chemosenses*, pp: 31–64. Enfield, NH: Science Publishers.

(cysteine- (or, neutral amino acid-), arginine- (or, basic guanidine-containing amino acid-), and glutamate- (or, acidic amino acid-) receptor types) exist, which play dominant roles in the discrimination of amino acids (**Figure 3**). Specific binding of alanine of the salmonid olfactory preparation is inhibited by neutral amino acids, but only partially by arginine or glutamate. Each receptor recognizes the characteristic features, or epitope, of an amino acid molecule, including (1) hydrocarbon chain length, (2) difference in functional groups, and (3) position of functional groups. Although the three receptor types are quite specific under the natural condition, because all amino acids have some of these features in common (generic structural plan), they could all function as partial agonists, activating all available receptors depending on their affinities and concentrations. For example, the cysteine receptor is activated not only by its primary ligand cysteine, but also by other neutral amino acids including alanine, glutamine, and methionine, with lesser affinities, and generates receptor potentials accordingly. Also, electrophysiological and binding analyses show that the cloned goldfish olfactory receptor 5.24 is preferentially tuned to recognize basic amino acids; of 20 amino acids tested for competition binding, arginine and lysine have the highest affinities, suggesting that this receptor may in fact represent an Arg-, or more generally guanidino-containing amino acid receptor for this species. This would verify the existence of the Arg-receptor predicted electrophysiologically earlier in salmonids. It should be noted that the 5.24 receptor shares amino acid sequence identity to mammalian pheromone receptors, the Ca-sensing receptors, the T1R taste receptors, and the metabotropic glutamate receptors (mGluRs).

Recently, kynurenine, a metabolite of tryptophan and technically an amino acid, released by ovulating female masu salmon has been found to be a potent olfactory stimulant for spermiating males, with an amazingly low detection threshold of 10^{-14} M. Even immature or sexually regressed males as well as ovulated females detect it at 10^{-12}–10^{-10} M. The urine of the reproductively mature female masu salmon contains high levels of kynurenine that is released into the water at a rate of 0.40×10^{-6} mole/female per hour, where it is thought to act as a male-attracting pheromone (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior). Whether this is a reproductive pheromonal cue specific for this salmonid species and behaves like ordinary amino acid odorants await future study.

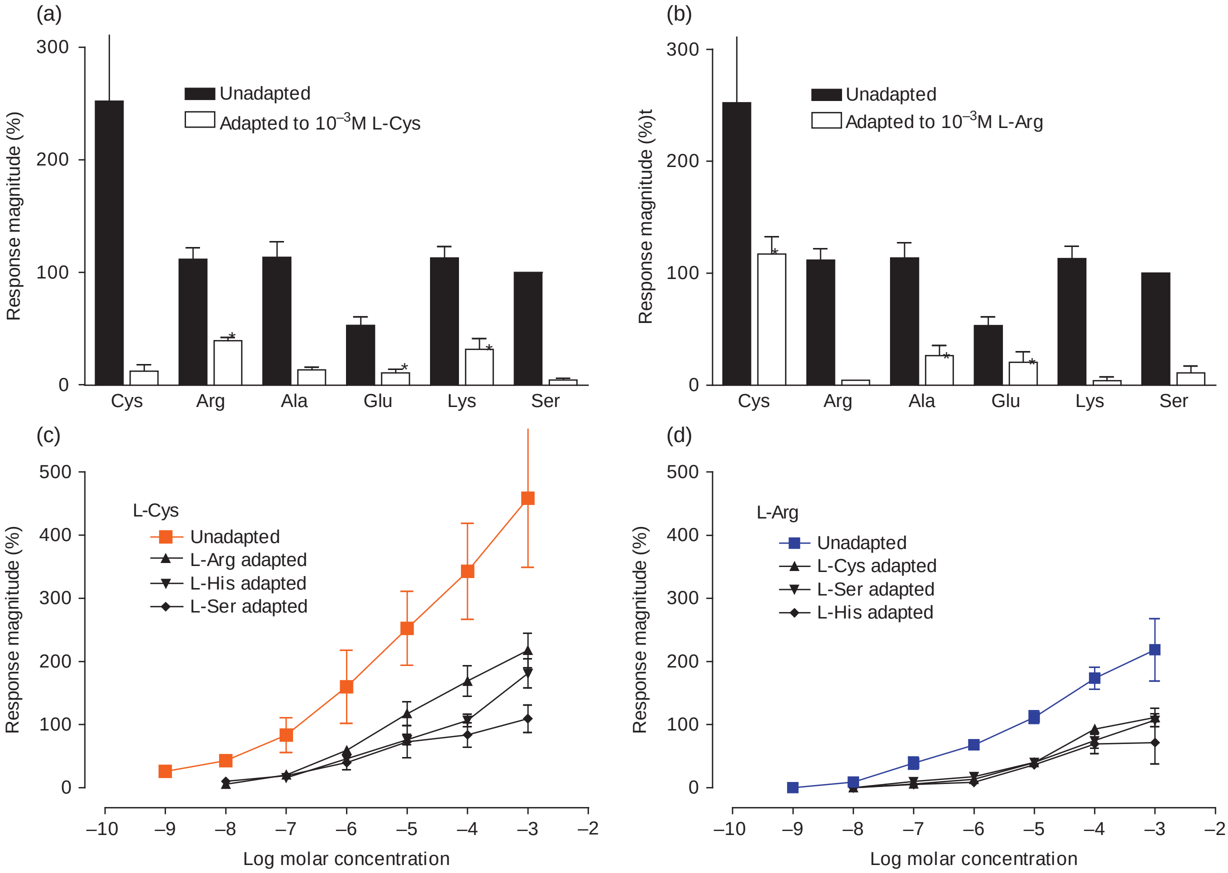

Figure 3 Bar graphs (top) show inhibition of selected amino acids when adapted (pretreated) to cysteine (a) or arginine (b). Effects of adaptation to various amino acids on C–R relations of cysteine (c) and arginine (d) (bottom). Modified from Hara (2005) Olfactory responses to amino acids in rainbow trout: Revisited. In: Reutter K and Kapoor BG (eds.) *Fish Chemosenses*, pp: 31–64. Enfield, NH: Science Publishers.

Bile Acids

Bile acids, synthesized in the liver from cholesterol, are a family of structurally related sterols. They are essential for food digestion and various aspects of organic and anionic transport in the digestive system, which are then either resorbed or released to the environment. Bile acid composition and conjugation pattern are markedly different in various animals; however, closely related species tend to have similar bile acids. In teleosts, 5α-cyprinol is widely produced in ostariophysians, whereas in salmonids taurocholic acid and taurochenodeoxycholic acid are released. Lake char (*Salvelinus namaycush*), for example, release an average of 4 nmol min^{-1} bile acids per kg of body weight via feces into water.

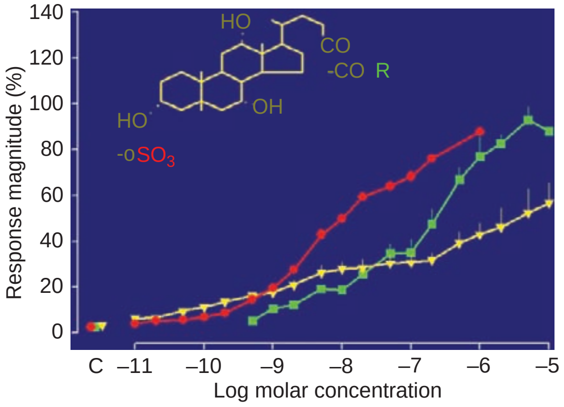

Figure 4 Concentration–response relationships for chenodeoxycholic acid (yellow), taurocholic acid (green) and taurolithocholic acid 3α-sulfate (red), representing respectively free, amidated, and sulfated bile acids. Inset: structural formula of cholic acid, a typical bile acid in vertebrates.

High olfactory sensitivity and specificity to bile acids have been shown in salmonids, zebrafish, and channel catfish. In lake char, 9 out of 38 bile acids tested are detected at thresholds 2×10^{-11}–5×10^{-10} M (**Figure 4**). The most stimulatory include chenodeoxycholic acid, cholic acid, taurochenodeoxycholic acid, and taurolithocholic acid 3α-sulfate. Structure–activity analysis indicates that substituents in the side chain or hydroxyl sulfation are determinant elements for the recognition of individual bile acid receptors, while the position and orientation of hydroxyl or the type of amidation are important for effective stimulation. Lake char also detect petromyzonol sulfate, a sea lamprey (*Petromyzon marinus*) bile acid, at 10^{-9} M. The *C–R* relationship, cross-adaptation, and binary mixture studies suggest that the detection of bile acids is mediated by at least four receptor subtypes: free-, amidated-, 3a-sulfated-, and petromyzonol-like bile acid receptors. These bile acid receptors are specific and independent of olfactory receptors for other known fish odorants, including amino acids, PGs, and gonadal steroids. Petromyzonol sulfate is detected by its own highly specific and independent receptor site in the sea lamprey. Besides petromyzonol sulfate, of 10 bile acids tested allocholic acid is the most potent bile acid in this species.

Gonadal Steroids

Steroid hormone, 17*α*,20*β*-hydroxy-4-pregnen-3-one (17,20P), promotes oocyte final maturation in preovulatory female goldfish and functions as a pheromone that stimulates serum gonadotrophin (GtH) release, enhanced sperm production, and sexual arousal in mature males. Little is known about exactly how these hormonal pheromones are released in any fish species. Of the 24 sex steroids tested for olfactory stimulatory effectiveness in goldfish, 17,20P is the most stimulatory, with a detection threshold of 10^{-13} M, and at a concentration of 10^{-8} M elicits an electro-olfactogram (EOG) response 3 times that elicited by 10^{-5} M L-serine (**Figure 5**). Mature male and female as well as gonadally regressed fish respond to all compounds tested, suggesting that differences in olfactory receptor functions are not responsible for the fact that only mature males exhibit behavioral and endocrine responses to pheromonal 17,20P.

The olfactory responsiveness to steroid hormones seems to be highly species specific; only members of Cyprinidae (11 species), including common carp (*Cyprinus carpio*) and crucian carp (*Carassius carassius*), detect any of the steroids. Interestingly, crucian carp show high gender specificity; most olfactory bulb neurons in males respond exclusively to one of the steroids, but females show little responsiveness. No olfactory sensitivity to steroid hormones in salmonids has been shown, except that precocious male Atlantic salmon (*Salmo salar*) become acutely sensitive to testosterone, with a threshold concentration of 10^{-14} M, and, amazingly, only during October of the year. In African catfish (*Clarias gariepinus*), some steroid glucuronides found in the male seminal vesicles stimulate the female olfactory system, at a threshold 10^{-11} M. These fish are insensitive to 17,20P.

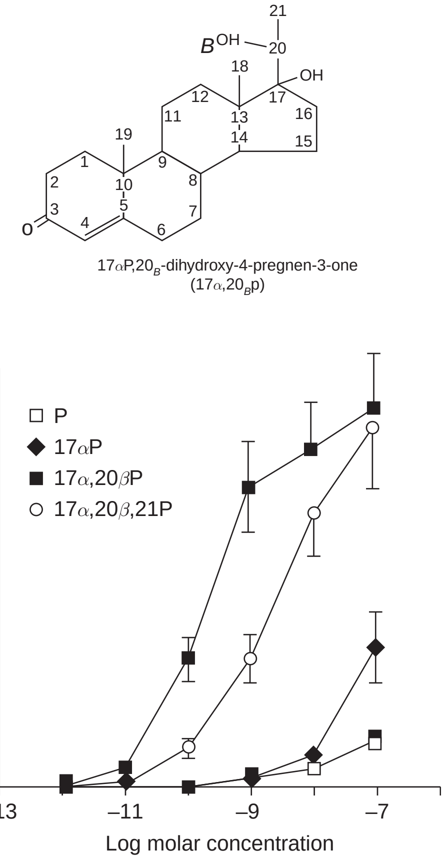

Figure 5 Electro-olfactogram responses to progesterone (P), 17*α*-hydroxyprogesterone (17*α*P), 17*α*,20*β*-dihydroxyprogesterone (17*α*,20*β*P), and 17*α*,20*β*,21-trihydroxyprogesterone (17*α*,20*β*,21P) recorded from mature male goldfish. Inset: structural formula of 17*α*,20*β*P. Adapted from Sorensen PW, Hara TJ, Stacey NE, and Dulka JG (1990) Extreme olfactory specificity of male goldfish to the preovulatory steroidal pheromone 17*α*,20*β*-dihydroxy-4-pregnen-3-one. *Journal of Comparative Physiology* A 166: 373–383.

Prostaglandins

To date, 14 cyprinids, 4 catostomids, 4 salmonids, and 1 cobitid are known to have acute olfactory sensitivity to PGs. F-type $PGF_{2\alpha}$, and its metabolites, for example, are released into the water by ovulating female goldfish, where they function as a pheromone that triggers male courtship. Of the PGs tested, $PGF_{2\alpha}$ and 15-keto-$PGF_{2\alpha}$ are the most potent, detected at a threshold of 10^{-10} and 10^{-12} M, respectively. Goldfish have separate olfactory receptor sites for $PGF_{2\alpha}$ and 15-keto-$PGF_{2\alpha}$ that are independent from those that detect other olfactory stimuli (**Figure 6**). In a Japanese cobitid (*Misgurnus anguillicaudatus*), ovarian $PGF_{2\alpha}$ increases during ovulation, and males show sexual behavior toward females as well as unovulated females treated with PGFs. These fish detect PGFs at thresholds between 10^{-13} and 10^{-10} M, and exhibit extremely high EOG response magnitudes; at 10^{-7} M they induce 8–12 times that of 10^{-5} M L-serine.

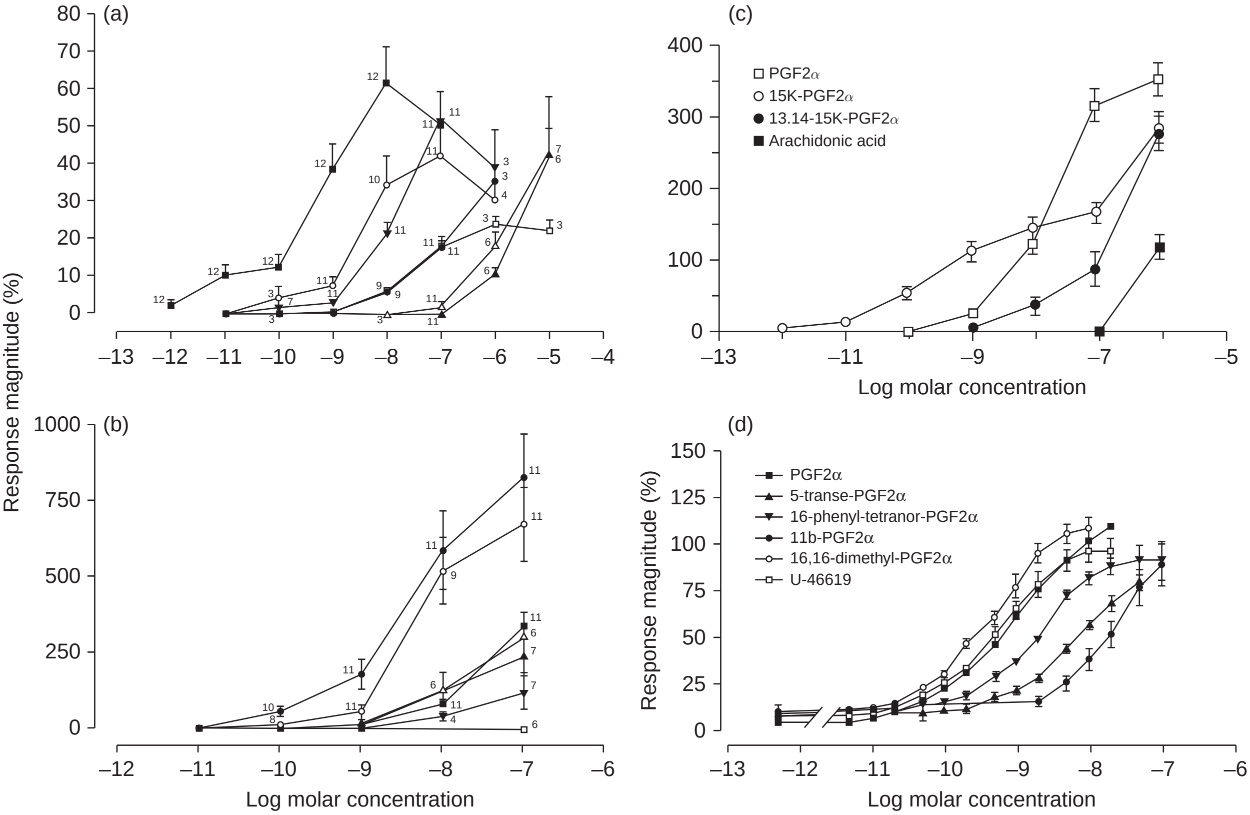

Figure 6 Electro-olfactogram responses to prostaglandins recorded from (a) male goldfish, (b) Arctic char, (c) brown trout, and (d) lake whitefish. Adapted from (c) Sorensen *et al.* (1989) and (d) Sveinsson and Hara (2000), and (a and b) Laberge F and Hara TJ (2003) Behavioural and electrophysiological responses to F-prostaglandins, putative spawning pheromones, in three salmonids fishes. *Journal of Fish Biology* 62: 206–221.

In Arctic char (*S. alpinus*), lake whitefish (*Coregonus cluperformis*), and brown trout (*Salmo trutta*), PGs play important behavioral roles. Of 19 PGs and analogs tested in Arctic char, PGF_{2a}, 16,16-dimethyl-PGF_{2a}, and U-46619 are the most stimulatory (thresholds, 10^{-9}–10^{-8} M). No differences exist in the olfactory sensitivity and specificity for PGFs at different stages of sexual maturity. PGFs are released by ripe male Arctic char on the spawning grounds to attract females and stimulate digging behavior. Brown trout are most sensitive to PGF_{2a} with a threshold of 10^{-11} M, while lake whitefish are most sensitive to both 15-keto-PGF_{2a} and 13,14-dihydro-PGF_{2a}. Cross-adaptation and binary mixture experiments show that only one olfactory receptive mechanism is involved. Exposure to PGFs increases locomotor activity in both lake whitefish and brown trout; female brown trout exhibit digging and nest probing behavior. Most interestingly, PGFs are potent stimuli for these salmonids when measured by EOG, but they do not induce electroencephalogram (EEG) responses in the olfactory bulb (**Figure** 7). The synaptic responses due to the hormonal pheromones in the olfactory bulb may be asynchronous, because the recorded EEG response in the bulb reflects a synchronized activity of a number of synapses. Alternatively, olfactory responses to hormonal pheromones are mediated by extrabulbar primary olfactory fibers that bypass the bulb.

Noticeably, all salmonids tested, including rainbow trout, amago salmon (*Oncorhynchus rhodurus*), sockeye salmon (*O. nerka*), and possibly masu salmon (*O. masou*), excluding Japanese ayu (*Pleccoglossus altivelis*), lack the olfactory sensitivity to PGs. It is also striking that in lake whitefish, in contrast to other odorant classes, a distinct neural structure exists in the olfactory bulb-telencephalon area, through which PGF signals are integrated. Also, the olfactory signals due to sex steroids and PGFs are mediated by the medial olfactory tracts in goldfish. These results provide evidence for the existence of the two functional olfactory subsystems in fish, one for odorants and the other for pheromones, as seen in mammals. Olfactory signals from pheromones are processed in a manner distinct from those for odorants such as amino acids and bile acids, and may be mediated by extra-bulbar primary olfactory fibers bypassing the olfactory bulb.

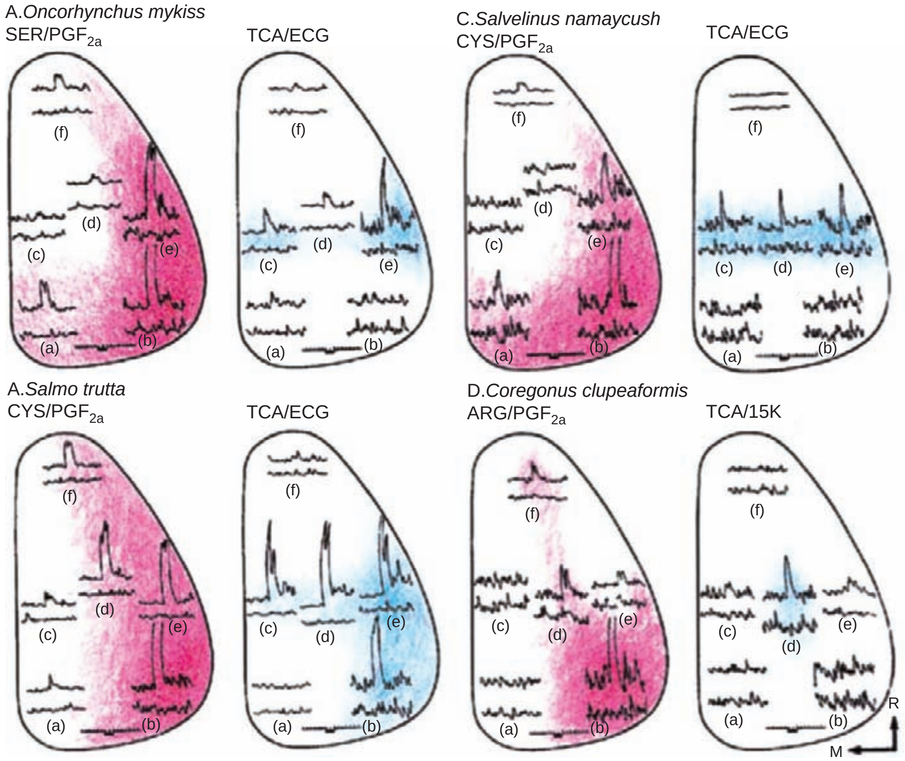

Figure 7 Spatial distribution of electroencephalographic responses to amino acids (Ser, Arg, and Cys), bile acid (TCA), prostaglandin (PGF2, 15K), and sex steroid (ECG) onto the surface of the right olfactory bulb in rainbow trout, brown trout, lake char, and lake whitefish. Recordings are made at six positions: (a) medioposterior, (b) lateroposterior, (c) mid-medial, (d) central, (e) mid-lateral, and (f) rostral. R, rostral; M, medial. Modified from Hara TJ and Zhang C (1998) Topographic bulbar projections and dual neural pathways of the primary olfactory neurons in salmonids fishes. *Neuroscience* 82: 301–313.

Other Chemical Compounds

A new family of chemosensory receptors, called trace-amine-associated receptors (TAARs), that show amino acid sequence identity with receptors for biogenic amines (serotonin, dopamine, etc.) are present in human, mouse, and fish. As many as 57 TAARs receptors exist in zebrafish, while fugu (*Takifugu rubripes*) has only eight TAARs. In mouse, at least three can recognize volatile amines in urine, indicating they may be involved in the detection of social cues. The expansion of these genes in zebrafish is thought to have been shaped by repeated gene duplications, which makes the evolutionary history of this group of receptors more complex than for other GPCR families. In zebrafish, diamine and putrescine (1,4-diaminobutane), largely responsible for the foul odor of putrefying flesh, are nonstimulatory; whereas in goldfish, putrescine, cadaverine, and spermine are stimulatory, with thresholds of 10^{-8}–10^{-7} M, and elicit feeding behavior. Receptors for these polyamines are independent from those of amino acids, bile acids, or single amine-containing compounds. A monoamine, agmatine, the decarboxylation product of arginine, activates the olfactory systems, with thresholds 10^{-9}–10^{-8} M in goldfish, lake whitefish, and walleye (*Stizostedion vitreum*), but not in rainbow trout, brown trout, and lake char.

Morpholine, phenethyl alcohol, and hypoxanthine-3(N)-oxide have been implicated in chemosensory behaviors; however, none has been subjected to electrophysiological scrutiny (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior).

Ciliated, Microvillar, or Crypt Receptor Neurons – Functional Specialization?

Ontogenetically and morphologically different ciliated and microvillar receptor neurons generally exist in the fish olfactory epithelium. Immunocytochemically, the ciliated neuron expresses G-protein G_{olf}, whereas the microvillar expresses $G_{\alpha o}$ (**see also Smell, Taste, and Chemical Sensing**: Neurophysiology of Gustation). Electrophysiologically, no significant difference exists in membrane characteristics, including Ca^{2+}-activated Cl-conductance between the ciliated and microvillar neuron types in adult rainbow trout. The ciliated are much more abundant than the microvillar by the ratio of 11 to 1 and the latter respond specifically to amino acids (specialist) while the former respond to a wide variety of odorants (generalist). However, young developing embryos contain only ciliated neurons yet respond to both amino acid and bile acids. In goldfish, ciliated neurons regenerate before the microvillar following the olfactory nerve axotomy, and the former respond to amino acids and the latter to pheromones (e.g., PGFs). Consistent with this, *in situ* hybridization studies in goldfish suggest that odorant receptors are expressed in ciliated neurons, while pheromone receptors in the microvillar neurons. It could be confusing that odorant receptors preferentially tuned to recognize amino acid lysine and arginine, with significant similarities with some vertebrate vomeronasal organ receptors (V2Rs), are expressed in microvillar neurons.

In nonteleosts, lemon shark (*Negaprion brevirostris*) with only microvillar neurons and sea lamprey with only ciliated neurons both respond to amino acids. Taken together, there seems to be no clear-cut functional differentiation for the two neuron types; ciliated neurons respond generally to amino acids in some fish species, while the microvillar respond to pheromones in other fish species, and vice versa.

Signal Processing in the Olfactory Bulb and Telencephalon

In discussing signal coding in the olfactory bulb, it is important to recall the following two remarkable features of the axonal projection from the olfactory epithelium to the olfactory bulb: (1) individual glomeruli receive input from olfactory neurons that are distributed throughout the entire regions of the olfactory epithelium and (2) glomeruli are functional units that respond differentially to different odorants. Each odorant could elicit activity in more than one glomerulus, and the number of glomeruli involved varies among odorants and is dependent on stimulus concentration. However, higher concentrations of one same odorant could lead to the activation of more glomeruli, consequently resulting in the loss of specificity.

Odorant stimulation of nares induces large rhythmic oscillations in the olfactory bulb (induced waves; also known as EEG responses); spontaneous electrical activity (intrinsic waves) is interrupted by oscillatory waves that are terminated on cessation of the stimulus. In salmonids, EEG responses to amino acids and bile acids are induced in two segregated regions of the olfactory bulb. When olfactory rosettes are subjected to partial lamellectomy (removal of the anterior, posterior, medial, or lateral halves), both the EOGs and EEGs to these odorants are uniformly reduced and the degree of reduction does not depend on the rosette region removed, suggesting that olfactory neurons responsive to amino acids and bile acids are randomly distributed throughout the olfactory epithelium, and yet project to spatially segregated region. Furthermore, neither PGs nor sex steroids elicit EEG responses, despite strong activation of receptor neurons (**Figure 7**). In lake whitefish, a species characterized by high EOG and behavioral sensitivities to PGFs, a neuron population specifically responsive to PGs exists in the ventro-medial brain tissue strip connecting the olfactory bulb to the telencephalon. Furthermore, unlike responses to other odorants, this neuron population does not induce synchronized oscillatory waves (EEG responses) upon stimulation with PGFs, despite massive discharges. This is the first demonstration that the olfactory bulb-telencephalon area of the brain is a distinct neural structure through which putative reproductive pheromone signals are integrated.

In goldfish, by contrast, stimulation with pheromones activates olfactory neurons in the medial portion of the bulb. More precisely, in channel catfish ciliated neurons project predominantly to region of the olfactory bulb that respond to bile acid (medial) and amino acids (ventral), while microvillar neurons project almost entirely to the dorsal surface of the bulb where responses to amino acids (anterior) and nucleotides (posterior) predominate. Furthermore, gender specific bulbar chemotopy exists in crucian carp (*C. carassius*), the closest relative of goldfish, where neurons specifically sensitive to sex pheromones (17,20P, 17,20PS, androstenedione, and PGFs) are located in a central part of the ventral olfactory bulb in males. The majority of the responded olfactory bulb neurons are activated exclusively by one of the four sex pheromones. In females, of the 96 bulb neurons recorded, only one showed such a specific activation.

How is the EEG response topography established for different odorant classes correlated with olfactory bulbar neurons? Is the relatively independent amino acid receptor mechanisms maintained in the response profiles of the olfactory bulb neurons? Like rainbow trout, amino acids, bile acid, and PGFs activate independent receptor types in brown trout. Within the class of amino acids, different receptor types also are partially independent. Neurons responsive to bile acids and amino acids are segregated to the mid-dorsal and latero-posterior olfactory bulb, respectively (**Figure 8**). A majority of responsive bulb neurons (mitral cells) shows specificity for one odorant class. Neurons responsive to bile acids, though at extremely high concentrations, located in the medial region of the olfactory bulb of channel catfish are also activated by at least one member of each of the three classes of bile acids. Importantly, amino acid-responsive neurons gain responsiveness to new amino acids, or recruit more responsive neurons, with increasing stimulant concentration, resulting in the loss of the receptor specificity. A similar gradual loss of specificity in the activity patterns is also shown in zebrafish and a mammalian heterologous system. Thus, different odorant classes activate specific

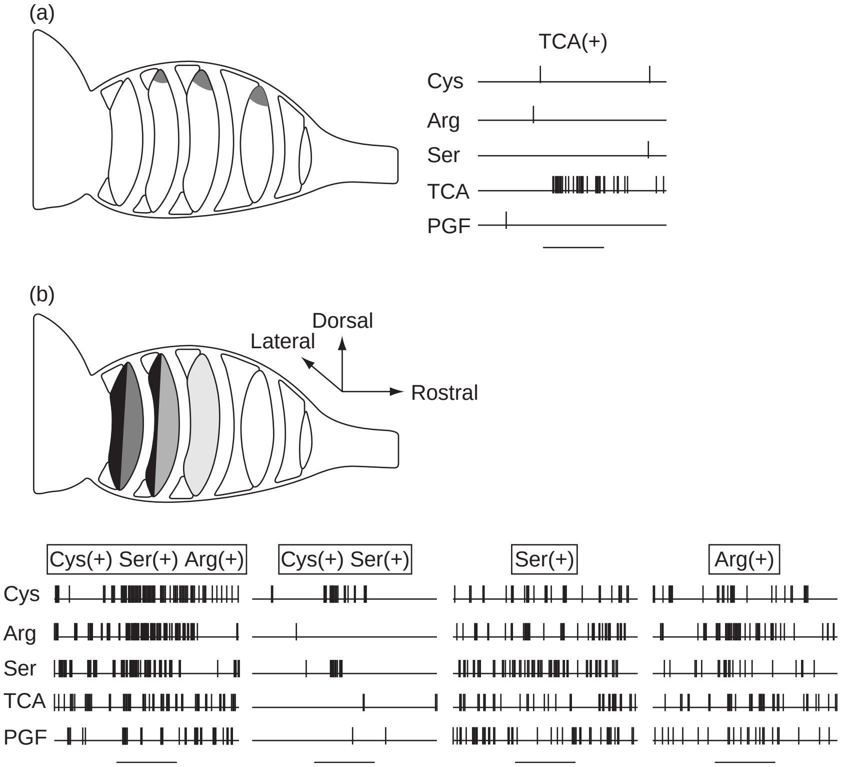

Figure 8 Distribution of bile acid (a) and amino acid (b) responsive units in the brown trout olfactory bulb. The drawings represent sections of the left olfactory bulb, the olfactory nerve to the right and the telencephalon to the left. The neuron response type is specified in boxes above the traces. Adapted from Laberage F and Hara TJ (2004) Electrophysiological demonstration of independent olfactory receptor types and associated neural responses in the trout olfactory bulb. *Comparative Biochemistry and Physiology* 137A: 397–408.

neurons located in different regions of the bulb, and that information distinguishing the related amino acids can be represented in a limited number of bulbar neurons with distinct response profiles, which could potentially encode amino acid quality. This supports, in principle, the idea that slight alterations in an odorant molecule, or a change in its concentration, can change its code, potentially explaining how such changes can alter perceived odor quality.

From the olfactory bulb, olfactory signals are transmitted to the telencephalon via the olfactory tracts. At present, little is known about how sensory information about different odorants might be projected in telencephalon. One study in channel catfish shows that a simple odotopy, the spatial mapping of different odorants, is basically maintained beyond the olfactory bulb. Amino acids are represented in lateral, pallial portion of the telencephalon, equivalent to the olfactory cortex of amniote vertebrates, whereas bile acids are represented in medial telencephalon, possibly homologous to portions of the amygdala. The teleost telencephalon receives inputs from other sensory systems and may function as a higher integrative center as in the terrestrial vertebrates.

Concluding Remarks

Olfaction begins at the olfactory epithelium, where millions of receptor neurons transduce the binding of odorant/pheromone molecules into a neural signal. The genomes of each fish species contain as many as 100 genes for olfactory receptors, with each neuron expressing only one gene. The receptor is a member of a multigene family of G-protein-coupled receptors, sharing sequence similarities with the calcium sensing, metabotropic glutamate, and vomeronasal receptors.

Considerable data on olfactory respond to several odorant classes in different fish species. How is information about an odorant's identity encoded by the olfactory system? A few attempts to identify specific odorant-receptor activation mechanisms have largely failed to identify unifying patterns, probably in part due to fish and protocol variability. To date, amino acid–receptor interactions in rainbow trout have been most studied.

The fish peripheral olfactory code is determined solely by the specific binding affinity between odorant and its specific receptor. Each odorant is recognized by a single receptor, and not combination of receptors, with one receptor to one glomerulus. Morphologically distinct neuron types use different transduction cascades and maintain distinct patterns of projections to the olfactory bulb. As a consequence, each odorant is represented spatially in the olfactory bulb by a unique combination, or ensemble, of glomeruli. Each glomerulus could serve as part of the code for numerous different odorants, thus providing for the discrimination of a vast variety of different odors. This contrasts with the mammalian model in which each odorant is recognized by a variety of olfactory receptors, many of which recognize different structural features of the odorant.

The olfactory system of fish, the only vertebrate group in which the sensitivity and specificity data are available for specific ligands, provides an excellent starting point for the molecular characterization of odorant receptors. For example, the 5.24 odorant receptor is an amino acid-sensing receptor expressed in the olfactory epithelium of goldfish not tuned broadly to detect all 20 naturally occurring amino acids. This is why goldfish 5.24 and its ortholog from zebrafish, receptor ZO6, have very different ligand specificities.

Glossary

Amino acids Molecules with an amine group, a carboxylic group, and one of 20 R groups that are the building blocks of proteins.

Bile acids Steroid acids found predominantly in the bile of vertebrates. The two major bile acids are cholic acid and chenodeoxycholic acid.

Channels Proteins located in cell membranes that control the movement of ions across the membrane.

Gustation The sense of taste.

Response magnitude The intensity or size of the response of a receptor to a stimulus, in this case the response to a chemical stimulus.

Tuned Refers to the extent to which a receptor is specialized to respond to a specific chemical stimulus. Broadly tuned receptors respond to a variety of chemical stimuli.

Responses to Chemical Stimuli

General

The pioneering recordings of electrical responses of facial nerve in response to various stimuli in bullhead catfish (*Ameiurus nebulosus*) by Hoagland in 1933 clearly demonstrated that the fish gustatory systems are very sensitive to mechanical stimuli (touch and water current) but generally insensitive to the classical vertebrate taste stimuli (salts, sugar, and acids). Subsequent studies over the last several decades show that fish gustatory receptors are stimulated by dilute aqueous solutions of low-molecular-weight substances, including amino acids, peptides, and steroids. Of these, amino acids are by far the best-studied gustatory chemicals for fish. Even so, response spectra for amino acids vary considerably among fish species, in contrast to those of the olfactory system (**see also Smell, Taste, and Chemical Sensing**: Neurophysiology of Olfaction). Of the 27 species of teleosts (comprising 14 families and 20 genera) whose facial gustatory amino acid specificities have been examined systematically, two general types have been identified: type 1, 10 species whose gustatory system respond to many different amino acids (i.e., wide response range), for example, channel catfish, and type 2, 17 species that are highly selective and respond to only a few amino acids (i.e., limited response range), for example, salmonids.

Olfaction in vertebrates is recognized as a distance chemical sense with high sensitivity and specificity. In contrast, gustation is primarily a contact or close-range sense with moderate sensitivity. However, the chemical sense of fish is unique in that many studies indicate that gustatory receptors are equally sensitive to the same chemical stimuli or even more sensitive than olfactory making the distinction between these two sensory modalities blurred (**Figure 1**). Furthermore, the gustatory system may not be the sole player in feeding in fish. In fact, recent studies demonstrate that feeding behavior in fish is initiated primarily by olfaction, and complemented by gustation.

Amino Acids

Most electrophysiological responses of the peripheral gustatory receptors are recorded from branches of the facial nerves (whole bundles or single fibers) innervating taste buds inside the upper or lower lips, or maxillary barbells. Electrical responses to amino acids are generally characterized by a fast adapting, rapidly returning to the baseline activity even with continuous stimulation, which contrasts with a slow-adapting olfactory response. Threshold concentrations for the more stimulatory amino acids range from 10^{-8}–10^{-7} M for most fish species tested to 10^{-11}–10^{-10} M for channel catfish. Threshold determinations, however, are highly sensitive to the background water in studies when the receptors are perfused with water. Natural water is required for response activation; replacing natural perfusing water with distilled

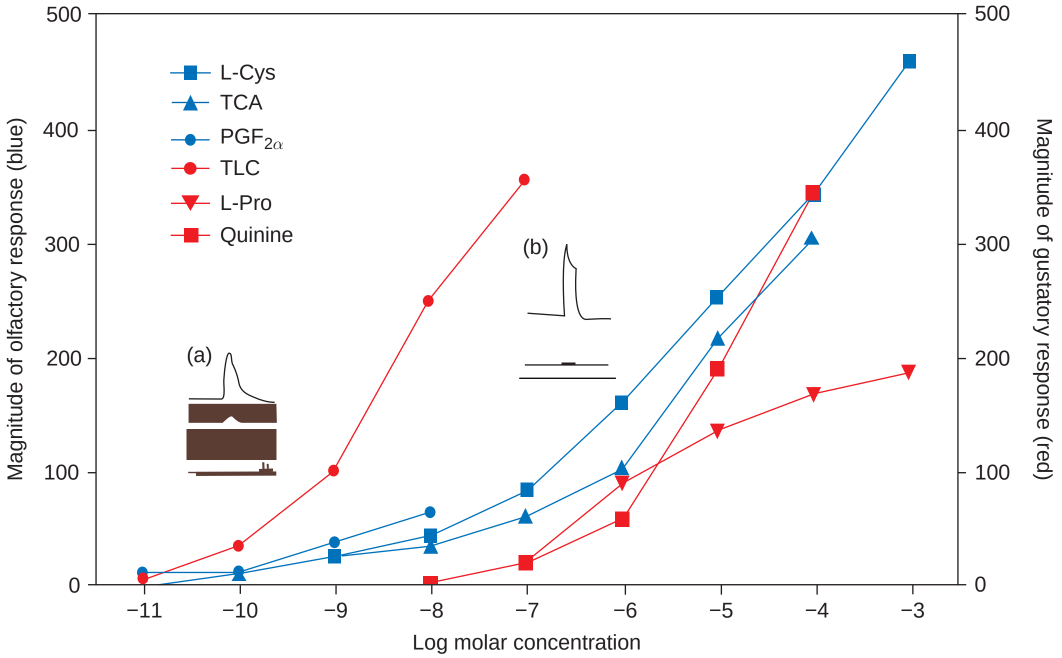

Figure 1 Comparison of the olfactory electro-olfactogram (EOG) and gustatory (palatal nerve response) sensitivities to representative chemical stimuli in rainbow trout. Insets; typical integrated palatine nerve response (a) and EOG (b), respectively. Modified from Hara (1994) The diversity of chemical stimulation in fish olfaction and gustation. *Reviews in Fish Biology and Fisheries* 4: 1–35.

water eliminates responses to stimulant chemicals, and artificial water only partially restores it. Thus, unknown factor beyond cations in the natural water plays an essential role in eliciting maximal gustatory reception.

All fish species in type 2, typically salmonids, respond to L-proline (L-Pro), L-alanine (L-Ala), and several other amino acids and related compounds, to a varying degree (**Figure 2**). Both carp and goldfish can also be placed in type 1. In rainbow trout, only L-Pro, L-Ala, hydroxyl-L-proline (L-Hpr), and L-α-aminoguanidinopropionic acid (L-Agp) are stimulatory, with thresholds 10^{-8}–10^{-5} M, although some strain differences exist. No difference exists in the response patterns to amino acids recorded either from the facial or from glossopharyngeal nerves. A structure–activity study indicates that heterocyclic-imino acids with four-, five-, or six-membered rings, and also of thioproline and hydroxyproline are effective.

The most characteristic feature common to all species of type 1 is that L-Pro is the dominant stimulant amino acid and it is the only naturally occurring amino acid that is not detected by the olfactory system (**see also Smell, Taste, and Chemical Sensing**: Neurophysiology of Olfaction). Chemically, proline is unique because an amino group is secondary and it cannot act as a hydrogen donor lacking a hydrogen atom on the amide group, which is required for binding of odorant molecules. These data suggest that the gustatory and olfactory systems detect distinct portions of amino acid molecules, thus minimizing redundancy. Cross-adaptation (desensitization) data further suggest that three receptor types are involved in the detection of these amino acids: (1) proline-receptor (L-Pro, L-Hpr, and L-Ala), (2) betaine-receptor (Bet and L-Agp), and (3) leucine-receptor (L-Leu, L-Phe). Of the salmonids, *Salvelinus* spp. are the simplest, detecting only three amino acids L-Pro, L-Hpr, and L-Ala. Salmonids may have developed gustatory receptors for L-Pro and, with phylogenetic advancement, gained greater response capabilities by acquiring new receptor types and by decreasing specificity of existing receptors.

Type 1 fishes detect virtually all natural amino acids by gustation, with the sensitivities higher (lower thresholds) than those of their olfactory counterpart. In channel catfish, for example, responses of the facial nerves innervating the maxillary barbels to L-Ala (the most effective for this species) show thresholds averaging 5×10^{-11} M. Analyses of single fiber responses reveal two clusters: L-Ala and L-Arg. Fibers comprising the latter cluster are divided into two subclusters, Arg and Arg/Pro, and the former, interestingly, is not responsive to Pro but broadly tuned. Responses of the superficial ophthalmic nerves innervating the nasal barbels and the palatine nerves innervating the anterior palate are similar in their amino acid specificities (**Figures 3** and **4**). Fishes in which Ala and Arg are the two major gustatory amino acids are also characterized by high sensitivity to Gly and include most marine species examined.

In summary, although an accurate estimation of the number of effective amino acids and their detection

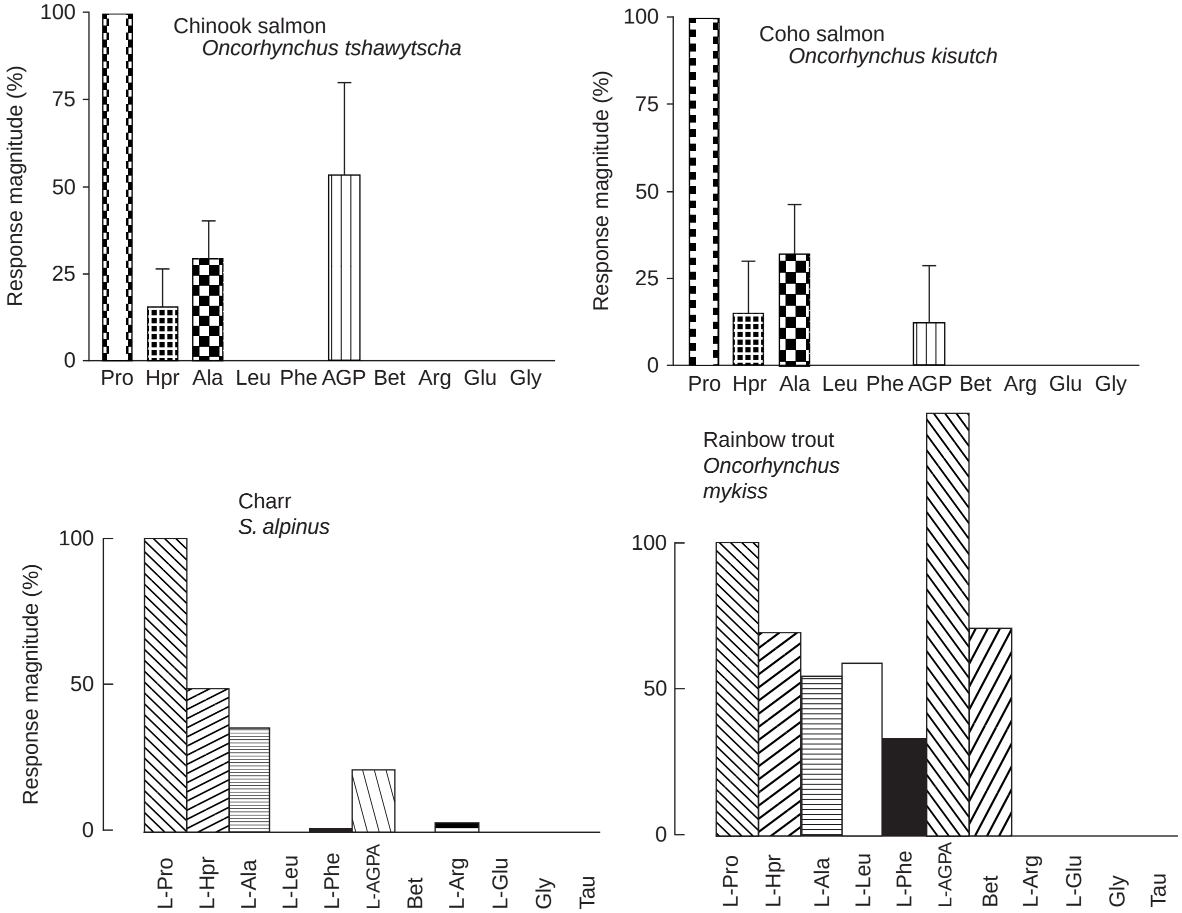

Figure 2 Relative stimulatory effectiveness of amino acids on the palatine nerve responses in four salmonid species. All chemicals are tested at 10^{-3} M. Pro, L-proline; Hpr, hydroxyl-L-proline; Ala, L-alanine; Leu, L-leucine; Phe, L-phenylalanine; AGP, L-α-amino-β-guanidinopropionic acid; Bet, betaine; Arg, L-arginine; Glu, L-glutamic acid; Gly, glycine. (1999) The variability of the gustatory sensibility in salmonids, with special reference to strain differences in rainbow trout, *Oncorhynchus mikiss*. *Canadian Journal of Fisheries and Aquatic Sciences* 56: 13–24.

thresholds may be difficult to make due to inconsistencies in experimental conditions employed by different researchers, it is not unreasonable to conclude that Pro is the dominant amino acid in the type 2 fishes, minimizing the redundancy between the gustatory and olfactory systems. In all type 1 fishes, Ala and Arg are dominant, and considerable overlaps exist between the two fiber systems.

Quinine, Strychnine, and Tetrodotoxin

Quinine hydrochloride (Q·HCl), strychnine, and the pufferfish toxin tetrodotoxin (TTX) stimulate the gustatory receptors of salmonids. Both Q·HCl and strychnine taste extremely bitter to humans, whereas TTX is a potent neurotoxin, specifically blocking voltage-gated Na-channels on the surface of nerve and skeletal muscle membranes. Rainbow trout and three char species (*Salvelinus* spp.) detect these chemicals at thresholds 10^{-8}–10^{-7} M, with extremely high-response magnitudes (**Figure 5**). Pretreatment with strychnine in rainbow trout inhibits responses to Q·HCl and TTX, but without any effect on amino acid and bile acid responses, suggesting that all three chemicals might share the same receptor and transduction mechanisms, despite vastly different molecular structures (**Figure 4**). Or, as in mammals, a receptor family with a wide response diversity coexists in a single gustatory cell. In channel catfish, Q·HCl suppresses responses of chemo-sensitive fibers but not the tactile. It also suppresses responses to other bitter substances, denatonium benzoate (the most bitter substance known) and caffeine, neither of which suppresses amino acid responses. It is suggested that the Q·HCl inhibition is caused by blocking voltage-gated calcium channels in the gustatory cells.

TTX and a paralytic shellfish toxin, saxitoxin (STX), are potent gustatory stimuli for salmonids. Rainbow trout detect TTX at 2×10^{-7} M, and at 10^{-5} M it evokes a response magnitude 4 times that of 10^{-3} M L-Pro (cf. **Figure 2**). These two chemicals are vastly different structurally, do not cross-adapt, and are therefore unlikely to share the same

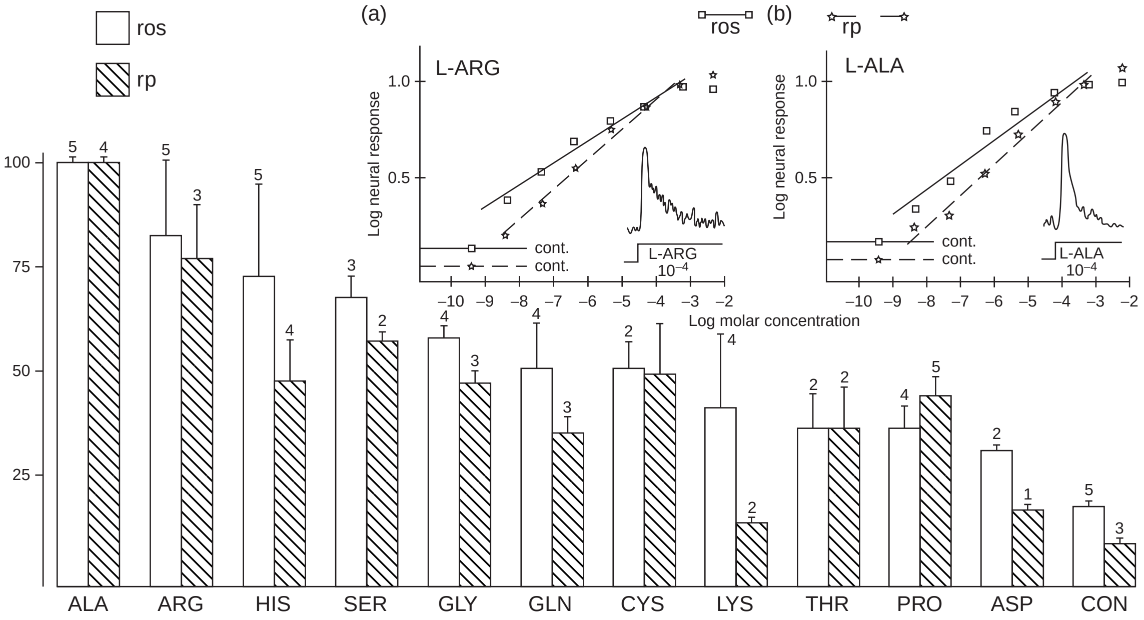

Figure 3 Relative stimulatory effectiveness of amino acids recorded from ophthalmic superficial (ros) and palatine (rp) nerves of channel catfish. All chemicals are tested at 10^{-3} M. Insets: Concentration–response curves for L-arginine (a) and L-alanine (b) recorded from ros and rp. Adapted from Kanwal JS, Hidaka I, and Caprio J (1987) Taste responses to amino acids from facial nerve branches innervating oral and extra-oral taste buds in the channel catfish, *Ictalurus punctatus*. *Brain Research* 406: 105–112.

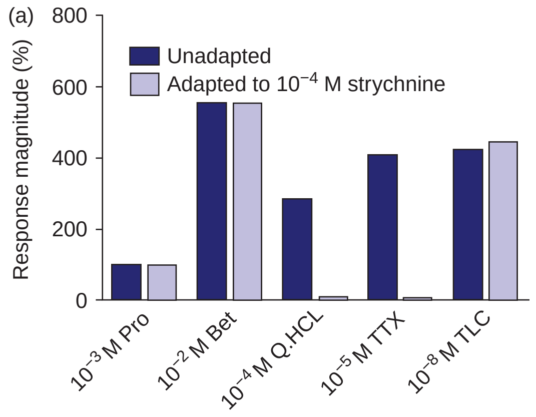

Figure 4 Interactions between strychnine, quinine (Q·HCl), bile acids (taurolithocholic acid, TLC) and tetrodotoxin (TTX) in rainbow trout, demonstrating that Q·HCl and TTX are inhibited by strychnine, but L-Pro, betaine (Bet), and TLC are unaffected. Adapted from Yamashita *et al*. receptor type. TTX and Q·HCl cross-adapt each other. TTX and STX are known as two of the most potent neurotoxins, with a lethal toxicity to humans 300 times that of cyanide. Both exert essentially the same toxic action by blocking the voltage-gated sodium channels in neural tissues including the gustatory receptors in higher vertebrates. In fish, however, the treatment of the gustatory receptors with TTX does not affect amino acid-induced responses, suggesting that TTX-sensitive sodium channels may not be involved in the gustatory transduction mechanisms in fishes.

Bile Acids

To date, the gustatory systems of only salmonids are known to be extremely sensitive to some bile acids. In rainbow trout, taurocholic acid (TCA), one of the most potent bile acids tested, is detected at a threshold concentration 10^{-12} M, with the maximum response magnitude almost double that of Pro, making TCA as sensitive as its counterpart the olfactory (cf. **Figure 1**). Both taurine- and glycine-conjugated forms are generally more stimulatory than the free form of TCA (**Figure 6**). The response pattern to bile acid is characterized by its slow adapting, tonic response. Contrary to the olfactory, responses to all tested bile acids are inhibited by pretreatment with taurolithocholic acid (TLC), suggesting that all bile acids share the same receptor/transduction system. Or, alternatively, a nonreceptor system may be involved in the bile acid stimulation. The only other fish species whose gustatory systems have been shown similar response sensitivities and specificities to bile acids are three char species (*Salvelinus alpinus*, *S. fontinalis*, and *S. namaycush*). The gustatory systems of carp, sea catfish, and tilapia are not sensitive to bile acids, up to a concentration of 10^{-4} M.

CO_2/pH

Fish generally orient negatively to localized increase in hydrogen ions (H^+) concentration, where pH (or a change in pH) is a major directive factor in the distribution of fishes. However, the effects of acid are often confounded with those of CO_2, which is released when acid is added to water containing carbonate salts. In pH-controlled decarbonated natural water, rainbow trout detect CO_2 with a threshold 4×10^{-5} M, which is only slightly higher than the CO_2 level found in natural water (1.8×10^{-5} M) equilibrated with air. The threshold for H^+ is approximately 4×10^{-5} M. Responses to CO_2 are independent of pH, and little affected by pretreatment with amino acid or bile acid (**Figure 7**). None of the single gustatory fibers responsive to CO_2 respond to other stimuli, except Q·HCl. The rainbow trout gustatory receptors are thus capable of distinguishing between CO_2 and H^+, and CO_2 receptors are distinct from those that detect other gustatory stimuli. The CO_2-responsive single fibers are characterized by higher amplitudes of action potentials compared with those responsive to amino acids. The concentration–response curves for both CO_2 and H^+ recorded from a whole palatal nerve bundles show two discrete components, a slow increase from the threshold up to about 2×10^{-3} M and pH 3, respectively, followed by a sharp increment with further increase in concentration. It is assumed that the former responses represent respective receptor-mediated responses transmitted through the palatine nerve, whereas the latter are caused by activation of nonreceptor mechanisms involving trigeminal nerves. In support of this, responses of the palatal gustatory nerves of the Japanese eel to CO_2, when recorded from the facial nerves that lack a trigeminal component, exhibit a single component concentration–response curve. Also in mammals, although

taste buds are predominantly distributed in the oral cavity, especially on the tongue and palate, they are also found on the epithelia of the pharynx and larynx. Both the intraepithelial-free nerve endings and the taste buds are sensitive to CO_2, and suggested that they may play a role in respiratory modulation rather than food appreciation.

Molecular Basis of Gustatory Receptors and Transduction

Analyses of genomic sequences encoding proteins homologous to mammalian T1Rs and T2Rs reveal two families of G-protein-coupled gustatory receptors fT1Rs and fT2Rs in pufferfish (*Fugu rubripes*), medaka (*Oryzias latipes*), and zebrafish. These receptor genes show high (60–70%) similarities to those of mammals: T1R and T2R. The former consist of three subtypes, and are expressed in different gustatory cell populations, whereas the latter, consisting of two to three subtypes, show low degree of similarity to those of mammals, and are expressed in different cell groups from those for T1R genes. This suggests that two types of distinct gustatory receptor and signaling pathways are common to vertebrates. Electrophysiologically, the zebrafish gustatory system is of type 2 fish, responding primarily to L-Pro and L-Ala. A calcium imaging analysis of T1Rs and T2Rs from both zebrafish and medaka, using an HEK293T (human embryonic kidney 293T) heterologous expression system, further reveals that both T1R1/3 and a series of T1R2/3s respond to several amino acids, while zebrafish T2R5 and medaka T2R1 respond to denatonium, one of the most bitter substances. Interestingly, mouse T1R1+3 receptors recognize a broad range of L-amino acids, both in cell-based assays and *in vivo.* T1R1 and T1R3 combine to function as a broadly tuned L-amino acid sensor specifically responding to most of the 20 amino acids. By contrast, the T2R family containing approximately 30 genes represents bitter receptors, detecting diverse organic molecules (caffeine, nicotine, and strychnine) that originate from plants. Unlike T1Rs, most T2Rs are co-expressed in one cell population that does not contain T1Rs, suggesting that each gustatory receptor cell may be capable of recognizing multiple bitter substances. Thus, the discovery and functional characterization of the cell and receptors for amino acids, bitter and sweet tastes in mammals suggest that receptors for these gustatory substances are expressed in distinct populations of cells that operate independently of each other to trigger stereotypic behavioral responses.

Two possible transduction sequences for gustation have been suggested. The binding of gustatory stimulus to receptors activate G-proteins, which, in turn, activate second messenger producing enzyme phospholipase C (PLC). PLC metabolizes phophatydylinositol biphosphate (PIP2) into two second messengers: inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 releases Ca^{2+}, while DAG activates protein kinase C (PKC). An increase in Ca^{2+} activity triggers neurotransmitter release. In contrast, binding of L-Arg and L-Pro to their respective receptors is

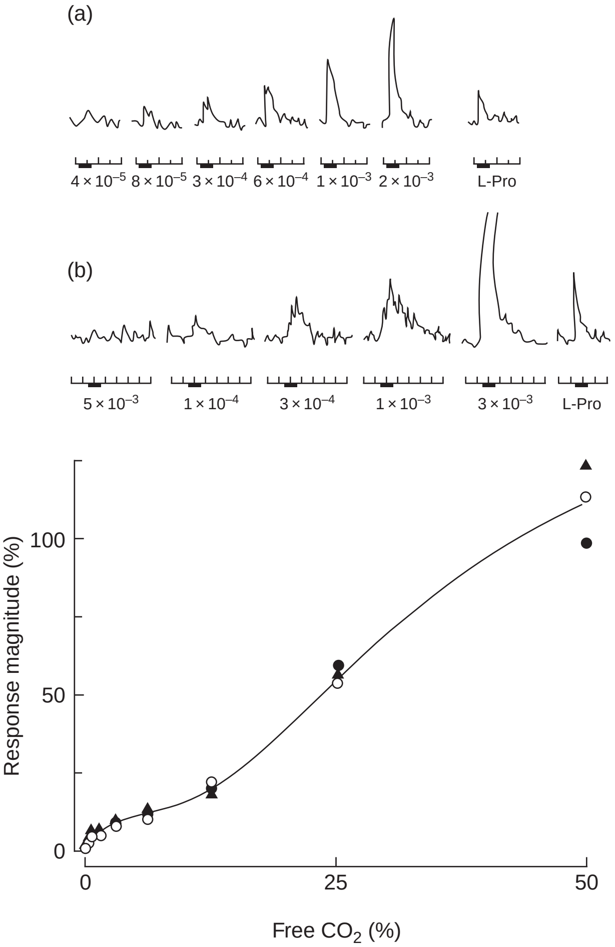

Figure 7 Typical gustatory responses to CO_2 (a) and HCl (b), recorded from the rainbow trout palatine nerve bundles. Concentration–response curves (bottom) show the effects of pretreatment with 10^{-3} M L-proline (open circles) and 10^{-8} M taurolithocholic acid (solid triangles) on CO_2 responses. Control responses to CO_2 before adaptation are shown by solid circles. Adapted from Yamashita *et al*. (1989) Specificity of the gustatory chemoreceptors for CO_2 and H^+ in rainbow trout (*Oncorhynchus mikiss*). *Canadian Journal of Fisheries and Aquatic Sciences* 46: 1730–1734.

directly coupled to the activation of nonselective cation channels. Stimulation of gustatory receptor cells release neurotransmitters onto afferent nerves that innervate taste buds. Analogous to neurotransmitter release in other excitable cells, it is expected that neurotransmitter release in gustatory cells depends on an increase in intracellular Ca^{2+} ($[Ca^{2+}]$). In isolated channel catfish gustatory cells, some respond to L-Arg with an increase in $[Ca^{2+}]$, while others elicit decrease in $[Ca^{2+}]$. These heterogeneous responses of the $[Ca^{2+}]$ to L-Arg is consistent with depolarization or hyperpolarization of gustatory cells, suggesting that excitatory and inhibitory responses to a single gustatory stimulus can potentially play a role in increasing the sensitivity of the gustatory system.

Responses to Mechanical/Tactile Stimuli

Behavioral studies show that both chemical and mechanical (tactile) cues are closely involved in feeding in many fish species (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior). For example, catfish find food by touch but not by vision; at the moment food touches a barbel or the fish's body, the fish turns toward it with reflex speed and snaps it up. The need for direct contact with food suggests that relevant receptors are tactile and that the central mechanosensory pathways are involved in activating the feeding behavior. However, as we have seen (**see also Smell, Taste, and Chemical Sensing**: Morphology of the Olfactory (Smell) System in Fishes), the barbels are richly supplied with taste buds exclusively innervated by the facial nerve and paralleled by the free nerve ending plexus via the trigeminal nerve. A question then arises whether the mechanosensitivity originates from the taste bud proper (gustatory nerves) or adjacent nervous components such as trigeminal nerves.

As every fish chemosensory electrophysiologist encounters, it is essential to eliminate electrical noises caused by mechanical disturbances by changing water flow during stimulus application, before any genuine response due to chemical stimuli can be established. Hoagland, in his pioneering study, not only found high sensitivity of the catfish facial nerve complex, but also noticed the striking differences in the impulse amplitudes, that is, low amplitude due to chemical stimuli and high amplitude to the mechanical stimuli (touching or water current). He suspected that the specificity of impulses for the two sense modalities is correlated with cell sizes of origin of the axons: large cells in the Gasserian ganglion supplying tactile (trigeminal) nerve endings and small cells of origin in the geniculate ganglion sending axons to taste buds. However, since the finding that the carp glossopharyngeal nerve, consisting primarily of gustatory nature, responded to both chemical and tactile stimuli, a number of studies ensued identifying the origin of the bimodal nature of the gustatory nerve activities in catfish, carp, puffer, and rainbow trout. These studies show that the majority of fibers are highly sensitive to mechanical stimuli (touching, sliding, brushing, and water current). Although most fibers respond to either chemical or tactile stimuli, small fractions of the facial nerve fibers innervating maxillary barbels and recurrent facial nerve innervating the flank of channel catfish contain bimodal fibers responding to both chemical and tactile stimulation. These chemosensory and tactile fibers terminate in the facial and vagal lobes overlapped and loosely organized in a somatotopic manner in carp and catfish. In rainbow trout, none of single palatine nerve fibers sensitive to touch stimulation respond to amino acids, bile acids,

Q·HCl, or CO_2, while none of the chemosensitives respond to tactile stimulation. Thus, the facial nerve fibers innervating the anterior palate contain two types of afferent fibers, chemosensory and mechanosensory, although it is not clear whether they are derived from the gustatory receptor cell or the synapsing fiber *per se.* (**Table 1**)

Thus, the VII, IX, and X gustatory nerves all comprise chemical as well as mechano-sensitive fibers. The next logical question is whether all the mechanical sensitivity is derived from taste buds, *per se.* One of the morphological features shared by both the gustatory and olfactory, let alone the lateral-line system, is that all have developed ciliated cells of one type or another, directly exposed to the aqueous environment. Ciliated olfactory receptor neurons and lateral-line hair cells are characterized by their cilia having 9 + 2 microtubule configuration.

Concluding Remarks

The gustatory system is generally very well developed in fishes and highly specialized in several groups; the best investigated being the cyprinids, silurids, and mullids. Coupled with expansive peripheral receptors, they all have developed elaborate central structures, probably the most complex neural organization found in any vertebrate central nervous system. Intra- and extrapharyngeal distributions of taste buds provide fishes with detailed chemical and tactile information, as well as the means to detect food items and reject inedible or noxious substances. The extraordinary development of the vagal/facial lobe complex organized topographically receives very specific inputs. Amino acids, particularly proline, alanine, and possibly arginine, comprise major gustatory chemicals in most fish species. Gustatory receptors detect other chemical groups with extreme sensitivity, including bile acids, nucleotides and bitter substances. Gustatory receptors highly sensitive to CO_2 in fish gill epithelium suggest a linkage with ventilatory drive of much greater importance than has previously been acknowledged.

Using heterologous expression systems, functional characterization of the cells and receptors for amino acids and bitter substances provides a view of how gustatory signals are peripherally encoded. These receptors are expressed in distinct populations of gustatory cells that operate independently. With the application of new and powerful molecular techniques, we are hopeful that a more complete understanding of the physiology of the fish gustatory system will arrive soon.

Feeding Behavior

Gustatory, Olfactory, or Tactile – Historical Development

Feeding behavior of fish is complex and differs between species. Typically, three phases of food search can be differentiated: (1) an initial period of arousal or excitement, when the fish is alerted to the presence of the stimulus, (2) a subsequent search or exploratory phase to locate the source, and (3) a consummation phase, in which the fish seeks to ingest the potential food. In reality, however, these phases are a continuum without distinct transitions.

Various sensory systems contribute to the process of feeding. Their roles and significance vary at different phases and among fish species. Whether feeding behavior in fishes is mediated by gustatory, tactile, or olfactory stimuli has long been a subject of investigation. Bateson, as early as in 1890, listed more than 15 fish species that detect food by olfaction alone. Herrick, on the other hand, reported that barbeled fishes are able to localize food by a combination of tactile and gustatory stimulation, and emphasized that memory plays a part in gustatory and tactile discrimination, while vision and olfaction assumes greater importance during intake. Similarly, working on catfish (*Amiurus nebulosus*), both Parker and Olmsted claimed that responses to food substances are due to stimulation of the olfactory organ, and that blinded or barbel-less fish find food as readily as normal fish. In contrast, Bardach and others found that catfish (*Plotosus* sp.) can find distant chemical clues by gustation alone; olfactory deprivation does not impair their searching ability. By selective ablation of the entire sensory areas of the facial and vagal lobes, Atema further characterized distinct functional roles played by the two systems in catfish (*Ictalurus* sp); the former is involved in localization and pickup of food (in combination with tactile inputs), whereas the latter in the control of swallowing. Goatfish (*Upeneoides bensasi*), a mullet, seem to rely exclusively on barbels for feeding; they are unable to recognize a packet of meat, or to find a food hidden under mud when the barbels are removed, whereas blocking of olfaction has no effect. Barbels play a primary role in detecting food in all barbeled fishes (**see also Smell, Taste, and Chemical Sensing:** Morphology of the Gustatory (Taste) System in Fishes).

Contrary to the general belief, the gustatory system is not the sole player in feeding in fish, and at the same time, not limited to it. In fact, as described below, recent studies demonstrate that feeding behavior is initiated primarily by olfaction, and complemented by gustation. Ontogenetically, taste buds generally develop later than the olfactory system in larvae, by which time their feeding already has been established.

Searching for Feeding Stimulating Substances

Identifying the active ingredients in food has also attracted the interest of many investigators, sometimes from scientific curiosity and sometimes for its potential practical application. Some of the species studied include Japanese eel (*Anguilla japonica*), pigfish (*Orthopristis chrysopterus*), pinfish (*Lagodon rhomboids*), winter flounder (*Pseudopleuronectes americanus*), mummichog (*Fundulus heteroclitus*), Atlantic silverside (*Menidia menidia*), puffer (*Fugu pardalis*), and cod (*Godus morhua*).

All these studies, examining different aspects of feeding behavior elicited by natural food and/or food extract in diverse fish species, have shown conclusively that amino acids act either singly or in combination to play a major role in stimulating feeding behavior. Each species selectively responds to a specific mixture of compounds, but synthetic mixtures of amino acids seldom attain the effectiveness of the original extracts of natural foods. As Herrick emphasized, memory could play a part in olfactory and gustatory discrimination, while behavioral responses to chemical compounds may be learned by experience and probably are stored in temporary memory. Here, an observation on juvenile sockeye salmon (*Oncorhynchus nerka*) is suggestive; they respond only to extracts of those foods constituting their current diet, but they change their extract preference concomitantly after gradual weaning to a new diet.

Feeding Behavior Is Triggered by Single Amino Acids

The mechanisms by which feeding behavior are triggered by amino acids will be examined in two fish groups: (1) fishes in which olfaction is primarily used complemented, or in combination with gustation (salmonids and goldfish, *Carassius auratus*), and (2) fishes in which gustation is solely involved throughout feeding behavior (catfishes).

Rainbow trout, lake char (*Salvelinus namaycush*), lake whitefish (*Coregonus clupeaformis*), and goldfish respond to 10^{-6} M Cys, the most potent olfactory stimulating amino acid determined electrophysiologically (**see also Smell, Taste, and Chemical Sensing:** Neurophysiology of Olfaction), by increasing locomotor activity, an initial arousal behavior, in exactly the same fashion as in response to food extracts. The enhanced locomotor activity is followed by search behavior patterns distinct for each species: (1) bottom searching in rainbow trout, (2) exploratory behavior against the tank wall in lake whitefish, (3) surfacing/jumping in lake char, and (4) gravel picking in goldfish (**Figures 1** and **2**). Ala and Lys as well as Pro, a gustatory specific amino acid, are all effective at 10^{-6} M, to varying degrees, in most species (**Figure 3**). It is important to note that the behavioral responses are stereotypic, eliciting the same behavioral patterns regardless of the type of stimuli, and concentration-dependent in all species, with thresholds 10^{-9}–10^{-8} M, which approximates the physiological thresholds (**see also Smell, Taste, and Chemical Sensing:** Neurophysiology of Olfaction). Effects of Arg and Glu vary in different species suppressing locomotor activity in rainbow trout, while stimulating feeding behavior in others. For example, in rainbow trout, the elevated locomotor activity by Cys is suppressed, when a mixture of Cys and Arg is introduced (**Figure 4**). Goldfish display typical gravel pecking searching behavior, positioning their bodies almost perpendicular to the bottom, accompanied by increased locomotor activity in response to stimulation with food extract or amino acids. Unlike in rainbow trout, Arg, Glu, and Pro are as effective as food extracts and other amino acids in inducing both locomotor and pecking activities (**Figure 3**). These results clearly indicate that single amino acids initiate appetitive feeding behavior (arousal and searching) primarily by olfaction, and interchangeably and/or complemented by gustation in naive fishes. It is thus highly likely that, in the absence of visual cues, the olfactory system plays a major role in triggering feeding behavior in these species, and possibly others. Agmatine, decarboxylated arginine, also elicits strong feeding behavior in goldfish, most likely through olfaction, because it evokes electro-olfactogram (EOG) responses with a threshold 10^{-9} M in goldfish as well as in lake whitefish and walleye, but not in rainbow trout (**Figure 3**). Agmatine is converted by bacteria from Arg to form polyamines such as putrescine, cadavarine, and spermine that stimulate the goldfish olfactory system and

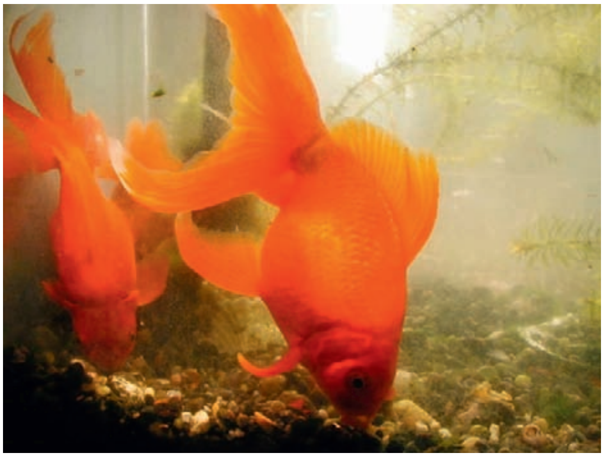

Figure 2 Pecking behavior of goldfish; food is sorted from gravel.

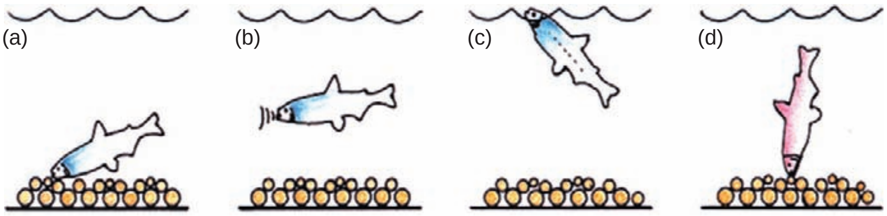

Figure 1 Diagram showing feeding behavior patterns elicited by food extract and chemical stimulation in fishes. On detection of stimuli, fish increase locomotor activity (appetitive behavior) followed by species-specific search behavior patterns: (a) bottom searching in rainbow trout, (b) exploratory/escape behavior against the wall in lake whitefish, (c) surfacing/jumping in lake char, and (d) gravel pecking in goldfish. Modified from Hara (2005).

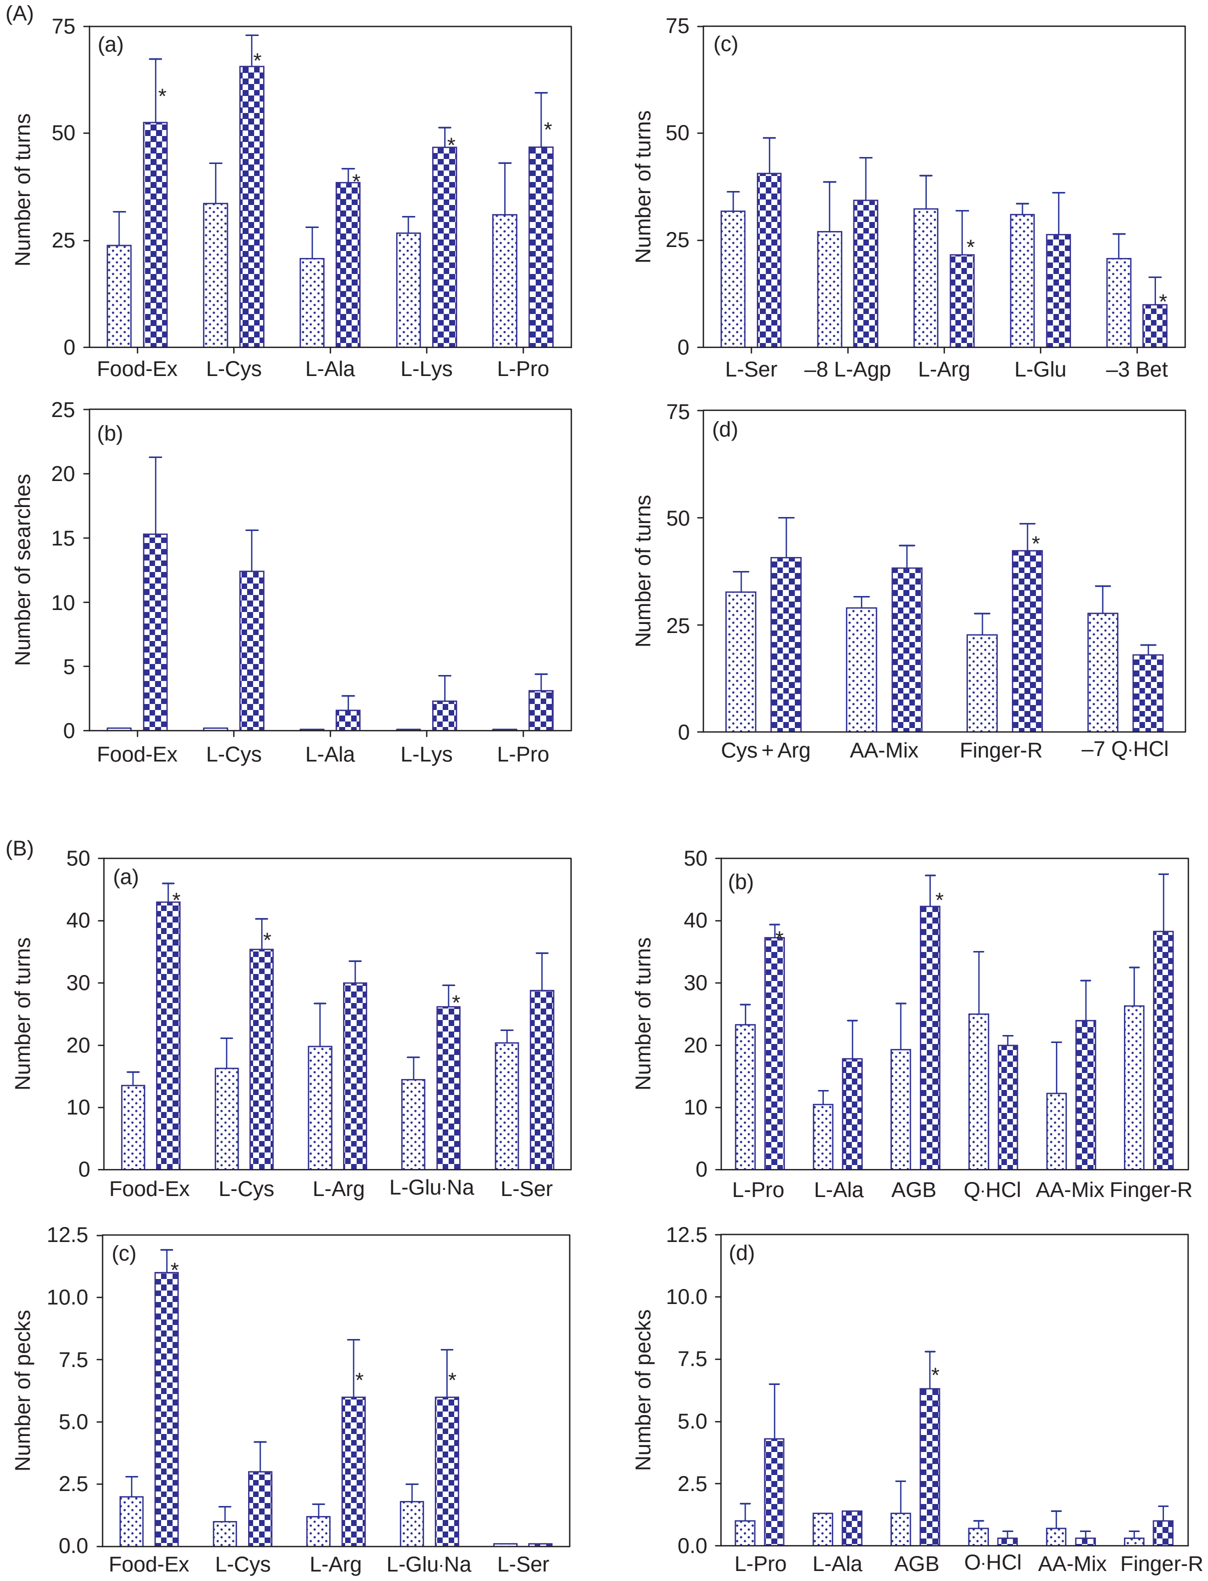

Figure 3 Feeding behavior elicited by food extract (Food-Ex) and chemicals at 10^{-6} M in rainbow trout (A) and goldfish (B). Light bars, control; dark bars, stimulus. L-Agp, L-α-amino-guanidinopropionic acid; AA-Mix, amino acid mixture containing all tested amino acids; Finger-R, finger rinse; Q·HCl, aquinine·HCl; LGlu·Na, monosodium L-glutamate (MSG); AGB, 1-amino-4-guanidinobutane (agmatine). Modified from Hara (2006).

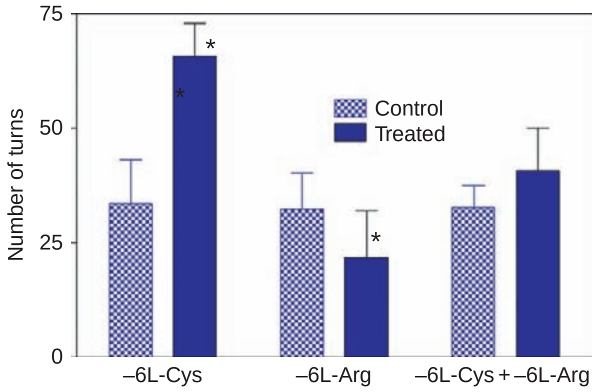

Figure 4 In rainbow trout, L-Cys stimulates locomotor activity (arousal behavior), while L-Arg suppresses it. Thus, when a mixture of both is applied, the Cys-elevated locomotor activity is suppressed.

elicit feeding behavior. Omnivorous cyprinids and catfishes are not only predators of live invertebrates but are also scavengers of dead baits.

Similarly, channel catfish elicit the entire sequence of feeding behavior in response to single amino acids. Arg, Ala, and Pro ($>10^{-7}$–10^{-4} M) induce consummatory behavioral patterns, turning, pumping of water across the gill arches, and biting–snapping. However, feeding behavior in these fish is indistinguishable in both the intact and anosmic, indicating that the entire sequence of feeding behavior is mediated by gustation alone, although which subpopulations of the taste bud systems (oral cavity, barbels, flank, and gills) are involved in which behavioral patterns is not clear. The behavioral pattern elicited by either Ala or Arg is identical, despite the fact that considerable differences exist in the biochemical (receptor binding) and biophysical (transduction) characteristics between the two, though, electrophysiologically, both the olfactory and gustatory systems are equally sensitive to the same amino acid spectrum. Toxicants can directly or indirectly affect the fish's olfactory ability (**see also Toxicology:** The Effects of Toxicants on Olfaction in Fishes).

Avoiding and Spitting the Noxious/Unpalatable

Alkaloids such as quinine, strychnine, and caffeine stimulate the fish gustatory receptors at extremely low concentrations, and induce avoidance behavior and suppress locomotor activities in salmonids and goldfish. When food pellets soaked in quinine solution are sprinkled on the surface of an aquarium, both rainbow trout and goldfish pick off, apparently by vision; the former ingest them immediately, but the latter spit them out after a brief mastication. Salmonids are able to avoid the noxious at a distance, but not once they are taken into the mouth. Goldfish, by contrast, have the specialized palatal organ that enables them to sort food particles from un-palatable particulates. They suck up the mixture, if mixed with gravel, sand, or mud, and manipulate the mix in the mouth, then finally spit out. The well-developed reflex system in the vagal lobe activates the musculature of the palatal organ to effect the sorting operation (**see also Smell, Taste, and Chemical Sensing:** Neurophysiology of Gustation). The protrusion of the upper jaw and the palatal organ is basic to the substrate feeding habits of many cyprinoids (**Figure 5**).

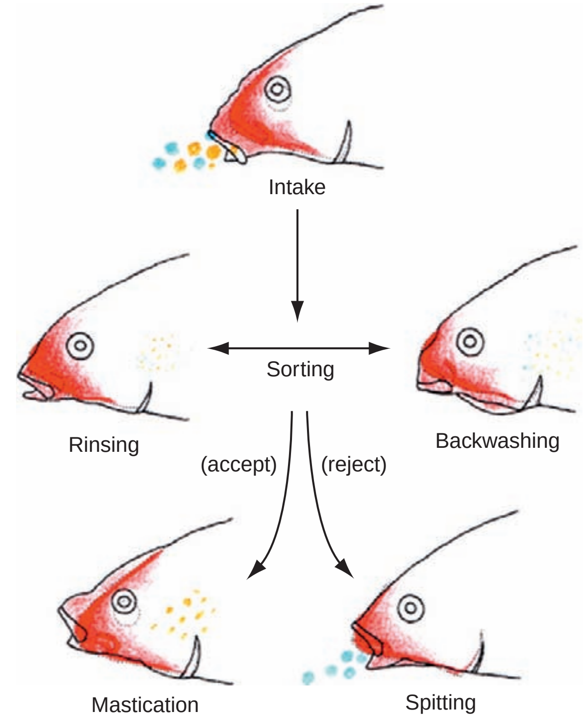

Figure 5 Feeding behavior of goldfish includes: (1) a suctorial intake of food particles, (2) a sorting stage where food is separated from nonfood within the oropharyngeal cavity, and (3) a final stage involving either acceptance or rejection of the particles. Modified from Lamb and Finger (1995).

Reproductive Behavior

In fish, olfaction exerts a functional role in every aspect of the reproductive process, from initial attraction and recognition of sexual status to sexual development of the young. The demonstration that hormones and their metabolites commonly serve as reproductive pheromones in fish has revolutionized our understanding of the importance of chemical signals in influencing vertebrate behavior in general (**see also Hormones in Communication:** Hormonal Pheromones). Pre-ovulatory female goldfish sequentially release two hormonal pheromones, $17\alpha,20\beta$-dihydroxy-4-pregnen-3-one (17 $\alpha,20\beta$P) and prostaglandins (PGFs). The former induces female oocyte maturation and is released into the water to function as a pre-ovulatory pheromone. This pheromone is detected by the male olfactory system and stimulates the synthesis of testicular $17\alpha,20\ \beta$P, which in turn evokes an increase in milt production by the time of ovulation and spawning. At the time of ovulation, females produce PGFs to mediate follicular rupture and to trigger female spawning behavior. Circulating PGFs are subsequently metabolized and released into the water, where they function as a post-ovulatory pheromone that stimulates male sexual arousal, thus resulting in spawning synchrony (**Figure 6**). This goldfish model of hormonal pheromone system, coupled with the development of the EOG method of pheromone assay, has dramatically accelerated the investigation into both the complexity and diversity of their functions in a variety of fishes.

In all salmonids except lake char, the female selects the spawning site and digs a redd by turning on her side and flexing her tail (**Figure 7**). The first convincing evidence that spawning behavior is controlled by hormonal pheromones came from the studies on Arctic char, *Salvelinus alpinus*. Actively spawning male Arctic char release PGF2α into the water, which attracts ovulated females and evokes their digging behavior, and also attracts ripe males. In brown trout (*Salmo trutta)*, exposure to PGF2α and 13,14-dihydro-PGF2α increases swimming activity in individually exposed fish, and further stimulates digging and nest-probing behaviors in females. In addition, in lake whitefish, PGF2α and 15-keto-PGF2α increase locomotor activity. However, rainbow trout that lack the olfactory sensitivity to these chemicals do not show any behavioral response. Thus, the *Oncorhynchus* genus including rainbow trout, may have lost the use of PGFs, and instead employ other chemical compounds. In fact, masu salmon (*Oncorhynchus masou*), which are nonsensitive to PGFs, use an amino acid (L-kynurenine) that is released from ovulated female urine as a powerful male-attracting pheromone. Furthermore, as in the sea lamprey (*Petromyzon marinus*), the high olfactory sensitivity and specificity to bile acids released by conspecifics are suggestive of their functioning as pheromones in salmonid in general. Curiously, a cyprinid rose bitterling (*Rhodeus ocellatus*) exhibits a peculiar sexual behavior in response to general amino acids, known to be feeding. Exposure to amino acids causes male fish to nudge against females under dark condition, while they elicit spermiation under light condition (**see also Hagfishes and Lamprey:** Lampreys: Energetics and Development and Lampreys: Environmental Physiology).

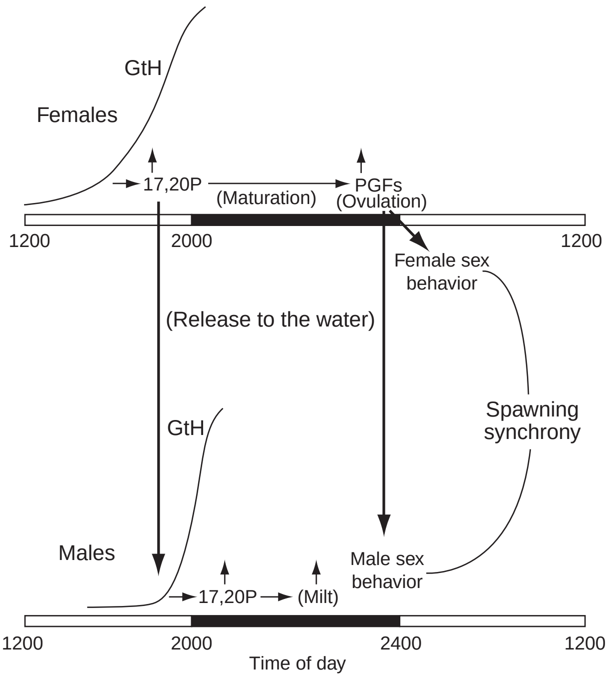

Figure 6 A model of the goldfish sexual pheromone system. Environmental cues trigger an ovulatory surge in gonadotropic hormone (GtH) in vitellogenic females that subsequently stimulates $17\alpha,20\beta$-dihydroxy-4-pregnen-3-one ($17,20\beta$P) synthesis by the ovary. Hormonal $17,20\beta$P induces final oocyte maturation and is released to the water where it functions as a preovulatory pheromone. This evokes a surge in circulating GtH in males, which stimulates the synthesis of testicular $17,20\beta$P. Elevated hormonal $17,20\beta$P in turn evokes an increase in milt production by the time of ovulation and spawning. At the time of ovulation, females produce F-prostaglandins (PGFs) to mediate follicular rupture and trigger female spawning behavior. Circulating PGFs are subsequently metabolized and released to the water where they function as a postovulatory pheromone that stimulates male sexual arousal, effecting spawning synchrony. Adapted from Sorensen *et al*. (1988).

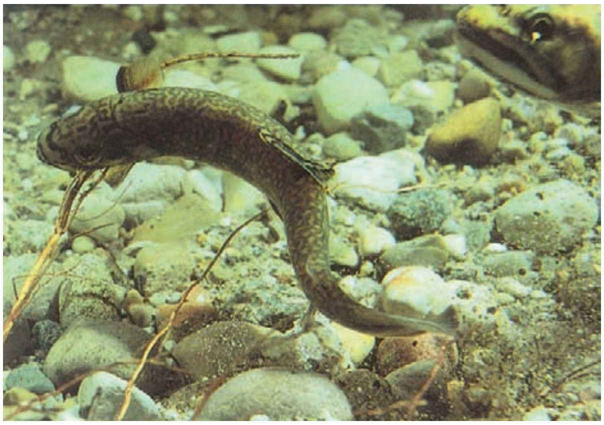

Figure 7 Digging behavior triggered by putative pheromones, prostaglandins in trout.

Alarm Substance and Fright Reaction

Nearly 70 years ago, Von Frisch discovered that a school of minnow (*Phoxinus phoxinus*) become frightened and dispersed, when an injured individual is introduced. An incident that first drew his attention to this problem was his observation of a kingfisher swooping down and attacking a school of minnows. After successfully capturing one, the bird dropped the minnow when flying away.

The other minnows, still schooling, suddenly dispersed. The general characteristics of the phenomenon are that when the skin of a fish is damaged by a predator, alarm substance cells are broken and release alarm substance (Schreckstoff). Nearby conspecifics smell the alarm substance and show a fright reaction (Schreckreaktion). The fright reaction thus produced may then be treated as a visual signal by other conspecifics, leading to rapid transmission of the danger signal through a group of fish. Thus, the alarm-signal system consists of two main components: a chemical component, the alarm substance, and a behavioral component, the fright reaction.

Despite extensive investigations, there remain a number of unanswered questions regarding the fundamental issues of the alarm substance–fright reaction: (1) characterization of the alarm substance, and its olfactory activation, (2) release of the putative alarm substance, hypoxantine-3-N-oxide into the surrounding water, and (3) the nature of the fright reaction. The alarm substance–fright reaction system is generally understood to be restricted primarily in ostariophysan species, though not universal. The fright reaction is not species specific, but the intensity of the response is related to the phylogenetic proximity of the species. Furthermore, the fright reaction is genetically determined, and appears at a certain stage of development, regardless of prior experience. Individuals likely gain protection as a result of their responses to alarm substance released by a conspecific upon attack by a predator. However, whether the release of alarm substance can provide protection or other benefits to the damaged individual is highly questionable.

Putative Alarm Substance

The alarm substance is believed to be contained in a large epidermal cell, the club cell (**Figure 8**), but not without controversy, because they are distributed abundantly in the orobuccal cavity. Unlike mucous cells, club cells lack openings at the skin surface, and release their contents only when the skin is injured. The alarm substance has variously been characterized as being purine or a pterine-like, small-ringed or double-ringed, polypeptide-like or histamine-like. Of these, hypoxanthine-3(N)-oxide (H3NO) is thought to be the most likely candidate alarm substance in the minnows. Both fathead minnows (*Pimephales promels*) and finescale dace (*Chrosomus neogaeus*) exhibit anti-predator responses (increased shoaling and decreased area use) when exposed to conspecific skin extract, synthetic H3NO or purine-N-oxide, but not upon exposure to a molecule lacking a nitrogen oxide functional group. Thus, the nitrogen oxide group is likely the determinant in triggering fright reaction, and H3NO may be one of several possible molecules that function as a chemical alarm cue. In support of this, the fish no longer detect alarm substance under acidic pHs, possibly due to nonreversible covalent changes in the molecules. Despite these efforts in laboratory investigations, skin extracts have been used exclusively as the source of the alarm substance, of which basic chemical characterization is still lacking. It should be noted that the epidermal layer of the fish skin also contains numerous mucous cells, and that the mucus, while primarily serving as a protector of the skin, also plays an important role in individual recognition and schooling. Amino acids, the main ingredients of olfactory stimuli in the mucus, are responsible for these behaviors (**see also The Skin:** Functional Morphology of the Integumentary System in Fishes).

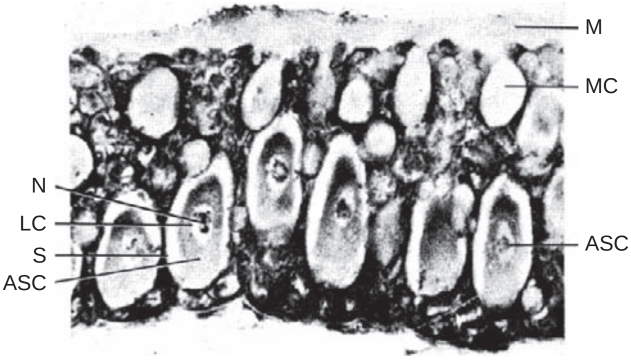

Figure 8 Photomicrograph showing club cells (alarm substance cells) in the epidermis of the minnow (*Phoxinus phoxinus*). ASC, alarm substance cells; LC, light colored region; M, mucus; N, nucleus. Adapted from Pfeiffer (1960).

Olfactory Detection

It is generally accepted that an alarm substance is detected by the olfactory system. This is based on the von Frisch's classical experiment, in which minnows with their olfactory nerves and bulbs removed, lost their responsiveness to alarm substances, even though the possible involvement of gustatory and/or other senses was not totally ruled out. As seen below, anosmic fathead minnows failed to respond behaviorally to predator odor, demonstrating the role of olfaction. Thus, despite a long history of studies on the alarm substance–fright reaction, no direct physiological evidence has been presented, including the studies where the structure–activity relationship of H3NO is investigated, indicating that the substance is indeed detected via the olfactory system.

Fright Reaction

The fright reaction is not stereotyped; von Frisch defines seven behavior patterns, changing from the slight crowding to sudden fright, and to rapid swimming into the hiding place depending on the type of stimuli and its strength. For instance, slow and fast movements, resting and motionlessness, aggressive interactions and area use, time under shelter and time moving, and so on are indiscriminately employed, depending on fish species in different laboratory conditions. In a recent field experiment, wild European minnows failed to modify their behavior or leave the area when exposed to skin extract, which cast a doubt on the hypothesis that the primary function of club cells is to signal alarm to conspecifics. This strongly contrasts with those behavioral patterns described in the feeding and reproductive behaviors, where the response patterns are generally stereotyped, and only the intensity of the specific behavior pattern increases as the stimulus increases. In the case of feeding, fish are generally very cautious, responding only to extracts of those foods constituting their current diet, and establish their extract preference after gradual weaning over to a new one. In some fish species, the elevated locomotor activity, an arousal, by a single amino acid is suppressed, a fright reaction, by other amino acids. This also raises a question whether some of the behavior patterns comprising the fright reaction described might be ones caused by general substances indifferent of alarm substance.

Evolution of Alarm Substance

While the evolution of the signals involving alarm substance–fright reaction has been a topic of great debate and controversy, recent studies now reveal that the alarm substance has evolved as a defense against environmental stressors such as pathogens, parasites, and ultraviolet (UV) radiation, and that it is secondarily co-opted by predators and prey as a chemical signal. This conclusion is based on the recent studies indicating that predation pressure does not influence alarm cell production in fishes; rather, it is stimulated by exposure to skin-penetrating pathogens (water molds, parasites, and UV radiation). Basic chemical characterization of the contents of club cells is again lacking. These authors hypothesize that individual ostariophysan and percid fishes benefit from investing in club cells owing to the protective function the cells provide. When these cells are ruptured by predation, nearby receivers have driven the development of receptors and responses to these alarm cues, thus reducing the probability of predation (**see also Hormones in Communication:** Hormonal Pheromones).

Predator–Prey Interactions

Not to be confused with the alarm substance–fright reaction system, *per se*, is the threat-sensitive predator avoidance hypothesis, which states that prey behave according to the degree of threat posed by their predators. For example, pike-experienced fathead minnows have the ability to differentiate individual pike in a mixture of odors from several pike, and can assess the relative concentration of the odor from each pike. The information carried by predator odors allows preys to accurately assess their level of risk, and respond to predation threats in a threat-sensitive manner. However, if the fathead minnow/pike predator/prey system is to be used as a model system for studying predator odor recognition, researchers need to establish that behavioral responses of minnows to pike water used in these studies is indeed specific for the predator pike.

Homing of Salmon

Evidence of Homing

Salmon are known for their spectacular migration (**see also Fish Migrations:** Pacific Salmon Migration: Completing the Cycle). This impressive feat comprises three migratory phases: (1) downstream journey of the young to the oceans, (2) return of spawning adults to the coastal area near the entrance to their home streams, and (3) the upstream migration. Phases 1 and 2 are thought to rely primarily on non-chemosensory mechanisms, and will not be discussed here. Over 100 years ago, in 1880, Buckland postulated an olfactory basis for salmonid homing, and his statement is quoted even today. The olfactory hypothesis, cast into modern terms by Hasler and his students, proposes that during a developmental period (parr-smolt transformation, PST), salmon imprint to home-stream odors, and adults later use this odorant memory as a migratory cue to guide them back to their natal home stream. The results of olfactory impairment experiments repeated over 20 times using seven different salmonids species are remarkably consistent; in 16 experiments, the olfactory sense appeared to be necessary for correct homing, and, in addition, two studies demonstrated that blind fish homed nearly as well as control fish, indicating that vision is not essential for relocating the original stream during upstream migration.

Olfactory Imprinting

Experimental evidence indicates that olfaction is essential for successful completion of the homing migration. Transfer studies clearly indicate that the salmon do not return to the stream to which their parents returned, but return instead to the stream where they themselves spent the period between the time of transfer and release. Thus, homing is not a genetically determined character, but depends on learning during early critical life of salmon. Salmon must learn the chemical cue without reinforcement during ocean residence, and respond to it as adults.

To test this hypothesis, Hasler and his colleagues exposed juvenile coho salmon (*Oncorhynchus kisutch*) to one of two synthetic chemicals, morpholine or β-phenylethyl alcohol (PEA) at Lake Michigan tributaries, and were able to attract the salmon into unfamiliar streams scented with one of these chemicals during their spawning migration 1.5 years later. Approximately 95% of the morpholine fish were captured in the morpholine-scented stream and 92% of the PEA fish were recovered in the PEA-scented stream. Further studies show that coho salmon learn the odors of their home stream during the PST, a developmental process characterized by physiological and behavioral changes, which prepare freshwater residents (parr) for life at sea. These results are consistent with the general finding that salmon reared at one site but released from a second site prior to, or during PST, return as adult to the release site, not the rearing site. This olfactory imprinting during PST has become an important component of salmon enhancement programs.

Molecular Mechanisms of Imprinting

The most characteristic feature of the olfactory imprinting in salmon is that it is linked to a sensitive period of development. Electrophysiological and biochemical studies provide compelling evidence that populations of olfactory receptor neurons are selectively tuned to respond to odor molecules present during a sensitive period, 'peripheral odor memories'. Olfactory neurons isolated from PEA-imprinted fish are nearly twice as likely to respond to PEA compared with those of nive fish, and neurons from the imprinted showed a sixfold increase in responsiveness to PEA compared with the control. However, neurons isolated from both groups responded similarly to the amino acid L-serine, suggesting that the change in the sensitivity is specific to the imprinted odorant. Generally, in olfaction, receptor activation by odors stimulates adenylyl/guanylyl cyclase activities, causing a rapid increase in intracellular cyclic adenosine monophosphate, which, in turn, activates cyclic nucleotide-gated channels, resulting in membrane depolarization and the generation of action potentials (**see also Smell, Taste, and Chemical Sensing:** Neurophysiology of Olfaction). Stimulation of guanylyl cyclase activity is significantly greater in olfactory cilia isolated from PEA-imprinted salmon compared with PEA-naive fish only at the time of the homing migration, 2 years after PEA exposure. These results suggest that exposing salmon smolts to nanomolar concentration of PEA for as little as 10 days could be correlated with dramatic and measurable changes in their peripheral sensitivity to odors even years later. However, before these data are reconciled into a workable model, the following questions would have been answered: (1) do salmon possess a specific olfactory receptor gene for either morpholine or PEA, and thereby detect them physiologically, and (2) why do salmon become sensitive selectively to exposed morpholine or PEA, when there exist hundreds of other odorants including L-serine? Modern olfactory theory explains that olfactory receptors are encoded by a large multigene family belonging to the superfamily that encodes G-protein-coupled receptors, whose repertoire is around 100 in fishes. Each olfactory neuron expresses one or a few genetically determined olfactory receptors.

What makes the home stream so specific to migrating salmon? A number of attempts have been made to isolate and identify the home stream odor substance, which has been variously characterized as being volatile, water-soluble, neutral, dialyzable, and heat labile. Recent studies show that amino acids in stream water are essential for the homing migration of salmon. Each stream contains a specific amino acid composite that derives from organisms in a tributary. It would not be surprising if amino acids play an essential role in all aspects of behaviors involving feeding, reproduction, kin-recognition, and possibly predator–prey interaction.

Glossary

Agnatha Primitive jawless (a = without; gnathos = jaw) fish dominant in the early Paleozoic, and represented today by hagfish and lamprey.

Bony fish The majority of extant fishes – more than 30 000 known species.

Cupula A gelatinous structure found associated with sensory hair cells in the vestibular part of the ear, the macula neglecta, and the lateral line. Motion of the cupula stimulates the sensory cells.

Eighth cranial nerve The nerve that transmits information between the ear and brain.

Elasmobranch The subclass of fishes (Elasmobranchii) found within the class Chondricthyes that includes sharks, skates, and rays, making up the Chondricthyes or cartilaginous fishes. Their bones are made up of cartilage rather than calcium found in all other vertebrates.

Inner ear The part of the ear that is located inside of the head that is responsible for detection of sound (hearing) and movement of the head relative to gravity (vestibular). It consists of three semicircular canals and three otolith end organs, as well as a macula neglecta.

Lateral line Sensory structure consisting of a series of mechanoreceptor cells on the surface of the body of fishes and for detection of water motion relative to the body and low-frequency sound.

Neuromast The functional unit of the lateral line consisting of a patch of hair cells, supporting cells and the overlying cupula.

Otolith A structure found in the inner ear made up of calcium carbonate. Motion of the otolith relative to the sensory cells of the ear results in stimulation of the cells and detection of sounds.

Sensory epithelium The tissue that contains the sensory hair cells in the ear and lateral line.

Sensory hair cell The cell that is the stimulus detector used in the ear and lateral line. The cell has special cilia on its apical (top) surface that are bent by either the cupula or otolith. Once bent, various chemical events start and result in the release of a chemical (neurotransmitter) that then stimulate the eighth nerve that carries the signal to the brain.
Sound localization Determination of the direction of the source of sound around the body of an organism.
Soundscape The acoustic environment around an animal. It may consist of sounds produced by biotic (biological) and abiotic (nonbiological) sources.
Swimbladder A gas-filled structure in the abdominal cavity of many bony fishes. The swimbladder is involved with buoyancy control as well as in sound production and detection.
Teleost The most recently evolved of all the bony fishes (Osteichthyes). Teleosts include everything from goldfish to tuna to salmon.
Vestibular The sense that is found in the ear that detects motion of the head and body relative to gravity.

Origin of the Ear and Hearing

Where and why did hearing evolve among the vertebrates? While not a question that people often ask themselves, the answers are of considerable interest, and may even help humans think about their own sense of hearing. The general view of humans is that hearing has reached its pinnacle with speech, and that we are the foremost users of sound.

The truth, however, is that hearing is highly evolved in most vertebrates, and while no groups other than humans use speech, numerous species use sound to communicate and to learn about their environment. Indeed, it is very likely that the major selective pressure for the evolution of hearing in vertebrates was not for communication, but so that the most primitive animals could glean information about their environments.

Consider that the first vertebrates arose in water. Water is not very conducive to visual communication because the environment is often dark due to murkiness of the water or depth (as well as night), and objects can often block direct visualization of things at any substantial distance from an animal. Moreover, because the eyes are firmly planted in a specific location on the head, the visual field, or area around an animal that is in sight at any one time, is limited. It turns out, however, that the underwater environment is ideal for use of sound. Sound travels very rapidly in water (about five times faster than in air) and it attenuates (loses energy) much more slowly than in air. As a consequence, a sound can travel a considerable distance and it is not interfered with by objects in the environment, darkness, or even the currents that prevent chemical cues from moving quickly or in a straight line.

Thus, one may speculate that the very earliest vertebrates may have evolved a mechanism to detect sound so that they could gather information about objects that were at considerable distances, and all around them, and so they could gather the same information with or without visual cues. Sounds, though detectable to the earliest vertebrates, may not have been communication sounds that are used now, but more likely they were abiotic sounds produced by the surf, rain on the water, movement of currents around rocks, and other things in the environment. Sounds may also have been biotic, or produced by living things, but in the earliest days of vertebrate evolution these sounds may not have been intentionally produced. Such biotic sounds may have been produced by the swimming of predators or prey, chewing of animals on coral reefs, and in any number of other ways, all of which would tell the animal a good deal about its extended environment – its acoustic scene.

It is hard to know what the earliest sound-sensing devices were because there is not a good fossil record of sensory receptors in aquatic organisms. However, in 1967 Willem van Bergeijk speculated that the earliest receptors were located on the skin, and were probably somewhat similar to the surface lateral line system found in modern fishes and sharks, as described by Montgomery and Coombs in **Hearing and Lateral Line**: Lateral Line Neuroethology and by Webb in **Hearing and Lateral Line:** Lateral Line Structure. The most primitive lateral line probably only detected very low frequency water motions, even as it does today.

Van Bergeijk then went on to speculate that the lateral line evolved so that a region became embedded under the skin, as is found in the modern lateral line. He went on to suggest that a portion of this lateral line then developed some kind of associated structure, now known as the otolith, and became the most primitive ear. Since this ear had both a mass (the otolith) and receptor cells (the sensory cells of the lateral line), it would function as primitive accelerometer that could detect low-frequency signals, both from head motion and sound. Once the ear was established, one can hypothesize that, over time, it evolved the ability to detect higher-frequency sounds.

Finally, as the ear evolved, there may have been the co-evolution of better hearing and the production of sounds used in communication.

Origin of Knowledge of Fish Hearing

Historically, it appears that Aristotle and other older thinkers understood that fishes make sounds. Indeed, in about 350 BCE Aristotle wrote: "Fishes can produce no voice, for they have no lungs, nor windpipe and pharynx; but they emit certain inarticulate sounds and squeaks, which is what is called their 'voice', as the lyra or gurnard, and the sciaena (for these fishes make a grunting kind of noise) and the caprus or boar-fish in the river Achelous, and the chalcis and the cuckoo-fish; for the chalcis makes a sort piping sound, and the cuckoo-fish makes a sound greatly like the cry of the cuckoo, and is nicknamed from the circumstance. The apparent voice in all these fishes is a sound caused in some cases by a rubbing motion of their gills, which by the way are prickly, or in other cases by internal parts about their bellies; for they all have air or wind inside them, by rubbing and moving which they produce the sounds. Some cartilaginous fish seem to squeak. But in these cases the term 'voice' is inappropriate; the more correct expression would be 'sound'."

It may have been Gaius Plinius Secundus, better known a Pliny the Elder, who first wrote about fish hearing sometime in the earliest part of the first century CE (see **Figure 1** for a 1601 translation). Other more recent people further mentioned fish hearing in their writing, though mechanisms were not discussed. For example, Izaak Walton, in his monumental *The Complete Angler*, in 1653 wrote: "...has made me to believe that *Eeles* unbed themselves, and stir at the noise of the Thunder, and not only as some think, by the motion or the stirring of the earth, which is occasioned by that Thunder" (chapter V). He also noted that "And this reason of Sir *Francis Bacons* Exper. 792 has made me crave pardon of one that I laught at, for affirming that he knew *Carps* come to a certain place in a Pond to be fed at the ringing of a Bel; and it shall be a rule for me to make as little noise as I can when I am a fishing" (chapter V).

However, despite these observations, nothing was really known about fish ears until the first description of a fish ear by Giulio Cesare Casserius, who, in 1601, published *De vocis auditusq[ue] organis historia anatomica singulari*. This volume included the first description of otoliths. This was followed by the brilliant anatomical work of E. H. Weber (1820) who, in his book *De Aure et Auditu Hominis et Animalium. Pars I. De Aure Animalium Aquatilium*, described the Weberian ossicles, a series of bones in the otophysan fishes (goldfish, catfish, and relatives) that are involved with hearing, as well as other structures we now associate with hearing by fishes (**Figures 2(a)**, **2(b)**, and **3(a)**) (**see also Hearing and Lateral Line**: Auditory System Morphology and Psychoacoustics: What Fish Hear). This was followed in 1881 by a two-volume anatomical work by G. Retzius that presented a brilliant set of drawings of the ears of vertebrates from fish to man (see **Figure 3(b)** and figures in **Hearing and Lateral Line**: Auditory System Morphology and The Ear and Hearing in Sharks, Skates, and Rays).

However, it was not until the early 1900s when the great American physiologist G. H. Parker did a series of

Tavolga, the modern pioneer in the field.

definitive experiments that showed that fishes could hear. This was followed by a series of wonderful studies by Karl von Frisch (who later went on to win the Nobel prize for his brilliant deciphering of the dance language of bees) and his students Stetter and Dijkgraaf, who not only further demonstrated that fishes could hear, but also that they could discriminate between sounds (**Figure 3**(**c**)). However, von Frisch and his students were not able to establish if fishes can tell the direction of a sound source (sound source localization), an area of intense research even today (**see also Hearing and Lateral Line**: Sound Source Localization and Directional Hearing in Fishes).

While there was some work on fish hearing in the first half of the twentieth century, studies of fish bioacoustics first really took off with a conference organized in 1963 by William Tavolga (**Figure 3**(**d**)) and a definitive study that he did with Jerome Wodinsky that measured hearing

capabilities of nine species of marine fishes. Tavolga also provided a definitive history of the field in 1971 and this, combined with another history by James Moulton in 1963, provides a complete historical perspective on how the field grew until the mid-1900s.

Perspectives on Fish Bioacoustics

Bioacoustics is an encompassing term that covers hearing, sound production, and communication using sound. This section attempts to provide an overview of these topics (as well as the lateral line and vestibular systems) as they are associated with fishes. These topics certainly do not cover everything that is known about fish bioacoustics, but they are intended to serve as a primer for someone new to the field, while also offering a review and stepping-off point for the next generation of scientists.

The ear originally served to enable fishes to orient within a three-dimensional environment. This detection of movement is the function of the vestibular part of the inner ear and brain. It is a sense that is vital to all vertebrates as discussed by Baker and Straka in **Hearing and Lateral Line**: Vestibular System Anatomy and Physiology, but one about which most people are unaware until the sense does not function correctly.

The thrust of bioacoustics is involved with hearing and sound production, as well as the detection of water motion. Hearing involves the inner ear and, in some cases, ancillary structures such as the swimbladder. Detection of water motion is the function of the lateral line. Sound production involves a wide range of structures, including, in many species, the swimbladder. Before one can truly comprehend the importance of sound and the auditory system to the behavior and survival of fishes, it is first important to understand how fishes detect a signal and the types of signals to which they might be listening. The fish auditory system is not as well understood as the auditory system of terrestrial vertebrates, but it contains all of the necessary components for the detection of sound in an aquatic environment including anatomical structures that are very similar to those in terrestrial vertebrates (including mammals). Moreover, the auditory structures of fishes are capable of performing all the major functions of hearing that are found in more so-called advanced vertebrates.

The anatomy of the ear is described in detail for fishes by Popper in **Hearing and Lateral Line**: Auditory System Morphology and for sharks and rays (elasmobranchs) by Casper in **Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays, while the mechanisms of the ear that result in sound detection are described by Hastings in **Hearing and Lateral Line**: Biomechanics of the Inner Ear in Fishes. In addition to understanding the ear and its function, one must consider hearing capabilities of fishes because they reflect not only ear function, but also processing of sound by the brain. Thus, Fay, in **Hearing and Lateral Line**: Psychoacoustics: What Fish Hear, discusses hearing capabilities of fishes, whereas how the brain processes sounds is considered from the standpoint of brain anatomy by McCormick in **Hearing and Lateral Line**: Auditory/Lateral Line CNS: Anatomy and Physiology by Lu in **Hearing and Lateral Line**: Physiology of the Ear and Brain: How Fish Hear.

It is also important to understand what types of sounds fishes are listening to. The auditory soundscape makes up the sum total of what fishes encounter in their aquatic environments and is discussed by Fay in **Hearing and Lateral Line**: Psychoacoustics: What Fish Hear. It is also important to understand the physical properties of how sound travels within water and the adaptations fishes utilize to accommodate for these factors as discussed by Hastings in **Hearing and Lateral Line**: Biomechanics of the Inner Ear in Fishes. Further associated with these physical properties of sound is the ability, and difficulties, of fishes to localize the source of a sound (estimate the direction of the sound), and this is discussed by Zeddies, Fay, and Sisneros in **Hearing and Lateral Line**: Sound Source Localization and Directional Hearing in Fishes.

One of the critical issues today in fish bioacoustics is not just what and how fishes hear, but how the sounds produced by humans in the waters may affect the way fishes hear and use sound. This question is of growing national and international concern, and it is discussed by Hawkins in **Hearing and Lateral Line**: Effects of Human-Generated Sound on Fish.

The other part of bioacoustics is the production of sound. Humans have known for thousands of years that fishes produce sounds (**Figure 1**), but we are only just realizing how many species accomplish this. Luczkovich, Sprague, and Krahforst in **Hearing and Lateral Line**: Acoustic Behavior, as well as Kaatz in **Sensory Systems, Perception, and Learning**: How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling, provide an overview of the sounds fishes produce and the behavioral contexts in which the sounds are used. Sound production by fishes involves mechanisms very different from those in terrestrial animals because there is generally no release of air by fishes, whereas sound production in terrestrial animals generally involves the release of air over some kind of structure, such as the mammalian larynx. The mechanisms used by fishes are discussed by Ladich and Bass in **Hearing and Lateral Line**: Vocal Behavior of Fishes: Anatomy and Physiology.

As mentioned several times in this article, the lateral line is a very early evolved vertebrate system that uses sensory hair cells for the detection of signals. These hair cells are very similar to those of the ear in fishes and terrestrial vertebrates. The function of the lateral line was not really understood until the last half of the twentieth century, and we now know that it shares a place with the auditory system in the overall mechanosensory system in fishes and represents a unique sensory receptor that is only found in aquatic organisms. The lateral line provides for what Dijkgraff called ‘distance touch’, and enables fishes to sense their immediate surroundings as well as other organisms that might be within their vicinity. (The detection of water motion by the lateral line is called Svenning, and was named by Platt, Fay, and Popper in honor of Professor Sven Dijkgaaf.) The role of the lateral line in fish behavior is discussed by Montgomery and Coombs in **Hearing and Lateral Line**: Lateral Line Neuroethology, while Webb, in **Hearing and Lateral Line**: Lateral Line Structure discusses how the basic organization of the lateral line system is similar among most fishes.

Conclusions

The history of our understanding of the role that sound plays in the lives of fishes is a long one, stretching back at least to 350 BCE. However, the first formal scientific recognition of how fishes might hear was not until 1601, and then it was not until around 1902 that it was first demonstrated experimentally that fishes hear and that they use their ears for sound detection. Subsequently, the twentieth century saw a substantial increase in interest in bioacoustics and contributions from a wide range of investigators who asked, and continue to ask, questions about communication, sound production, hearing, the lateral line, and the vestibular sense. The articles referred to here provide a broad overview of our current knowledge as well as insights into the most important scientific questions on fish bioacoustics for the next decades.

Glossary

Egocentric direction Navigation in space with a self-centered reference frame.

Gaze stabilization Maintenance of stable eye and/or head position in respect to the environment.

Gravitoinertial function Detection of static changes in head/body position relative to the Earth's gravitation vector.

Labyrinth A peripheral sensory compartment within the inner ear that includes semicircular canal and otolith end organs.

Lagena An otolith end organ specialized, together with the sacculus, for detecting acoustic stimuli.

Octavolateral nuclei Assembly of functional subgroups in the hindbrain that process sensory signals related to detection of water (lateral line) or object motion (electroreceptive), acoustic stimuli (hearing), or body motion (vestibular).

Otolith Solid calcium carbonate crystal in the saccule, lagena, and utricle, which are involved in the detection of vestibular and auditory stimuli.

Otolith end organs Separate structures that contain sensory epithelia overlain by solid calcium carbonate crystals for detection of vestibular and auditory signals.

Placode Region in the embryonic epithelial layer which gives rise to sensory organs and other structures.

Sacculus An otolith end organ specialized, together with the lagena, for detecting acoustic stimuli.

Semicircular canals Three interconnected membranous ducts within the inner ear that detect angular rotations during turning.

Utricle An otolith end organ specialized for detecting both static and dynamic head motions.

Vestibuloocular reflex Compensatory eye movements in response to vestibular stimulation that minimizes retinal slip to facilitate visual processing.

Introduction

Vestibular neurons and circuits process information related to self-motion (i.e., head/body) in all vertebrates, including fish. The vestibular system is one component of a multisensory brainstem network because other sensory organs also detect self-motion (e.g., eyes and lateral line). Importantly, the most prominent signals triggering the motor behaviors essential for both escape and predation originate from sensory end organs in the inner ear.

All fish use the vestibular system to transduce and then process information about their body position and motion in three-dimensional (3D) space, irrespective of either active or passive body movement arising from underwater currents. For a fish to maintain a particular posture in water, all motion-related sensory signals have to be transformed within the central vestibular networks into motor commands appropriate for controlling the eyes, fins, body, and tail. The coordinated temporal and spatial activation of multiple and widely distributed appendages stabilize whole body position both at rest and during active swimming.

As expected, all vertebrates are confronted with the effects of individual locomotor actions on their ability to perceive the surrounding environment. They must distinguish self from world/object motion. Self-generated as well as passive body motion cause retinal image displacements, with a resultant degradation in the processing of visual information. To maintain visual acuity, retinal image drift must be counteracted by dynamic (rapid) compensatory adjustments in eye position, largely provided by vestibuloocular reflexes (VORs). In essence, a fish must have precise knowledge about its body motion to maintain retinal constancy of objects in the environment by distinguishing whether the objects or their retinal locations are either stationary or moving. Achieving stable gaze with the VOR illustrates perfectly how the vestibular system functions to enable continuous accurate perception of objects moving in the external world with respect to the self. Thus, the fact that the eyes are held still with respect to the environment under all conditions of body motion, especially independent of object motion, evolved many hundreds of millions of years ago by innovations in the hindbrain developing in parallel with cerebellar circuitry.

Evolution also further utilized the vestibular system to compute the perceptual attribute commonly referred to as egocentric direction. Viewed from the context of motor control, a robust egocentric reference frame must exist in the hindbrain and cerebellar circuitry for an animal to choose an appropriate locomotor trajectory during swimming. Thus, vestibular signals that originate from activation of the equilibrium organs in the inner ear during active and passive body motion play a crucial role in the ability to precisely perceive the environment and maintain appropriate body position during locomotion. Perhaps the most significant vestibular attribute, therefore, is distinguishing self-motion from that of the world. Without doubt, vestibular reflexes are essential for survival independent of the ecological niche, life style, and locomotor pattern of a particular species of fish. They allow a fish to distinguish self and self-motion from object motion in the world.

Organization of the Vestibular Sensory Periphery

Sensory signals related to body position and motion are processed and transformed into respective motor commands in an assembly of hindbrain neuronal subgroups, collectively described in the literature as the octavolateral nuclei (**see also Hearing and Lateral Line:** Auditory/Lateral Line CNS: Anatomy). Functionally, these heterogeneous subgroups of neurons process four different sensory modalities: lateral line for detection of either water motion (mechanoreceptive) (**see also Hearing and Lateral Line:** Lateral Line Structure and Lateral Line Neuroethology) or objects (electroreceptive) (**see also Detection and Generation of Electric Signals:** Detection and Generation of Electric Signals in Fishes: An Introduction), auditory for acoustic stimuli (**see also Hearing and Lateral Line:** Auditory System Morphology, The Ear and Hearing in Sharks, Skates, and Rays, and Psychoacoustics: What Fish Hear), and vestibular for body motion. The peripherally located epithelial end organs for these sensory modalities appear during early development from a common embryological region called the 'placode' (**Figure 1**). Individual placodal regions give rise either to lateral line/electroreceptive sensory structures on the body surface (AD, AV, M, P, and ST in **Figure 1**) or to inner ear vestibular/acoustic organs (OT in **Figure 1**). The sensory transduction mechanism in all cases is largely based on the same ancestral hair cell type (**see also Hearing and Lateral Line:** Auditory System Morphology). This ubiquitous mechanoreceptor-type cell is used to detect and convert respective physical forces into neuronal activity, clearly distinguishing between electro- and mechano-sensory stimuli.

Peripheral vestibular end organs of most fish consist of three separate semicircular canals attached to a single sac-like structure, the utriculus (fishes; **Figure 2**) (**see also Hearing and Lateral Line:** Auditory System Morphology). Two additional sac-like structures, the sacculus and the lagena, are largely utilized for hearing in nearly all fish species (**see also Hearing and Lateral Line:** The Ear and Hearing in Sharks, Skates, and Rays, Psychoacoustics: What Fish Hear, Physiology of the Ear and Brain: How Fish Hear, and Sound Source Localization and Directional Hearing in Fishes). Three semicircular canals are oriented at right angles from each other comprising three different planes, which likely offer the optimum physical arrangement for sensing 3D motion in a neutrally buoyant environment. Nevertheless, only one (hagfish; **Figure 2**) or two vertical canals (lampreys; **Figure 2**) were present in the most recent jawless fish ancestors; hence, the addition of a horizontal canal in

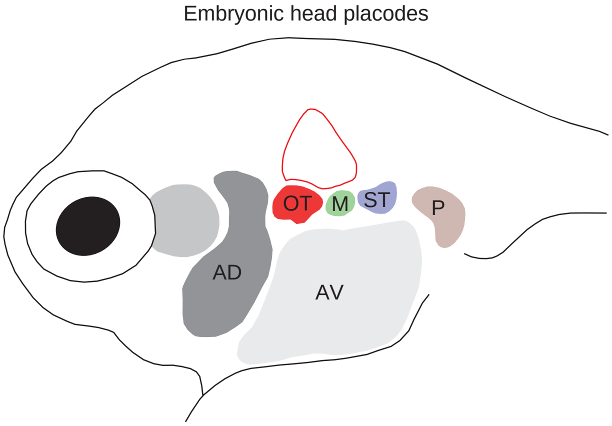

Figure 1 Ontogenetic origin of mechanoreceptive sensory organs (lateral line, electroreception, inner ear vestibular, and auditory sensation). Schematic side view of a fish embryo depicting common placodal origins. AD, anterodorsal placode; AV, anteroventral placode; M, middle placode; OT, otic placode; P, posterior placode; ST, supratemporal placode.

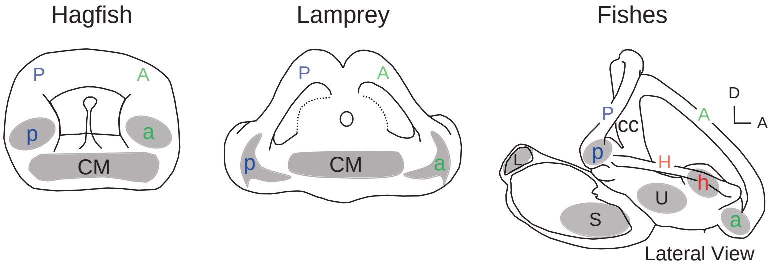

Figure 2 Phylogeny of vestibular labyrinths. A single semicircular canal with two patches (a, p) of sensory epithelia for sensing both anterior (A) and posterior (P) motion (hagfish). Separate anterior (A) and posterior (P) semicircular canal with specialized (a, p) sensory epithelia are found in jawless fish (lamprey). A common central macular organ (CM) is present for graviception in both species. In elasmobranchs and bony fishes, two vertical (A, P) and one horizontal (H) semicircular canal are oriented perpendicular to each other for detection of 3D angular acceleration by cupular deflections (a, p, h). Three separate macula organs (U, L, and S) serve as graviceptive (utricle) and pressure-detecting sensors (lagena, saccule).

elasmobranchs and bony fish arose as a new invention during fish evolution. This newly acquired mirror-image arrangement of the sensory periphery (fishes; **Figure 2**) is a major structural design of the vestibular system that allows the semicircular canals and the utricle to act reciprocally during head motion.

The semicircular canals, as well as the otolith organs (utricle, sacculus, and lagena), are filled with endolymph, a potassium-rich fluid that plays an essential role in the sensory signal transduction process. Each canal has an expansion known as an 'ampulla' containing a crista, covered by a gelatinous cupula, which is deformed by fluid movements during head/body motion. The canals detect turning movements of the head/body about their respective axis (**Figure 2**), thus acting as force transducers of angular acceleration. The utricle contains a single calcium carbonate stone, called an 'otolith', overlying a fixed macula of hair cells and this organization is highly effective for transducing linear acceleration. The presence of single otolithic masses in teleosts is the reason for initially referring to these sensory structures as otolith organs (**see also Hearing and Lateral Line:** Auditory System Morphology). The major role of the utricle in fish relates to sensing inertia through detection of static changes in head/body position relative to the Earth's gravitation vector, thereby creating an internal frame of reference for establishing egocentric direction responsible for orientation and locomotor behaviors. These major utricular roles observed in fish fit well with an earlier evolutionary appearance of this end organ than that of the semicircular canals, which require a critical spatial dimension to allow fluid movements for the detection of head motion. For this reason, it seems inappropriate to call the peripheral vestibular end organs simply the inner ear (**see also Hearing and Lateral Line:** Biomechanics of the Inner Ear in Fishes).

Peripheral hair cells in both the lateral line/electrosensory neuromasts on the body surface as well as the specialized vestibular/auditory end organs in the inner ear are chemically linked to first-order afferent nerve fibers that forward the sensory signals to distinct nuclear regions in the dorsal hindbrain. Vestibular afferent fibers that innervate the different semicircular canal organs and utricle are segregated from all other VIIIth nerve components. In addition, vestibular afferents project exclusively to the most lateral octavolateral subgroups in the hindbrain. Based on an evolutionarily conserved neuronal projection to brainstem and spinal regions, largely responsible for the control of balance and locomotion, the lateral portions of the octavolateral nuclei can be distinguished from the more medial and dorsal nuclei that process acoustic and lateral line sensory signals (**Figure 3**).

Central Location of Vestibular-Related Octavolateral Nuclei

The vestibular nuclei occupy a considerable part of the dorso-lateral hindbrain between the Vth and Xth cranial nerves (**Figure 3**) (**see also Hearing and Lateral Line:** Auditory/Lateral Line CNS: Anatomy). Comparison of morphological features in several species of fish generally identifies five major subdivisions of second-order neurons in the vestibular nuclei. Moreover, distinct functional groups, identified according to their neuronal signals, are associated with a particular behavior (e.g., eye or body motion) and correlate reasonably well with the anatomical map. The similarity of structure and function of the major vestibular cell groups that control eye, fin, body, and tail motion across different fish species, therefore, allows vestibuloocular, vestibulospinal, vestibulocommissural, and vestibulocerebellar neurons to be identified as distinct populations. By and large, the current delineation of vestibular subgroups is based on: (1) regionally restricted terminations of first-order afferent fibers from the different peripheral vestibular end organs; (2) anatomical tract tracing from efferent projection areas in the midbrain, hindbrain, and spinal cord; and (3) electrophysiological

correlates of second-order neurons during different behavioral paradigms. The most comprehensive topographical mapping and electrophysiological studies have been carried out in goldfish (*Carassius auratus*), and this species is used here as an example to summarize the overall organization of the vestibular subgroups within the octavolateral nuclei.

Origin of the Octavolateral Vestibular Subgroups

All vestibular subgroups take their origin from a hindbrain segmental framework, which begins in early development as eight well-defined neuroepithelial compartments. The early embryonic hindbrain patterning serves as a mechanistic guide that directs the development of particular vestibular functional phenotypes involved in stabilization of retinal images and body posture. Combinatorial expression of spatially restricted regulatory genes plays a dominant patterning role in the development of any neuron, vestibuloocular, or vestibulospinal, in any of the eight hindbrain compartments. This genetically specified compartmental blueprint is conserved between all species of fish, as well as for subsequent terrestrial vertebrates with only minor modifications.

Vestibular neuronal subgroups evolved long before modern fishes in the earliest and now-extinct groups of jawless vertebrates. Interestingly, in living lampreys, the two vertically oriented semicircular canals, anterior and posterior (**Figure 2**), contribute equally to detection of the horizontal components of angular head acceleration. Hence, there are two well-delineated horizontal vestibular subgroups in the hindbrain. However, a third (horizontal) canal was added to the ontogenetic blueprint in modern sharks and fishes (**Figure 2**) such that the two separate horizontal vestibular subgroups receive a common afferent input from one canal rather than a separate signal from the original anterior and posterior canal design. Notably, this structural design of two separate horizontal vestibular subgroups, unique to central horizontal eye movement circuitry, has been conserved ever since it evolved in jawless fishes to present-day mammals.

Ever since the earliest jawless vertebrates, the vestibular subgroups appear to align with the peripheral location of the anterior and posterior semicircular canals surrounding a central otolith. However, such a stereotyped arrangement is more apparent than real because first-order vestibular afferents exhibit the capability to contact neurons in any of the vestibular subnuclei. Thus, it is likely that the vestibular system in jawless and jawed fishes was quickly converted from a point-to-point, hardwired canal/otolith projection to a highly integrated network in which the appropriate vestibular signal could be utilized independent of the canal of origin but more dependent on the functional role of the targeted motor circuit.

The primitive vestibular system largely relayed purely sensory signals to subsets of neurons that effectively could both generate and relay online signals to motor nuclei. However, in most cases, the vestibular signal can be equally correlated with the sensory stimulus (head motion) or the motor response (eye motion). It turns out that, quite early in evolution, fishes had converted the sensory-related neural activity in many of their vestibular subgroups into motor coordinates (e.g., as seen in goldfish second-order neurons) that exhibit all of the horizontal eye movement signals for visuo-vestibular-induced eye movements. From a systems control point of view, the vestibular subgroups are much more than simple sensory relay neurons; they also represent the motor command for appropriate contractions of eye, fin, body, and tail muscles.

Central Terminations of Semicircular Canal and Utricular Afferents

The distribution of first-order afferent fibers from individual canals and the utricle allows individual vestibular nuclei to be recognized with respect to the direction of head/body motion. Anterior and posterior canal afferents terminate predominantly, though not exclusively, in the anterior octavolateral nucleus (AO) and the tangential nucleus (T) (**Figure 3**). Afferent projections from these two canals are less dense in the descending octavolateral nucleus (DO) and the posterior octavolateral nucleus (PO) (**Figure 3**). In contrast, the horizontal canal afferent termination coincides with one set of smaller neurons in the magnocellular octavolateral nucleus (MO), as well as more uniformly in another subset located throughout DO and T (**Figure 3**). First-order utricular afferents terminate predominantly in MO, T, and DO, thus overlapping to a considerable extent with those from the horizontal canal. Significant for all sensorimotor behaviors in fish, there are virtually no vestibular nuclei that receive exclusive afferent projections from a single peripheral end organ. Rather, first-order afferents overlap more or less completely, even though hot spots of terminations of fibers from particular vestibular organs exist in some nuclei. This widespread vestibular afferent pattern thus differs from topological maps of other sensory systems such as the closely related visual system. The absence of a sensory point-to-point map is consistent with the finding that signal processing in central vestibular nuclei is spatially organized more according to efferent (largely motor) targets rather than topological hindbrain location. Observations on the distribution of afferent inputs are, in turn, quite compatible with the demonstrated roles of the vestibular subgroups in sensorimotor transformations contributing to the control of gaze (eye/head) and posture.

Hindbrain Vestibuloocular Origins and Projections to Extraocular Motor Nuclei

Perhaps the dominant structural attribute of the vestibular system is the spatially precise projection of vestibular subgroups to extraocular motoneurons located in the oculomotor, trochlear, and abducens nuclei. These three-neuronal VOR pathways consisting of first- and second-order vestibular and extraocular motoneurons are responsible for compensatory, 3D eye movements in all species of fish. Continuous, unblurred vision during high frequency and large amplitudes of head motion would not be possible without the vestibular nuclei.

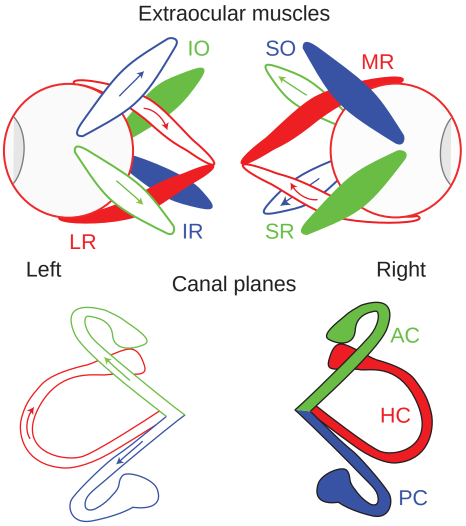

Figure 4 Extraocular muscles and pulling directions (view from dorsal) are illustrated with respect to semicircular canal orientation. Horizontal (HC, red), anterior (AC, green), and posterior vertical canal (PC, blue) are aligned with matching pairs of synergistic ipsi- and contralateral eye muscles (see matching color codes). LR, MR, lateral, medial rectus; IO, SO, inferior, superior rectus; IR, SR, inferior, superior rectus.

Compensatory eye movements are produced in fish, as in all other vertebrates, by a set of six eye muscles that insert on each eye bulb, such that any horizontal, vertical, or torsional movement can be performed (**Figure 4**). A major organizational principle of the angular VOR is the approximate alignment of the axes of a particular semicircular canal and the pulling directions of synergistic sets of two extraocular muscles (**Figure 4**). This arrangement illustrates the intricate link that has evolved between sensory and extraocular reference frames that in many species nearly perfectly stabilizes vision in response to eye/head body motion. The vestibular neuronal subgroups critical for sensorimotor transformation of angular as well as linear acceleration signals are located laterally within the borders of AO and DO/PO (**Figure 3**). In general terms, the fundamental rule underlying any vestibuloocular connection is matching the spatial vector orientations for body movements around the roll and pitch axes with the extraocular motoneurons producing vertical and torsional eye movements. Afferent input from the two vertical canals comprises the major input for vestibular subgroups activating extraocular muscles (SR, IR, SO, and IO) with corresponding spatially aligned pulling directions (**Figure 4**).

Second-order vestibular neurons form behaviorally different and spatially nonoverlapping subgroups within the vestibular portion of the octavolateral nuclei. The functionally distinguishable oculomotor/trochlear-projecting vestibuloocular neurons originate mainly from a rostral (AO) and to a minor extent from a caudal vestibular area (DO/PO). Each respective subgroup of vestibuloocular neurons receives afferent labyrinthine input from either the anterior or posterior vertical semicircular canal compatible with the spatial specificity of their target vertical and oblique extraocular motoneurons (SO, IO, SR, and IR). An additional organizational principle of the vestibulomotor projections is a push–pull arrangement that allows excitation of particular sets of eye muscles and simultaneous inhibition of the respective sets of antagonists. Accordingly, vestibuloocular projections consist of inhibitory neurons, whose axons remain ipsilateral, and excitatory neurons, whose axons cross the midline to match agonist/antagonistic extraocular motor targets. Axons from the excitatory and inhibitory vestibuloocular subgroups reach their respective subdivisions in the oculomotor/trochlear nuclei by pathways in the ipsi- or contralateral medial longitudinal fasciculus (MLF) (**Figure 3**).

Horizontal Vestibuloocular Subgroups

Horizontal eye movements (upper panel in **Figure 5**) are particularly important for scanning the visual horizon and both eyes move conjointly producing conjugate movements that together encompass a much larger oculomotor range. However, conjugacy of eye movements in fish is much more apparent than real because a fovea is absent and the fusion of targets between the two eyes (stereoscopic vision) is

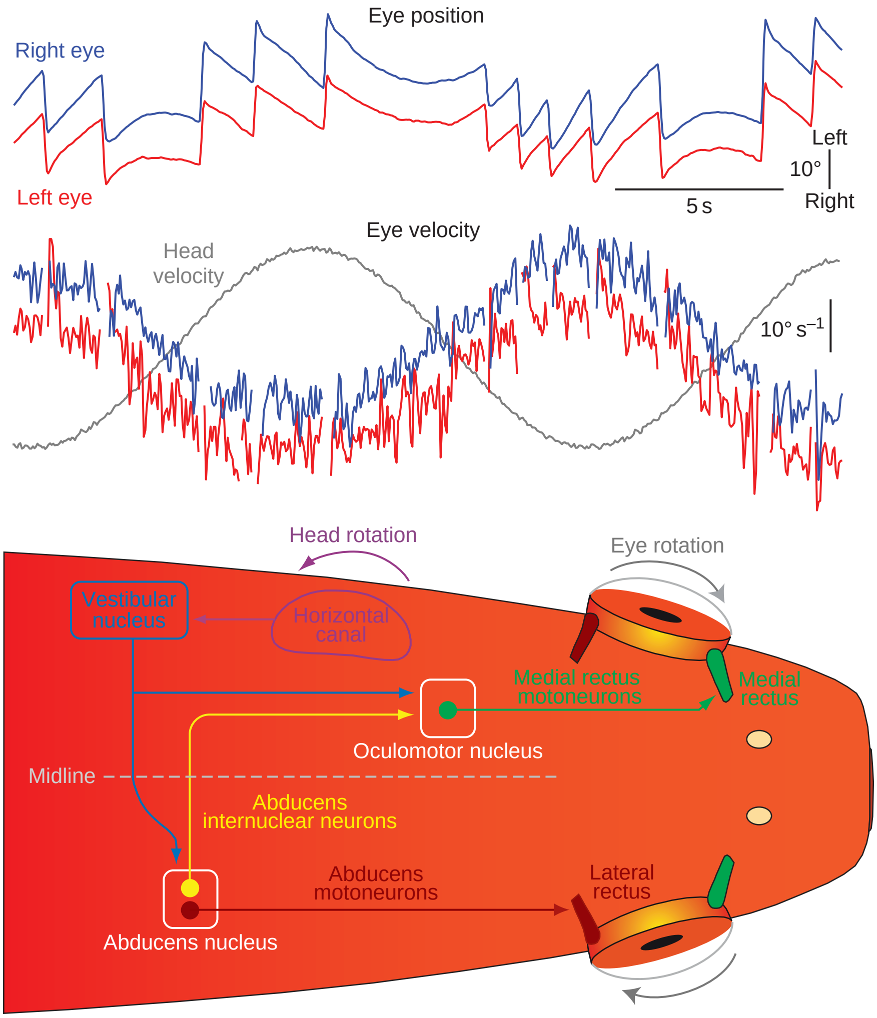

Figure 5 Brainstem circuitry and compensatory conjugate horizontal angular vestibuloocular reflexes. Both right (blue) and left (red) eye motion are equal and opposite to horizontal head rotation as illustrated best by the eye vs. head velocity traces. A simplified view of the brainstem vestibuloocular pathways is shown in the lower schematic.

limited, if present at all. The classical push–pull organization present for vertical eye movements with a nearly mirror-symmetrical, crossed excitation, and an uncrossed inhibition is only established for abducens motoneurons that innervate the ipsilateral lateral rectus (LR) muscle and internuclear neurons that innervate the contralateral medial rectus (MR; **Figure 5**). There is no direct uncrossed vestibular inhibition of MR motoneurons because internuclear neurons receive the same vestibular inhibitory input as LR motoneurons. This intrinsic difference in organization likely facilitates an independent bilateral activation of MR motoneurons for converging eye movements without activation of the LR motoneurons and vice versa for convergence and divergence eye movements.

The principal vestibular subgroups implicated in the horizontal VOR conveying a dynamic head/eye velocity signal are located in the ventral part of DO with projections to four separate, ventrally located, subgroups of abducens (Abd) motoneurons and internuclear (AI) neurons (simplified view with single subgroups in **Figure 5**). A subgroup of horizontal head velocity neurons is located in the rostral MO that project exclusively to ipsilateral MR motoneurons. While the head velocity signal on AI and MO subpopulations might be considered as redundant, it likely is not, because the MO neurons subserve an essential high-frequency vestibular role not provided by AI neurons. In addition, this vestibular subgroup is maintained in mammals, giving rise to a well-delineated pathway (ascending tract of Deiter's) to the oculomotor nucleus. The highly conserved locations of horizontal canal-related, second-order vestibuloocular neurons within the vertebrate hindbrain clearly indicate an organizational principle centered on motor coordinates rather than topography of spatially segregated inputs from the sensory periphery.

Both vertical and horizontal canal-related vestibuloocular neurons are complemented by a densely clustered subgroup that forms the T nucleus just caudal to the VIIIth nerve entry (**Figure 3**). The functional role of this nucleus is clearly demonstrated by the close relationship between torsional angle of the eye and head tilt that appears even in larval fish before semicircular canals become operational. This nucleus serves as a gravitoinertial center with crossed excitatory projections to the midbrain oculomotor/trochlear nuclei and the contralateral spinal cord. Second-order vestibular neurons in the tangential nucleus receive major inputs from the utricle as well as minor inputs from the three canals in a spatially specific pattern. In contrast to vestibular neurons in the semicircular canal-specific nuclei, tangential neurons exhibit a sustained sensitivity after small tonic changes of the head position, clearly indicating an appreciable tonic utricular influence. The likely convergence of spatially specific afferent canal inputs with sensory signals from utricular sectors with the same spatial vector orientation in individual tangential neurons forms a structural substrate that makes this nucleus a gravitoinertial relay center for vestibuloocular as well as postural reflexes.

Vestibulospinal Projections for Locomotor Control and Posture Stabilization

Vestibulospinal projections control gravitoinertial-related postural reflexes through the activation of spinal interneurons and motoneurons. Vestibular signals to spinal targets exhibit either low dynamics that are more correlated with changes in body posture, or high dynamics that are involved in the initiation of fast locomotor actions. Vestibulospinal neurons are generally well localized within a restricted region that coincides with a central position along the rostro-caudal extent of the vestibular areas in the octavolateral nuclei. This central location within the vestibular column is compatible with an early evolutionary appearance of gravitoinertial function utilizing utricular signals for compensating pitch and roll deviations of body position in space. The populations of ipsi- and contralaterally descending vestibulospinal neurons largely located in MO and the dorsal part of DO are morphologically heterogeneous and convey otolith as well as semicircular canal signals to the spinal cord. A number of vestibulospinal neurons are also located in the T nucleus intermingled with those that project to the contralateral oculomotor/trochlear nuclei, suggesting that this nucleus serves as a gravitoinertial relay center coupling eye motion and body posture control.

Auxiliary Vestibular Connections for Gaze and Posture Control

Commissural projections through midline crossing axons interconnect bilateral vestibular nuclei. Functionally, the spatially specific inhibitory brainstem commissural projections that interconnect vestibular neurons with bilateral coplanar canal-related signals (e.g., ipsilateral posterior–contralateral anterior; see **Figure 4**) reinforce the differential detection of angular head acceleration signals due to the mirror-image arrangement of the semicircular canals in the periphery on both sides. This connection increases the sensitivity for detection of angular head acceleration, such that very small signals can be distinguished. A somewhat similar organization exists for utricular commissural connections that link second-order vestibular neurons with signals from spatially aligned bilateral utricular epithelial sectors. However, the specific functional interconnections are more complex given the 360° response sensitivity of the sensory epithelium on each side. Vestibular commissural neurons that interconnect the two sides essentially subdivide into rostral and caudal subgroups in the AO and DO/PO, respectively. Given the dense projection and termination of anterior and posterior semicircular canal afferent fibers in AO, DO, and PO regions where commissural neurons are located, these latter cell groups likely establish a push–pull connectivity to increase the sensitivity for detection of vertical coplanar semicircular canal signals.

Vestibular projections to the vestibulolateral lobe of the cerebellum in fish play an important role in the adaptation and plasticity of gaze-stabilizing reflexes. These connections are evolutionarily very old and are based on an intimate phylogenetic linkage between the octavolateral nuclei and cerebellum. Both, first- and second-order vestibular projections, convey angular head/body acceleration as mossy fiber input to the granular layer of the vestibulocerebellum. In turn, Purkinje cells from the caudal lobe of the vestibulocerebellum provide a direct output to particular vestibuloocular subgroups. The major locations for vestibulocerebellar projection neurons are a rostral subgroup with ipsilateral projection predominance in AO and a second one in DO/PO. The caudal vestibular subpopulation is contiguous with another population of cerebellar-projecting neurons located ventrolaterally in the caudal hindbrain. Together, along with cerebellar-projecting inferior olivary neurons, these populations appear to have a common ontogenetic origin, such that all precerebellar nuclei responsible for eye/head motion derive from a common caudal hindbrain region.

Conservation of Fish Vestibular Organization in Other Vertebrates

Comparison of the spatial distribution of individual vestibular end-organ terminations among different groups of fish, such as damselfish, goby, toadfish, and elasmobranchs, reveals a vestibular pattern similar to that in goldfish. Notably, central projections from comparable populations of vestibular neurons originate from corresponding subdivisions, even though specific morphological details, particularly size, differ between the various species. This conservation also includes connectivity with particular targets, even in the exceptional case of flatfish, where both peripheral and central structural rearrangements occur during development. A comparison of vestibular system anatomy and physiology of fish with tetrapods also reveals a remarkably conserved pattern. In fact, afferent projections from the different vestibular end organs in all tetrapod taxa terminate differentially in areas that correspond to those in fish. Moreover, similar subgroups of major vestibular projection neurons originate from homologous positions in the hindbrain of mammals, birds, and amphibians. These comparative attributes suggest that, from basic wiring through function, the vestibular blueprint was established quite early during vertebrate evolution and has been largely conserved unchanged throughout 400 million years of vertebrate phylogeny.

Glossary

Auditory system The portion of the ear that is involved in sound detection. In fishes, this generally includes the saccule and lagena, though in many species the utricle may also be involved.

Hair cell The major sensory cell in the ear and lateral line of all vertebrates.

Inner ear The part of the ear that is located inside of the head that is responsible for detection of sound (hearing) and movement of the head relative to gravity (vestibular). It consists of three semicircular canals and three otolith end organs, as well as a macula neglecta.

Otolith A calcium carbonate structure that is located in the otolith organs of fishes. In teleosts, the otoliths take on distinct species-specific shapes.

Otolith organs The saccule, lagena, and utricle of the inner ear. Each has a sensory epithelium (or macula) and an otolith (or otoconia).

Semicircular canals Three mutually perpendicular structures associated with the ear and involved in detection of angular acceleration.

Swimbladder A gas-filled chamber in the abdominal cavity of most bony fishes. The swimbladder is used in buoyancy control in most species; it also subsumes roles in hearing and sound production in some species.

Vestibular system The portion of the ear consisting of the semicircular canals and utricle that are involved with the detection of head motion and balance.

Weberian ossicles A series of bones connecting the swimbladder to the inner ear in the otophysan fishes (goldfish and relatives).

Vertebrate Ears

The inner ears in all vertebrates serve two major functions. Portions of the ear make up the ‘vestibular system’ and which, whereas other parts of the ear make up the ‘auditory system’. Though both the vestibular and auditory portions of the inner ear are critical for the survival of any vertebrate, humans tend to be most aware of the hearing function of the ear because sound is such an integral part of communication. Although humans are not aware of the function of the vestibular system unless it is not functioning properly (e.g., in vertigo), it plays a major role in life because it provides information about the position and movement of the head (**see also Hearing and Lateral Line**: Vestibular System Anatomy and Physiology).

Inner Ear Anatomy

All vertebrates, with the exception of the jawless vertebrates (the lampreys), have very similar inner ear structures (**Figure 1**). The inner ears include three semicircular canals, each with its own sensory region (the ampullae), and several otolith end organs and their sensory regions. The basic ear pattern is the same whether one examines a shark (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays), a bony fish, a frog, or a human. The major difference across the various vertebrate groups is that reptiles, birds, and mammals have an elaboration of one of the otolith end organs, the lagena, that may have evolved into the cochlea in mammals and the basilar papilla in reptiles and birds. Many, but not all, vertebrates also have an additional sensory structure, the macula neglecta, the function of which is not known in any vertebrate group other than the sharks and rays where it appears to play a major role in hearing (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays).

Sensory Cells in the Ear

No matter the species, all vertebrate ears (and the lateral line found in fish and some amphibians; **see also Hearing and Lateral Line**: Lateral Line Structure) use the same cell type to detect and respond to motion. This motion may be in the form of head movement in the vestibular system, or sound in the hearing portion of the ear. The sensory hair

cell (**Figure 2**) has a cell body that is capped by a number of cilia that project into the lumen of the particular end organ. These cilia are of two types. Most are elaborated microvilli, or stereovilli (also called stereocilia in the older literature) that project from a cuticular plate lying just between the apical (top) membrane of the sensory cell. These stereovilli are often graded in size, in an organ pipe arrangement (**Figure 3**). The longest stereovilli are at one end of the bundle, and this end also has the single kinocilium. The kinocilium, a true cilium, is very similar in structure to the motile cilia of many species, including flagella that propel sperm and bacteria.

The sensory hair cell is a mechanical system that produces a chemical response to the bending of the cilia. When the cilia are bent, a series of chemical events occur that involve channels (tiny pores) opening in the apical ends of the streovilli, thereby letting calcium ions enter the cell. These ions cause a chain of chemical events that result in the release of neurotransmitters from the base of the cells, and these transmitters cause the production of impulses in the neurons of the eighth cranial nerve that innervates the cells (**see also Hearing and Lateral Line**: Auditory/Lateral Line CNS: Anatomy). The signal is then carried to the brain, indicating that some kind of stimulation has taken place.

The sensory hair cell is both morphologically and physiologically polarized. Morphological polarization comes from the fact that the kinocilium is located at one side of the ciliary bundle. The physiological polarization is related to the morphological polarization, and results in a different level of response from the sensory cell depending upon the direction in which it is bent. Thus, in effect, the sensory cell gives a different response to signals from different directions. More specifically, if the ciliary bundle is bent from the shortest stereovilli to the kinocilium, the cell gives maximum response (maximum release of neurotransmitter). However, if the bending is in the opposite direction, the cell releases very little transmitter. Bending in other directions (e.g., perpendicular to the axis of maximum stimulation), the level of neurotransmitter release is somewhat between maximum and minimum release. Thus, in effect, the sensory hair cell gives a different level of response for stimulation in any direction. This graded response is central to the ability of fish to detect the direction of a sound source (**see also Hearing and Lateral Line**: Sound Source Localization and Directional Hearing in Fishes).

Ciliary bundles also vary in length in different end organs, or even within a single end organ (**Figure 3**). While the correlation between length and function is not fully understood, there are some data that lead to the suggestion that the longer bundles respond to lower-frequency stimulation, whereas shorter bundles have their best responses to higher-frequency signals.

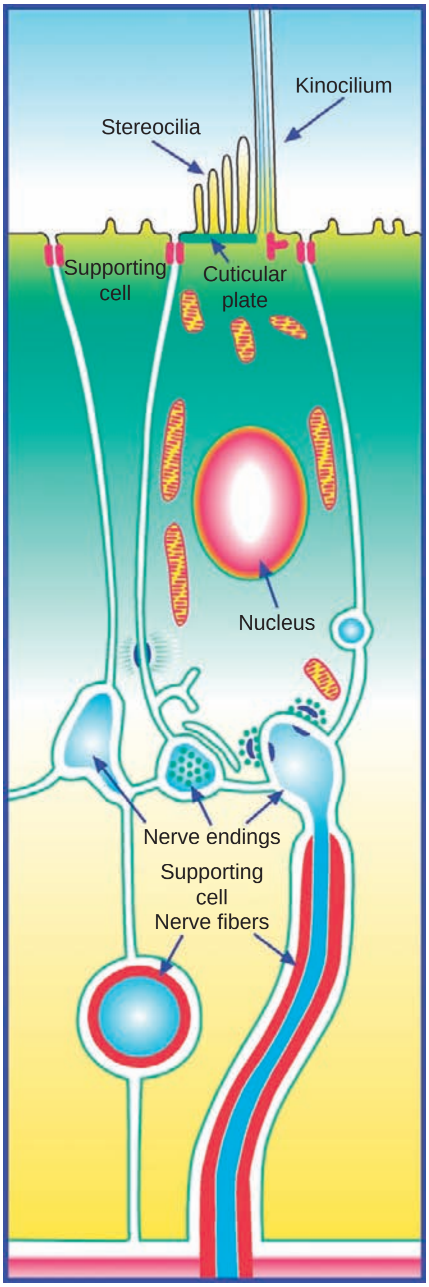

Figure 2 Drawing of a typical fish sensory hair cell. The cell body is innervated by afferent and efferent nerve endings at the basal end. The dorsal end of the cell has a cuticular plate in that are embedded the roots of the stereovilli. The kinocilium is located at one end of the ciliary bundle and terminates at a pair of basal bodies in the cell cytoplasm. Redrawn from Popper AN and Coombs S (1980) Auditory mechanisms in teleost fishes. *American Scientist* 69: 429–440.

Fish Ears

The ear in fishes is located in the cranial cavity just lateral to the brain (**Figure 4**) – there is no outer or middle ear as found in terrestrial animals (although sharks do have a distinct connection to the outside – **see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays). A typical fish ear is shown in **Figure 1**, and other ears, for comparative purposes, are shown in **Figure 5** (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays for illustrations of shark ears). While there are some differences in the shape of the semicircular canals, the greatest variation in shape and size across the fishes is generally associated with the otolithic end organs involved in hearing.

The ear in the Atlantic salmon (*Salmo salar*, **Figure 1**) has three semicircular canals (the anterior, posterior, and lateral (or horizontal)) and they, along with the utricle, make up the major vestibular parts of the ear (though in many species, the utricle also subsumes a role in hearing). A sensory region, or crista, is found at the base of each canal. Each crista has an epithelium of sensory hair cells, and these are overlain with a gelatinous structure, the cupula, that covers the crista. These ear regions have, at times, been referred to as the pars superior.

The ear in fishes also has three otolithic end organs – the saccule, lagena, and utricle (**Figures 1** and **5**). The saccule and lagena, and in many species the utricle, are involved with hearing (the saccule and lagena make up the pars inferior). These otolithic end organs contain very dense calcium carbonate crystals. In Agnathans (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development), sharks and rays (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays), and terrestrial vertebrates, as well as in more primitive bony fishes, the crystals, called otoconia, are embedded in a gelatinous matrix (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays). However in modern bony fishes (teleosts), the crystals are fused into a solid structure called the otolith (**Figure 6**).

The Otoliths

The otoconial mass or the otolith lies in the lumen of the otolith organs and in close contact with the sensory epithelium that contains the sensory hair cells. In teleosts, the otolith and sensory epithelium are connected to one another by a thin otolith membrane. During sound stimulation, the otolith (or the otoconial mass), which is generally about 3 times denser than the fish's body, moves at a different amplitude and phase than does the rest of the body (including the epithelium). This differential movement results in bending of the ciliary bundles and stimulation of the sensory cells, thereby sending a signal to the brain via the innervating eighth nerve (**see also Hearing and Lateral Line**: Biomechanics of the Inner Ear in Fishes).

While the otoconial mass has no particular shape, otoliths take on very specific shapes that are diagnostic of particular species (**Figure 6**). This is particularly true for the otolith of the saccular end organ.

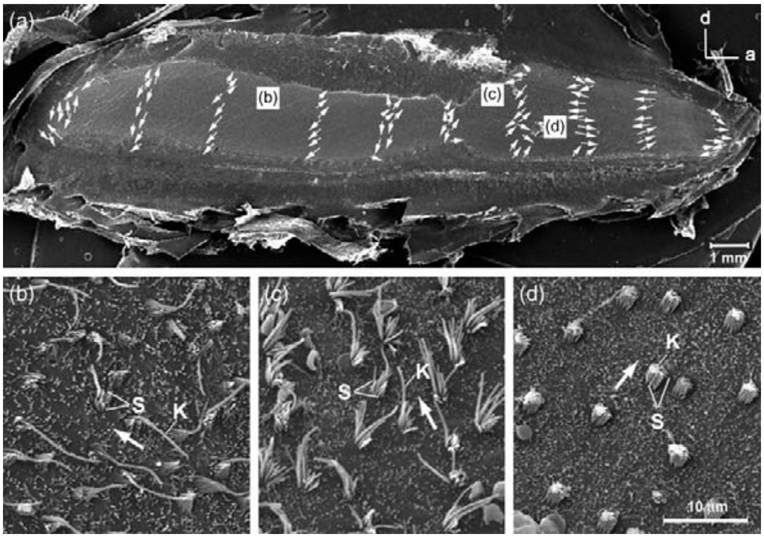

Figure 3 The saccular sensory epithelium of a bluefin tuna, *Thunnus thynnus*. The saccular epithelium (anterior to the right, dorsal to the top). Arrows indicate the direction of orientation of the sensory cells in different regions of the epithelium. The lower images are enlargements of the same lettered regions from the top image. Figure 4 Drawing of the ear and its location in the head from the European minnow, *Phoxinus laevis*. Top shows a dorsal view of the head with the bones removed to reveal the inside of the cranial cavity. The posterior part of the brain is also removed to show the two ears in this otophysan fish. The lower drawing shows a lateral view of the fish, with the brain and ear. Legend: Bo, C, M, Mo, parts of the brain; Ct, transverse canal; L, lagena; Mph, pharyngeal muscles; S, saccule; U, utricle; X, the 10th cranial nerve. From von Frisch K and Stetter H (1932) Untersuchungen über den Sitz des Gohörsinnes bei der Elritze. *Zeitschrift Fuer Vergleichende Physiologie* 17: 686–801.

A characteristic of otoliths is that they increase in size as the fish grows, and this results in the otoliths adding layers of calcium carbonate in a ring-like pattern, much as rings develop in trees. Fisheries biologists use these rings to estimate fish age, and recent studies have shown that there are not only annual rings, but also daily rings that can provide a good deal of information on fish food supply and other aspects of physiology and ecology.

Sensory Epithelia

The sensory surfaces in each of the otolith organs consist of numerous sensory hair cells, each of which is surrounded by supporting cells (**Figure 3**). The sensory cells themselves are organized into groupings, with all of the cells in each group being oriented with the kinocilium on the same side of the cell (**Figure 3**). The size and shape of each orientation group varies among the different otolith organs and among the same otolith organ of

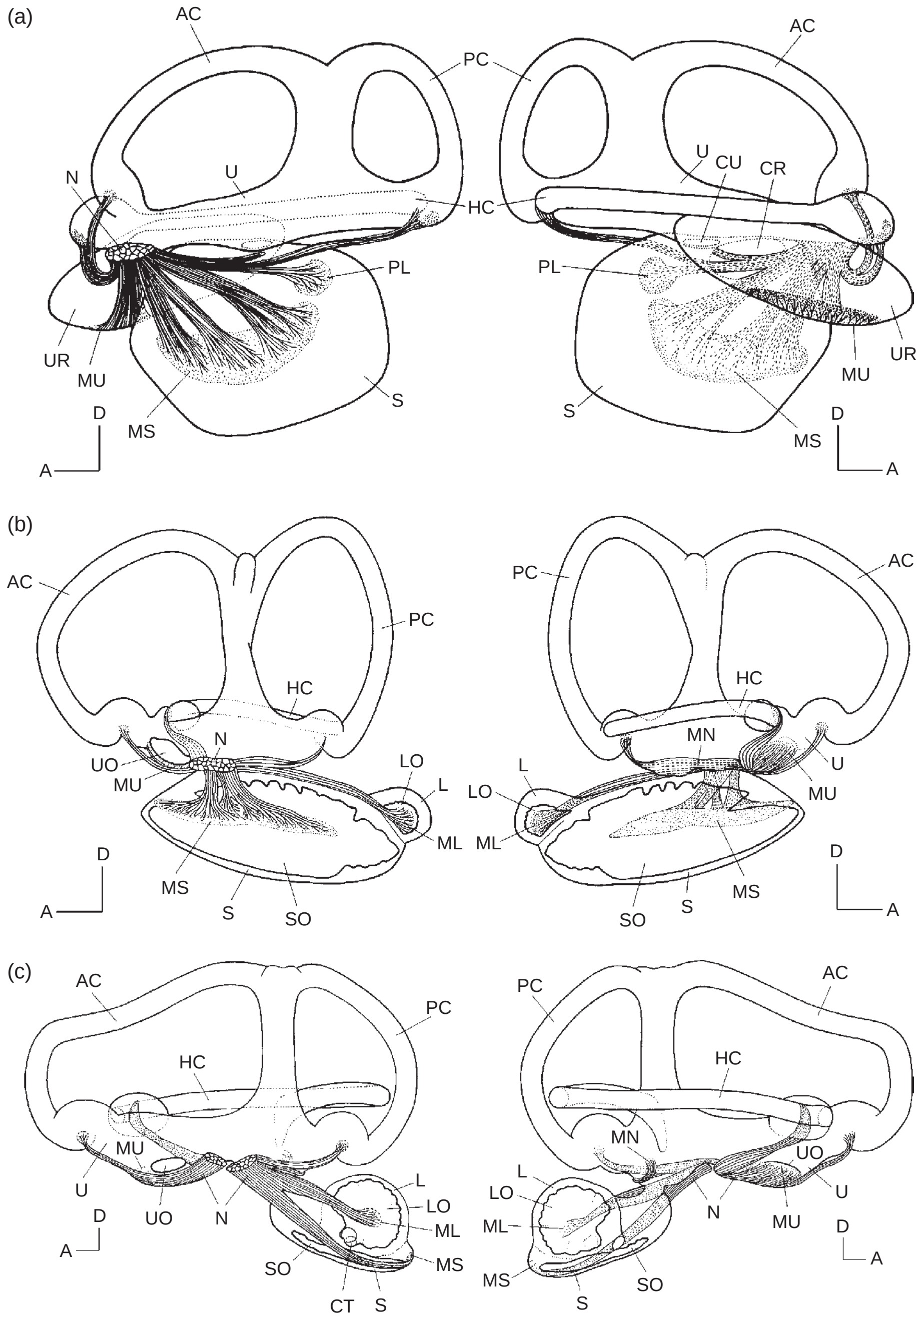

Figure 5 Drawings of the ears from various fish species to show variation. (a) a lungfish (*Ceratodus forsteri*); (b) pike perch (*Stizostedion lucioperca*); (c) European Wels (*Siluris glanis*). Legend: AC, HC, PC – anterior, horizontal, and posterior semicircular canals; L – lagena; LO, SO, UO – lagena, saccular, and utricular otoliths; ML, MS, MU – sensory epithelia of lagena, saccule, and utricle; N – eighth cranial nerve; S – saccule; U – utricle; UR – utricular recess.

different species. For example, **Figure 7** shows the hair cell orientation patterns from a hardhead sea catfish (*Arius felis*), a species with excellent hearing. The saccule has hair cells oriented in two orientation groups, one with the kinocilium oriented dorsally and the other with hair cells oriented ventrally. This bidirectional saccular pattern is similar to that found in primitive fishes, sharks and rays, and most terrestrial vertebrates.

The saccular pattern in hardhead sea catfish can be contrasted to the pattern found in most other modern teleosts where there are at least four hair cell groups on the saccule – two oriented dorsally and ventrally, as in the hardhead sea catfish, and at least two oriented anteriorly and posteriorly (**Figures 8** and **9**). There is considerable variation in this pattern in fishes, and while the functional significance of the differences is unknown, it has generally been suggested that the presence of four groups of cells

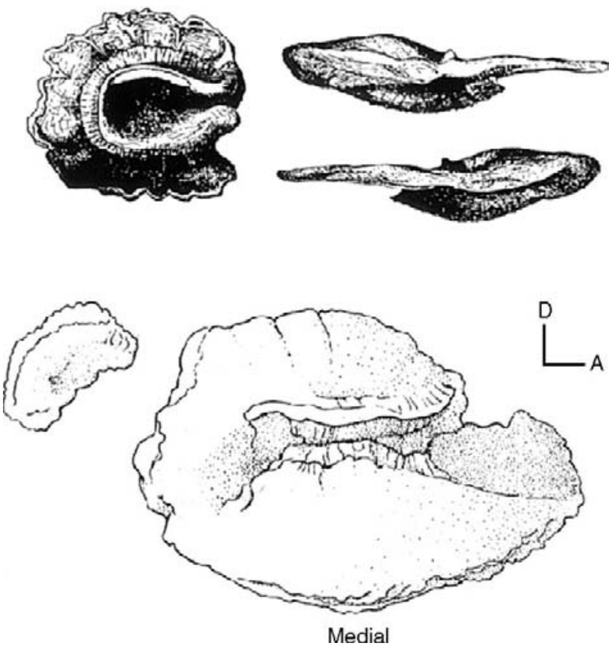

Figure 6 Otoliths from the Eurasian minnow, *Phoxinus laevis*, an otophysan (top) and (bottom) *Zebrasoma verliferum* (sailfin tang). The otolith on the right is from the saccule and left from the lagena. The utricular otolith generally looks like a slightly flattened ball. Note that in the Eurasian minnow the lagena otolith is large as compared with *Zebrasoma*, whereas the saccular otolith is smaller. The shape of the saccular otolith in the Eurasian minnow is rather complex and so two different views are shown along its horizontal axis. Ann Arbor, MI: University of Michigan Press.

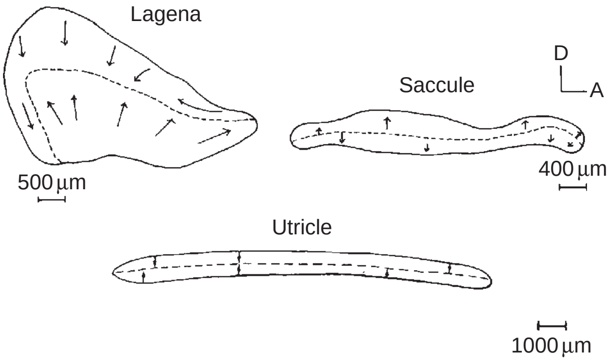

Figure 7 Hair cell orientation patterns from a hardhead sea catfish, *A. felis*. The arrows show the direction of orientation of the hair cells in different epithelial regions (separated by the dashed lines). Each arrow shows the side of the cell on which the kinocilium sits. From Popper AN and Tavolga WN (1981) Structure and function of the ear of the marine catfish, *Arius felis. Journal of Comparative Physiology* 144: 27–34.

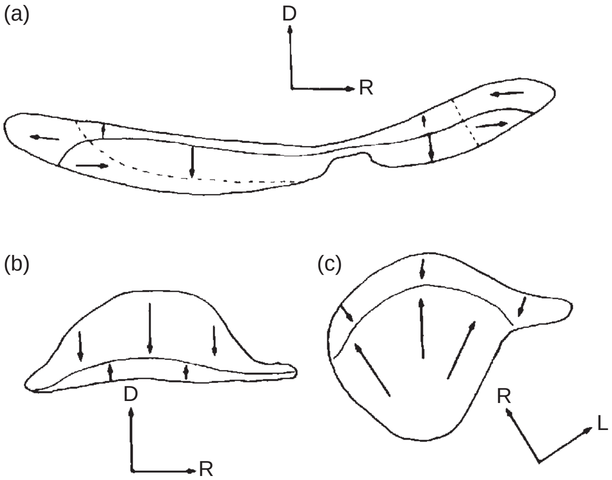

Figure 8 Hair cell orientations for the saccule (a), lagena (b), and utricle (c) from the Mediterranean hake, *M. merluccius*. Note the difference in orientation patterns between the saccule and lagena as compared to the hardhead sea catfish in **Figure 7**. In particular, the saccular epithelium has hair cells orientated both anteriorly and posteriorly as well as dorsally and ventrally. From Lombarte A and Popper AN (1994) Quantitative analyses of postembryonic hair cell addition in the otolithic endorgans of the inner ear of the European hake, *Merluccius merluccius* (Gadiformes, Teleostei). *Journal of Comparative Neurology* 345: 419–428.

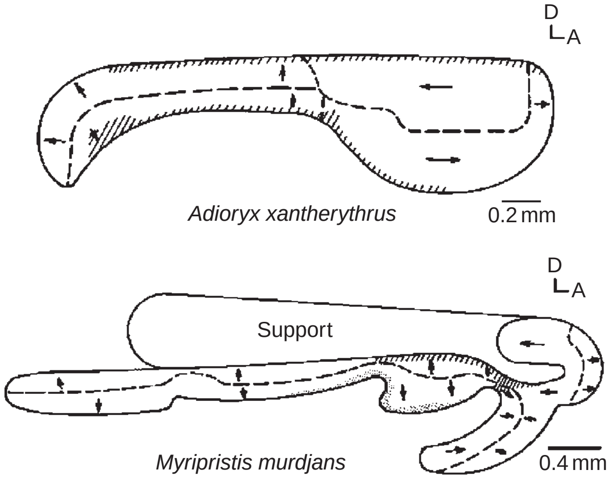

Figure 9 Saccular hair cell orientation patterns from two fishes from the family Holocentridae. The arrows indicate the orientation patterns of the hair cells in different regions. Top is from *Adioryx*, a fish that hears sound to about 1000 Hz, while the more elaborate pattern below is from the related *Myripristis*, a fish that hears to well over 3000 Hz. The anterior end of the swimbladder in *Myripristis* terminates on the chamber of the ear that includes the saccule, while not in *Adioryx*. From Popper AN (1977) A scanning electron microscopic study of the sacculus and lagena in the ears of fifteen species of teleost fishes. *Journal of Morphology* 153: 397–418.

assists fishes in estimating the direction of sounds because the cells in different groups are presumed to have different levels of physiological response to signals from different directions (e.g., sound source localization – **see also**

Hearing and Lateral Line: Sound Source Localization and Directional Hearing in Fishes).

It has also been noted that the more complex patterns of hair cell orientation are often found in fishes that have a wider range of hearing and better hearing sensitivity than fishes with less complex patterns (**Figure 9**). For example, the pinecone soldierfish *Myripristis* saccule has a very complex pattern, whereas the closely related Hawaiian soldierfish *Adioryx* has a simpler pattern. Interestingly, *Myripristis* hears sounds to well over 3 kHz, whereas *Adioryx* does not hear sounds much above 1 kHz.

Getting Sound to the Ear

In contrast to many terrestrial animals that have structures peripheral to the ear that enables the capture of sound and its transmission to the inner ear, there are no specific external sound gathering structures in fishes. Indeed, it is possible for the particle motion component of sound to directly stimulate the ear by producing relative motion between the otolith (or otoconia) and the sensory epithelium (**see also Hearing and Lateral Line**: Biomechanics of the Inner Ear in Fishes).

At the same time, one limitation of direct stimulation is that fish can only detect particle motion with the ear, and there is no direct detection of the pressure component of the sound field. This limits the bandwidth and sensitivity of fish hearing (**see also Hearing and Lateral Line**: Psychoacoustics: What Fish Hear); therefore, fishes that only rely on direct particle motion for sound detection generally do not hear as well as fishes that are able to also detect pressure.

The issue then becomes one of how fish can detect pressure and then convert it into a particle motion signal that can stimulate the ear. This is accomplished by having a discontinuity in the body, most often in the form of a gas bubble that responds to pressure motions. Such a bubble, which is much less dense than the fish body, is most commonly the swimbladder, a gas-filled chamber in the abdominal cavity that is used by most species to control buoyancy (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes, Swimbladder Function and Buoyancy Control in Fishes) and sound production (**see also Hearing and Lateral Line**: Acoustic Behavior, Vocal Behavior of Fishes: Anatomy and Physiology).

The swimbladder wall then vibrates in response to the pressure component of a sound field and re-radiates the signal, with a substantial particle motion component, to the ear, thereby stimulating the ear. In effect, the fish then becomes a detector of pressure signals. This results in the fish hearing a wide bandwidth of sound. At the same time, the strength of the re-radiated signal will impact hearing capabilities. If the re-radiated signal is weak by the time it gets to the ear, hearing will not be enhanced substantially. However, if the signal is strong, hearing bandwidth and sensitivity may be increased.

In order to increase hearing sensitivity, many species, including those that are taxonomically distinct, have evolved mechanisms whereby the signal from the swimbladder is brought into close proximity to the ear, or even directly to the ear, thereby decreasing any signal losses that might result from attenuation due to the distance between the swimbladder and ear (**Figure 10**). In other words, if the swimbladder is at a considerable distance from the ear, as in salmonids, tunas, and many other commercially important species, the amount of signal from the swimbladder is probably very limited, and this probably correlates with the species generally not detecting sounds to above 800–1000 Hz (**see also Hearing and Lateral Line**: Psychoacoustics: What Fish Hear).

There is a considerable range of mechanisms found in different fish taxa that presumably are present to acoustically couple the motion of the swimbladder to the inner ear. Perhaps best known of these is a series of bones, the Weberian ossicles, found in the goldfish and all other fishes in the taxonomic group Otophysi (this includes carp, catfish, etc.) (**Figure 11**). In these fishes, the posterior-most ossicle (bone) is directly attached to the swimbladder wall, whereas the most anterior bone in the chain makes up a wall of a chamber that contains fluid that is continuous with that of the inner ear. Motion of the swimbladder wall causes the posterior-most bone to move on its connection to the vertebral column, and this motion is transmitted through the ossicles, much as sound is transmitted through the (unrelated) ossicles in the mammalian inner ear, and results in motion of inner ear fluids that directly move the saccular otolith and thereby stimulates the sensory hair cells.

Other fish species have extensions of the swimbladder to a position close to, or actually contacting, the ear (generally the saccule) or additional gas bubbles lying near or in contact with the ear. For example, the aforementioned *Myripristis* has anterior swimbladder extensions that terminate on the bone surrounding the saccular chamber, whereas fishes of the family Mormyridae (elephant-nosed fish) have a separate air bubble that lies within the confines of the semicircular canals and which, in part, makes up the medial wall of the saccular chamber. Similarly, the Anabantidae (bubble nest builders) have an air pocket in the pharynx, which is close to the ear, and this bubble has been shown to enhance hearing in these species compared to related species without such a bubble.

While most specialized structures for bringing sound to the ear are associated with the saccule, in at least one group of fish, the Clupeiformes (herring, shad, and

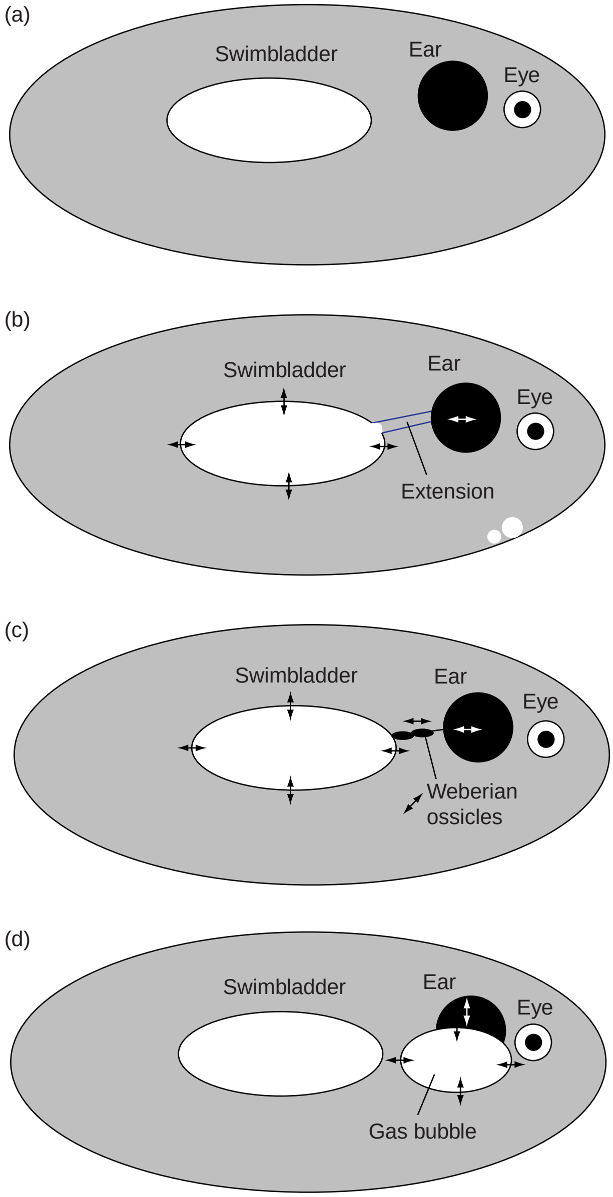

Figure 10 Schematic drawing of the relationship between the ear and the swimbladder in different species. There is no connection in (a), a condition that is typical of species that do not have a wide hearing bandwidth. In (b), the swimbladder projects forward and contacts the inner ear, as in *Myripristis* (**Figure 9**), while (c) shows the condition in the otophysan fish where a series of bones connects the inner ear to the swimbladder (see detailed drawing in **Figure 11**). Finally, panel (d) shows the special condition where there is a secondary bubble of gas near the inner ear, as is found in the mormyrids, anabantids, and clupeids. From Ladich F and Popper AN (2004) Parallel evolution in fish hearing organs. In: Manley GA, Popper AN, and Fay RR (eds.) *Evolution of the Vertebrate Auditory System,* pp. 95–127. New York: Springer.

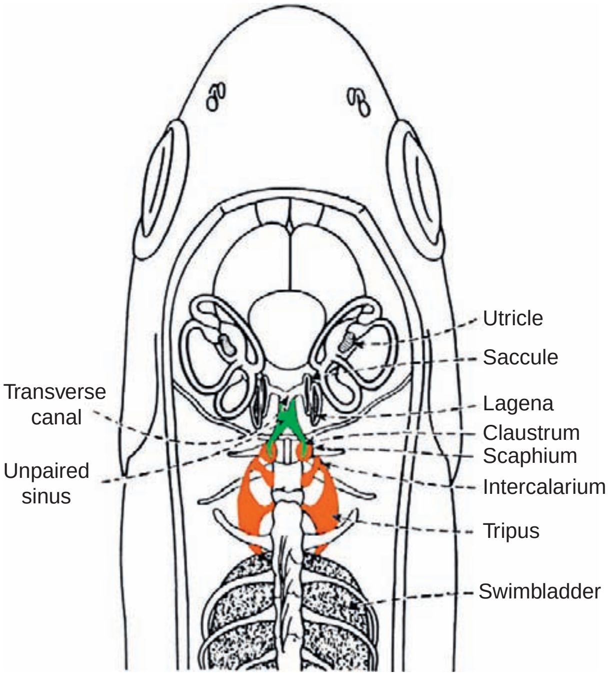

Figure 11 A drawing showing the dorsal view of an otophysan fish with the inner ear, the swimbladder, and the Weberian ossicles. Movement of the wall of the swimbladder results in movement of the Weberian ossicles (orange), and these move the fluids in the sinus (green) and thus of the inner ear and the saccular otolith.

menhaden), there is a thin anterior projection of the swimbladder that terminates in a gas bubble intimate with the utricular chamber of the ear. Moreover, whereas the structure of the utricle is generally the same in almost all aquatic and terrestrial vertebrates, the utricle in Clupeiformes has unique specializations associated with the air bubble. As a consequence, it is thought that this results in the utricle being a major part of the hearing apparatus of these fishes. Moreover, all members of the Clupeiformes can detect sounds to over 4 kHz. In addition, some members of this group, including all members of the genus *Alosa* (e.g., American shad and blueback herring), have even more extreme specializations in the utricle and can detect sounds to over 180 kHz, a range that may be greater than for any other vertebrate other than a few bats and dolphins.

There is considerable inter-specific variation in the way in which the pressure signals are brought to the ear and, quite significantly, it is clear that such specializations evolved over and over again in different fish taxa. Thus, with the exception of the Weberian ossicles in the Otophysi, other specializations are found repeatedly in different fish groups, even when close taxonomic relatives of the same species do not have such specializations. So, for example, anterior elongations of the swimbladder so that it contacts the ear occur in species as diverse as squirrelfish, clown knifefish (*Notopterus chitala*), and in many unrelated deep-sea fish that may have evolved enhanced hearing capabilities to compensate for lack of light.

Hair Cell Number and Fish Growth

One of the unique findings about fishes is that most species grow continuously through the life of the animal. In fishes, the general growth of the body is accompanied by growth of the inner ear, including an increase in the size of the otolith, and an increase in the number of sensory hair cells in each of the sensory epithelia. Thus, for example, a 1-cm-long Mediterranean hake (*Merluccious merluccius*) may have 5000 sensory hair cells in the saccular epithelium, whereas the same species of about 80 cm long (about 9 years old) may have close to 1 million cells per saccular epithelium. This dramatic increase in cell number has been documented in all species in which it has been looked for, including in sharks and rays.

There are many significant questions that arise from this finding. A fundamental question is how fish retain the ability to proliferate sensory hair cells throughout life when species such as mammals, which have the same type of hair cells, have all the hair cells they will ever have at birth, and the only change in number is loss due to cell death with aging.

The other question of interest is what this increase of hair cells means for function of the ear, and, more directly, does hearing change with size of the fish (or age). While data are limited, there is a small amount of evidence that there is a broadening of hearing bandwidth and sensitivity in very young fishes as they add more hair cells. However, a recent study in walleye pollock (*Theragra chalcogramma*) shows that there is no change in hearing ability in fish ranging from 1 to 3 years of age, despite a very substantial growth in the size of the fish and its ear. While still preliminary, these results support a hypothesis that hair cell addition in fishes is probably to maintain a constant level of hearing over time rather than to change hearing capabilities, thereby compensating for other changes associated with growth, such as a change in the relative position of the swimbladder and inner ear.

Related to the vast proliferation of sensory cells in the ear in fishes is the discovery that fishes can regenerate sensory hair cells that are lost due to treatment with ototoxic drugs (those that kill hair cells) or loud sounds (**see also Hearing and Lateral Line**: Effects of Human-Generated Sound on Fish). This ability is not found in mammals, and found only to a limited extent in other tetrapods. In contrast, fishes appear to be able to regenerate large numbers of sensory cells within a few days of damage, and there is good evidence that hearing recovers as the sensory cells are replaced.

Summary

There is very substantial variability in the structure of the ear in fishes, and this variation is particularly associated with the end organs involved with hearing. The functional significance of this variation is not known; however, there are several possible explanations. The first possibility is that the variation represents evolutionary experiments for hearing, each of which provides the brain with similar information about sound. A second possibility is that the differences represent different hearing mechanisms and/or capabilities in different species. What is most interesting, however, is that even when there are differences in ear structure, similar ear patterns have evolved in very different, and taxonomically unrelated, species, suggesting that even with the variation, there are only a limited number of ways that sound detection is most effective.

Glossary

Elasmobranch The subclass of fishes (Elasmobranchii) found within the class Chondricthyes that includes sharks, skates, and rays, making up the Chondricthyes or cartilaginous fishes. Their bones are made up of cartilage rather than calcium found in all other vertebrates.

Endolymphatic pores and ducts Opening on the dorsal cranium of elasmobranchs known as the endolymphatic pores that lead to a pair of ducts with direct access from the environment to the inner ear.

Fenestra ovalis Located near the saccular chamber, a specialized extension known as the posterior canal duct terminates at its dorsal end as a small membrane known as the fenestra ovalis. On the other side of this membrane is the ventral portion of the parietal fossa making contact with the dorsal cranium. This thin membrane (~7 μm thick) is believed to be part of the acoustic pathway that sound travels from the environment through the parietal fossa to the inner ear.

Otoconia Collections of calcium carbonate granules in a gelatinous matrix that overlie the saccule, utricle, and lagena sensory maculae.

Macula neglecta The nonotoconial end organ of the inner ear. The sensory epithelium of the macula neglecta, found in the posterior canal duct, is covered by a gelatinous cupula, similar to that found in the lateral line organ. Experimental evidence shows that this is one of the acoustically sensitive end organs.

Parietal fossa A depression in the cranium located between the otic capsules. This depression is primarily composed of loose connective tissue, and also contains the endolymphatic ducts. The ventral portion of the parietal fossa maintains contact with the skull, including a small membranous window known as the fenestra ovalis that separates the fossa from the inner ear.

Particle motion The actual movement of water molecules in response to an acoustic disturbance. This is the component of sound that elasmobranchs detect. The bulk of the energy of particle motion is near a sound source and then attenuates quickly with distance.

The elasmobranch fishes, including the sharks, skates, and stingrays, encompass a subclass that contains approximately 1200 extant species. This group of fishes has been around for hundreds of millions of years and, in most respects, has evolved little over this time period. Elasmobranchs represent the ancestral form of many of the teleostean fishes seen today and can provide a window to view many basal forms of anatomical features including the auditory system. However, with very little known about their auditory system across species, generalizations are made from a few species about all features from anatomy through to hearing sensitivities and behavior.

Anatomy

The inner ears of elasmobranchs are found within the otic capsules in the posterior of the chondocranium (skull). Each ear includes four sensory end organs and three semicircular canals, all of which contain groupings of hair cells that respond to unique stimuli and that transmit their information to the brain via the eighth auditory nerve (**Figure 1**(**a**)) (**see also Brain and Nervous System:** Functional Morphology of the Brains of Cartilaginous Fishes). Three of the sensory end organs (the saccule, utricle, and lagena) have their patches of sensory hair cells (maculae) (**see also Hearing and Lateral Line**: Auditory System Morphology) overlain by a calcium carbonate-based structure called the otoconia (**Figures 1**(**a**) and **1**(**b**)). The fourth end organ is the macula neglecta, which has hair cells that are covered only by a gelatinous cupula, unlike the other end organs. The macula neglecta is also uniquely located within the posterior canal duct, near the saccular chamber, rather than the widened ventral portion of the inner ear, where the saccule, utricle, and lagena are found (**Figure 2**).

The semicircular canals are aligned in the *X*, *Y*, and *Z* axes of the fish (**Figure 1**(**b**)) for the detection of

movement in three dimensions (**see also Hearing and Lateral Line:** Vestibular System Anatomy and Physiology). Each semicircular canal has a wider region, called the ampula, which contains a jelly-like cupula overlying a patch of sensory hair cells. As fluid moves through the semicircular canals in response to angular accelerations, the cupula moves causing bending of the hair cells and transmission of information to the brain (**see also Hearing and Lateral Line:** Auditory System Morphology and Vestibular System Anatomy and Physiology).

Elasmobranchs are unique in that they have specialized structures, the endolymphatic ducts, that connect from the saccular chambers to the outside environment (**Figure 2**). The role of these ducts is unclear with regard to hearing, though they may serve a role in otoconial growth and development. The composition of the otoconia in several species of elasmobranchs shows evidence of an exogenous origin for some of the minerals that compose these gelatinous structures. The logical conclusion would be that elasmobranchs are somehow able to facilitate the

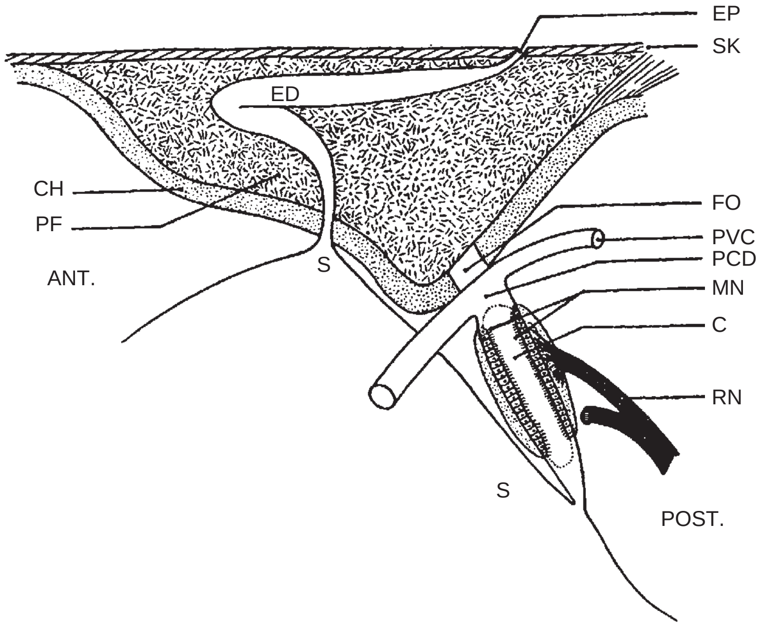

Figure 2 Dorsal portion of elasmobranch ear focusing on the location and relationship of macula neglecta and fenestra ovalis to the parietal fossa. The figure illustrates the nonotolithic pathway of sound travel to the inner ear, in which sound travels through the loose connective tissue of the parietal fossa, impinging on the membranous fenestra ovalis. The movement of this membrane results in the flow of fluid through the posterior canal duct, pushing against the cupula, and stimulating the hair cells of the macula neglecta. C – cupula; CH – chondrocranium; ED – endolymphatic duct; EP – endolymphatic pore; FO – fenestra ovalis; MN – macula neglecta; PCD – posterior canal duct; PVC – posterior vertical canal; PF – parietal fossa; RN – ramus neglectus nerve; S – saccule; SK – skin covering fossa. movement of particles through the endolymphatic duct, possibly through the contraction of paired muscles connected to the ducts, to increase the mass of otoconial structures. This idea is supported by the presence of sand grains throughout the duct in several species.

In the 1950s, a series of experiments with the thornback ray, *Raja clavata*, were conducted showing that the semicircular canals, along with the lagenar macula and part of the utricular macula, were sensitive to angular accelerations associated with body movements. Conversely, a portion of the utricular macula, all of the saccular macula and the macula neglecta responded to vibrations, and were the likely inner ear end organs responsible for acoustic detection.

The anatomy of the shark inner ear has been examined in great detail, resulting in two hypotheses about the pathways of sound traveling to the inner ear. The otolithic pathway involves the inner ear otoconial end organs (saccule, utricle, and lagena). As the density of a shark's body is approximately equal to that of the surrounding water, sound travels through the shark until it comes in contact with the otoconia, which have a greater density than surrounding tissues in the ear (**see also Hearing and Lateral Line:** Auditory System Morphology). Due to their greater density, the otoconia lag in movement relative to the rest of the body in the sound field. This time lag causes a bending of the cilia on the hair cells and stimulates the ear (**see also Hearing and Lateral Line:** Auditory System Morphology).

The nonotolithic pathway for stimulation of the inner ear involves the macula neglecta. It has been hypothesized that sound travels from above the head, through an area of loose connective tissue above the otic capsule called the parietal fossa, and into the posterior canal duct via the fenestrae ovalis, a membrane on the chondrocranium that separates the parietal fossa region from the macula neglecta in the duct (**Figure 2**). As fluid flows across the macula neglecta, movement of the cupula bends the ciliary bundles. The ciliary bundles of the macula neglecta are directionally polarized in the dorsal/ventral direction (**Figure 3**(**b**); **see also Hearing and Lateral Line:** Auditory System Morphology), further supporting the idea of sound detection from above the head. This pathway has been tested by directly vibrating the parietal fossa while recording from the part of the eighth auditory nerve that receives signals from the macula neglecta. Increased numbers of action potentials were obtained by stimulation of the parietal fossa region compared with stimulation of any other area of the head of the sharks.

Variations in inner ear anatomy exist among elasmobranchs, possibly reflecting differences in feeding behavior and habitat. In general, a more sensitive auditory system would be advantageous for a pelagic, actively swimming

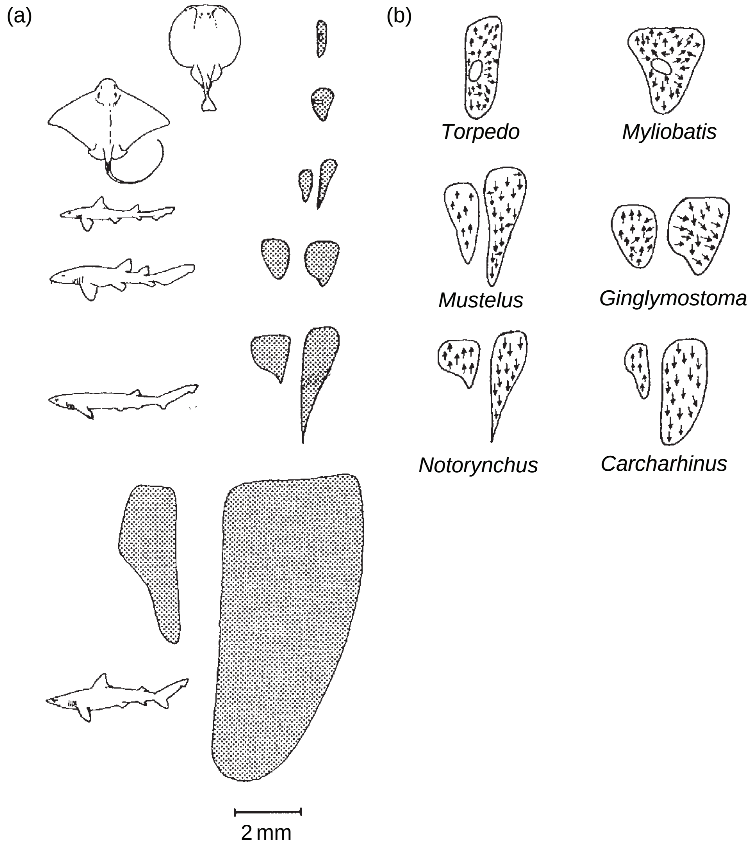

Figure 3 (a) Relative size of sensory epithelium of the macula neglecta for two active, piscivorous elasmobrancs, *Notorynchus* and *Carcharhinus*, and four demersal or nonpiscivorous elasmobranchs*, Myliobatis*, *Torpedo*, *Mustelus*, and *Ginglymostoma*. Note: Body size of all species has been normalized and does not reflect relative size scales. (b) Hair cell orientation patterns (arrows) of the macula neglecta of the same six groups of elasmobranchs from (a). The orientation patterns become more organized as the lifestyle of the species change from benthic to active/piscivorous. Reproduced from Corwin JT (1978) The relation of inner ear structure to the feeding behavior in sharks and rays. In: Becker RP and Johari O (eds.) *Scanning Electron Microscopy II*, pp. 1105–1112. Chicago, IL: Scanning Electron Microscopy, Inc, with permission of Scanning Electron Microscopy, Inc., copyright 1978.

lifestyle, whereas demersal elasmobranchs tend to hunt prey living on or buried in the substrate and likely use other senses (i.e., electroreception, lateral line, and olfaction) to locate their food (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior and **Detection and Generation of Electric Signals**: Morphology of Electroreceptive Sensory Organs). Correspondingly, pelagic elasmobranchs have a larger macula neglecta than demersal groups, with higher numbers of sensory hair cells spread out over two epithelial surfaces (**Figure** 3(**a**)). These patches of hair cells are organized into two oppositely polarized groups, with one epithelial surface in the dorsal direction and the other in the ventral (**Figure** 3(**b**)). This pelagic group also possesses a larger saccule than demersal elasmobranchs, as well as a larger, more dorsally positioned posterior canal duct and a shorter endolymphatic duct that positions the whole ear closer to the surface of the head (**Figure** 4). The more dorsally located positioning of these ear structures is speculated to lead to an increased ability to detect sounds from the anterior and dorsal directions.

Conversely, demersal elasmobranchs are characterized by a smaller, single epithelial patched macula neglecta (**Figure** 3(**a**)). The hair cells are unorganized and found in fewer numbers than in pelagic species (**Figure** 3(**b**)). Demersal species also have a smaller, more ventrally positioned saccule and posterior canal duct, a longer and narrower endolymphatic duct, and the ear is much farther from the surface of the head due to a deeper or broader parietal fossa (**Figure** 4). These generalizations, however, have been explored in only a few of the extant elasmobranchs. Moreover, cases of intermediate variations between these two categories are found in elasmobranchs that are more euryphagous (feed on fish as well as benthic organisms).

Auditory Sensitivity

Acoustic Attraction Studies

The general methodology to use sound to attract sharks to a location involves powerful underwater speakers to present a wide variety of sounds, varying the frequency

Chicago, IL: Scanning Electron Microscopy, Inc, with permission of Scanning Electron Microscopy, Inc., copyright 1978.

(25–1000 Hz), intensity, duration, tonal (pure tone and broadband noise) versus pulsed and regular versus irregular intervals. In total, 18 different species of sharks (including representatives of family Carcharhinidae, Ginglymostomatidae, Sphyrnidae, Lamnidae, and Alopiidae) were reported to be attracted to auditory signals produced through these speakers. Lower frequencies, with erratically pulsed tones, were the most attractive, with some sharks traveling as far as 400 m to the speaker location. That these erratically pulsed sounds closely mimick the sounds of wounded or distressed fishes, thought to attract sharks, was tested by playing back actual recordings of thrashing fishes as well as the sounds of soniferous fishes. All of these sounds attracted sharks. In cases where sharks were attracted from larger distances, the sound levels were loud enough that similar sounds would likely never be experienced in the sharks' native environments. Sounds played at ambient recorded levels attracted sharks only from <5 m.

While the field is a more ideal location for acoustic behavioral studies, lab studies can answer specific questions. The first behavioral study performed on sharks involved the simple stimulus of knocking on the side of a tank to elicit a startle response in a dogfish, *Mustelus canis*. Severing the eighth auditory nerve completely eliminated this response, providing the first evidence of hearing in elasmobranchs. Decades later, when repeated with a cat shark, *Scyliorhinus cannicula*, severing of the auditory nerve raised the threshold of detection. Lemon sharks, *Negaprion brevirostris*, discriminate between 40 and 60 Hz and orient to speakers placed as close as 9.5° of orientation in a circular pool.

Auditory Threshold Measurements

Most laboratory studies involving elasmobranch hearing have measured auditory thresholds or made more finite measurements of one or more of the individual end organs. These thresholds helped to estimate the range of frequencies (bandwidth) that elasmobranchs can detect as well as the lowest detectable signal by the auditory system.

The macula neglecta always has attracted interest to understand its role. Inspired by the experiment mentioned earlier that involved stimulation of the parietal fossa to elicit a response from the macula neglecta, two similar studies found that stimuli focused on the parietal

fossa yielded the strongest response from the elasmobranch auditory system. In both cases, without making contact with the skin, the stimuli utilized were an airborne sound source focused on the parietal fossa with the lemon shark, *N. brevirostris*, as well as an underwater vibrating ball to simulate a dipole acoustic stimulus with the horn shark, *Heterodontus francisi* (**Figure 5**).

Hearing thresholds are known from behavioral and electrophysiological studies, but for only a few of the extant elasmobranchs. The earliest audiogram measurements used operant conditioning methods on the bull shark, *Carcharhinus leucas*, and *N. brevirostris*, revealing a range of frequencies of 100–1500 Hz for *C. leucas* and 10–600 Hz for *N. brevirostris*. However, given that the thresholds were obtained with hydrophones and referenced to sound pressure, they do not provide an accurate reflection of auditory thresholds in a group of fishes that detect particle motions and not sound pressure. Lacking any type of air-filled bubble to act as a pressure-to-displacement transducer, elasmobranchs can only detect the particle motion component of sound directly with their inner ears (**see also Hearing and Lateral Line:** Biomechanics of the Inner Ear in Fishes, Psychoacoustics: What Fish Hear). Sound pressure thresholds for the little skate, *Raja erinacea*, ranged from 100 to 1000 Hz.

The first particle motion-sensitive audiograms were recorded in the lemon shark using a classical conditioning paradigm and revealed what would be a continuing trend in elasmobranchs, that lowest thresholds were detected in the lowest frequencies measured, with decreasing sensitivities as the frequencies increased (**Figure 6**). Using similar methods, thresholds were obtained in the horn shark but ambient noise levels during experimentation were likely loud enough to result in masking (or artificially raising) of the lower frequencies tested (**see also Hearing and Lateral Line:** Psychoacoustics: What Fish Hear).

Recently, the introduction of the auditory evoked potential (AEP) electrophysiological method has provided the opportunity for measuring hearing in larger numbers of fishes over a shorter period of time than using behavioral methods. Audiograms using AEP have been obtained in the yellow stingray, *Urobatis jamaicensis*, the nurse shark, *Ginglymostoma cirratum*, and the Atlantic sharpnose shark, *Rhizoprionodon terraenovae* (**Figure 6**).

The lemon and sharpnose sharks, which were the two most piscivorous, nondemersal elasmobranchs, have the lowest thresholds, especially at frequencies below 100 Hz. This further supports the anatomical observations that pelagic elasmobranchs could have more sensitive hearing than demersal species. Audiograms are displayed in terms of particle acceleration, which is the likely component of particle motion to stimulate the mass-loaded otoconial end organs.

All of the audiograms described above used an underwater speaker for presenting the acoustic stimuli to the elasmobranchs. An underwater speaker is considered to be a monopole stimulus, in which sound is radiated equally in all directions. A monopole, such as bioacoustical sounds produced by a vibrating fish swimbladder (air-filled cavity within fishes that functions primarily for buoyancy control and, in some fishes, has secondarily evolved vibratory muscles along the bladder that act as a mechanism to produce sounds for communication; **see also Hearing and Lateral Line:** Acoustic Behavior, Vocal Behavior of Fishes: Anatomy and Physiology, **Sensory Systems, Perception, and Learning:** How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling) is often thought to inaccurately portray the majority of acoustic stimuli that an elasmobranch might be detecting in the environment. Dipolar stimuli, such as the low-frequency oscillations created by fishes swimming in the water, are suggested to be more biologically relevant. A study using a dipole stimulus yielded significantly lower thresholds than using a monopole source (**Figure 6**). Although it is unclear if different end organs being stimulated in each study might account for the difference in thresholds, it certainly raises the possibility of dipole stimuli having the potential to be more attractive to sharks.

Discrepancies between Hearing Thresholds and Attraction Experiments

The field attraction studies show that sharks can localize acoustic stimuli from distances up to several hundred meters. In contrast, the hearing thresholds measured in several elasmobranchs suggest that these fishes are capable of hearing sounds, but likely not if the animals are too far away. Particle motion, the component of sound which elasmobranchs can detect, is dominant in the near field (approximately one wavelength from the stimulus source) and then quickly attenuates with distance where the propagating sound pressure wave dominates. For example, the near field of a 100 Hz signal is ~15 m and only ~1.5 m for 1000 Hz, assuming an ideal sound field. The lowest frequency broadcasted in the attraction studies was 25 Hz and would have a near field of ~60 m, certainly less than some of the distances reported. Another member of the genus of *Rhizoprionodon, Rhizoprionodon porosus*, was one of the sharks attracted to sounds in two of the studies. Far-field sound pressure levels estimated from the thresholds of *R. terraenovae* can be compared with the sound levels produced during the field attraction studies involving *R. porosus*. The *R. terraenovae* audiograms were shifted by an estimated critical bandwidth that is assumed to be 10% of the center frequency (i.e., the threshold is lowered by 10 log for direct comparison to the broadband noise stimuli used in the field attractionstudies (**Figure 7**)). Based on the sound pressure thresholds of *R. terraenovae*, it appears that the sound levels from the field attraction experiments were well below the hearing thresholds of the species. These results, however, need to be put into context. *R. terraenovae* was not one of the sharks specifically observed in the attraction studies, and could possibly have different thresholds than *R. porosus*. Moreover, many of the species observed in the attraction studies are pelagic, larger, and more piscivorous than any of the species in which audiograms exist and likely have subtle differences in the ear anatomy that might convey more enhanced hearing abilities than benthic species.

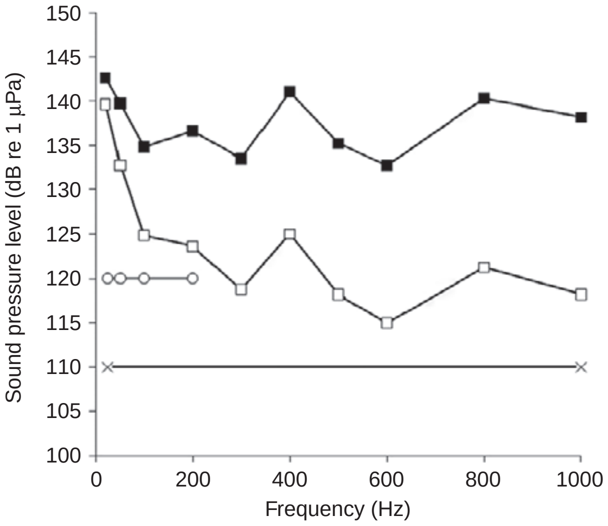

Figure 7 The sound pressure needed to produce particle accelerations equivalent to the Atlantic sharpnose shark, *R. terraenovae*, audiogram in a plane propagating wave (filled square symbols) and this same audiogram shifted by a critical bandwidth to compare with broadband noise signals (open square symbols). The sound pressure levels of broadband noise used in two field attraction experiments in which members of the *Rhizoprionodon* genus were attracted are plotted for comparison, suggesting that *R. terraenovae* would not have been able to detect the sound stimuli being presented. Distances from the sound source to the hydrophone for measurements of sound pressure level were 1 m for Richard (1968) (open circle symbols) and the *R. terraenovae* experiment, while they were made at 18.5 m for Myrberg *et al*. (1969) (× symbols). Reproduced from Casper BM and Mann DA (2009) Field hearing measurements of the Atlantic sharpnose shark, *Rhizoprionodon terraenovae*. *Journal of Fish Biology* 75: 2768–2776, with permission of John Wiley and Sons.

There are a variety of possible explanations for these observed discrepancies with *R. terraenovae.* It has been suggested that AEP measurements underestimate hearing thresholds in fishes compared to behavioral training methods. Another possible explanation could be that other stimuli may have attracted sharks to the testing locations. For example, in many of the test trials, sharks appeared to be following other fishes into the test area. Several of these fishes, including snapper and grouper, have swimbladders and likely can detect lower level sounds than *R. porosus.* It has also been observed in many of the field attraction experiments that the sharks responded erratically with agitated behaviors close to the speakers, which was likely due to the strong electromagnetic fields these speakers produce. This erratic behavior provides another strong visual stimulus to which other sharks could respond.

Summary

The first experiment to show that sharks can detect sounds was conducted over a century ago, yet, with exception to anatomical features, little is known about elasmobranch audition. Much of what is assumed about elasmobranch hearing is derived from just a few species, and certainly not a reflection of their wide range of body types, behaviors, and ecomorphotypes. Scant information exists on any aspect of audition for any of the larger, oceanic species. Enough observational data exist suggesting that sharks can detect loud, low-frequency sounds. However, beyond a variety of hypotheses, very little experimental data have been compiled to answer how these fishes are able to locate sound sources from any kind of distance or direction. Elasmobranchs provide the opportunity to study an ancestral stage in the evolution of hearing in vertebrates and represent a field of study ripe for further exploration.

Glossary

Acoustic particle velocity Fluctuation in the velocity of fluid particles that is caused by the fluctuating forces exerted on the fluid by acoustic pressure.

Acoustic pressure Fluctuation of pressure (force per unit area) above and below the ambient pressure in the fluid that is caused by sound.

Attenuation Reduction in acoustic power of a propagating sound wave.

Bandwidth Range of frequencies over which a sound is produced or received.

Far field Region far enough away from a sound source that the acoustic pressure behaves in a predictable way and acoustic particle velocity exists only because of the propagating sound wave.

Free field A region that has no reflections in which sound propagates from a source equally in all directions.

Frequency The number of wave cycles in a time interval (measured in Hz = 1 cycle s^{-1} or kHz = 1000 cycles s^{-1}).

Near field A region close to a sound source that has high levels of acoustic pressure and particle velocity which do not propagate into the far field.

Otolith A structure found in the inner ear made up of calcium carbonate and found in most teleost fishes. Motion of the otolith relative to the sensory cells of the ear results in stimulation of the cells and detection of sounds.

Propagation Movement of a sound wave through a fluid.

Swimbladder Gas-filled chamber in the abdominal cavity of many bony fishes that helps to not only control buoyancy, but can also serve as a sound-receiving structure that enhances auditory capability.

Wavelength The distance between repetitions, or cycles, of the spatial fluctuation of acoustic pressure in a sound wave.

Introduction

Sound is an extremely important means of communication for fishes and other aquatic animals. For example, fishes have the ability to detect low levels of sound that can alert them to an oncoming biological or anthropogenic predator, or help locate a mate (**see also Hearing and Lateral Line**: Acoustic Behavior, Vocal Behavior of Fishes: Anatomy and Physiology, Sound Source Localization and Directional Hearing in Fishes, and Fish Bioacoustics: An Introduction). The functional characteristics of auditory systems in fishes are almost identical to those of auditory systems in terrestrial mammals (**see also Hearing and Lateral Line**: Auditory System Morphology and The Ear and Hearing in Sharks, Skates, and Rays), yet fishes do not have an outer ear, middle ear, or cochlea in their inner ear, as do mammals. This article describes the mechanics of sound propagation in water and the interaction of sound with peripheral auditory systems in fishes. Understanding this interaction is critical to understanding reception of sound by fishes and the biomechanics of their ears.

Propagation of Sound Underwater

In air, sound travels at a speed of approximately $340\,\mathrm{m\,s^{-1}}$ and attenuates significantly with distance; however, underwater it travels with little attenuation and at a speed of about $1500\,\mathrm{m\,s^{-1}}$, and thus provides an effective way to transfer information over long distances. Sound is a mechanical disturbance that propagates as a longitudinal wave in air and water. The descriptor, ‘longitudinal’, means that the local motion of the fluid is parallel to the direction of propagation. As the wave propagates, small volumes of fluid particles at successive locations are compressed and then rarefied, creating a fluctuation in pressure above and below the ambient, respectively. This fluctuation is called the acoustic pressure, p. The rate of change in this fluctuation is described by the frequency, f, which has units of cycles per second or hertz (Hz). Tonal sounds, such as whistles, consist of a single frequency while sounds that are more complex are composed of multiple frequencies.

Sound is a function of both time and space, so p also has a repeated variation from one point to the next as the wave propagates. As pressure exerts a force in the fluid, spatial variation in p creates a differential force that causes fluid motion defined as the acoustic particle velocity; its amplitude, v, is proportional to p.

Repetition of spatial variation in p is described by the acoustic wavelength, λ, which has units of length (meters per spatial cycle). Wavelength is equivalent to the sound speed, c, divided by f: $\lambda = cf^{-1}$. So, at the same frequency, wavelength of sound underwater is nearly 4.5 times longer than the wavelength in air. **Figure 1** shows the relationship between λ and f in water.

Sounds range from the quietest whispers to the loudest explosions, so p is expressed on a logarithmic scale, called the decibel (dB) scale, by comparing it to a reference sound with pressure amplitude $p_0 = 2 \times 10^{-5}$ Pa in air and $p_0 = 1 \times 10^{-6}$ Pa in water ($1\,\mathrm{Pa} = 1\,\mathrm{N\,m}^{-2}$). The reference pressures are usually expressed in micropascals (μPa) where 2×10^{-5} Pa $= 20\,\mu$Pa and 1×10^{-6} Pa $=$ 1 μPa. Sound pressure level (L_p) is then defined as $L_\mathrm{p} = 10\ \log\ (p^2/p_0^2)$ dB re p_0, where 're' means 'with reference to'. For example, if $p = 1$ Pa in water then $L_\mathrm{p} = 10\ \log\ ((1\,\mathrm{Pa})^2/(10^{-6}\ \mathrm{Pa})^2) = 120$ dB re 1 μPa, while $p = 1$ Pa in air results in $L_\mathrm{p} = 94$ dB re 20 μPa.

The acoustic pressure and particle velocity combine to produce a flow of acoustic power associated with the passage of a sound wave. Power is the rate of change of energy, and sound power, W, is measured in watts, as is electrical power ($1\,\mathrm{W} = 1\,\mathrm{J\,s}^{-1}$; $1\,\mathrm{J} = 1\,\mathrm{N\,m}$). The amount of sound power is very small, so the reference power is $W_0 = 1 \times 10^{-12}$ W for both air and water. Sound power level (L_W) is then $L_\mathrm{W} = 10\ \log(W/W_0)$ dB re W_0.

Sound Sources

There must be motion of a surface in contact with the fluid to produce sound. Outward motion of this surface moves fluid particles and causes a local compression in the small volume of fluid it touches. This triggers propagation of a wave because pressure increases when the fluid is compressed, and the force due to increased pressure pushes on adjacent fluid causing it to move. Motion of adjacent fluid particles allows the originally compressed particles at the interface with the surface to move into the adjacent volume, which then causes pressure to increase at that location while decreasing in the originally compressed region. This process repeats itself as the wave propagates away from the moving surface, or source.

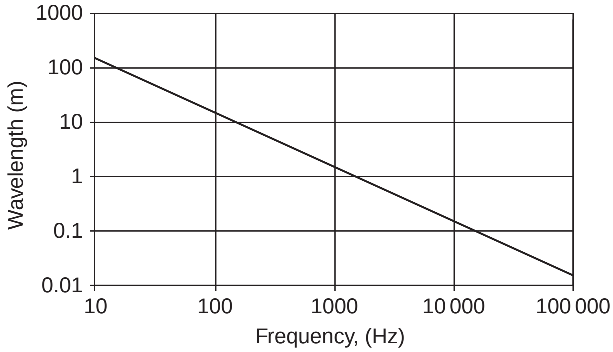

Figure 1 Frequency wavelength chart showing the decrease in wavelength of sound with increasing frequency in water with a sound speed of 1500 m s^{-1}.

The region very close to a sound source is called the 'near field'. In the near field, acoustic particle motion is controlled by a slug-type flow of fluid mass being pushed back and forth by the moving surface. Both p and v are very large near the surface of the source and then spatially decrease until the wave reaches a point far enough away that its propagation is controlled by the characteristics of the fluid and surrounding boundaries. The region at this point and beyond is called the 'far field' of the source. In practical terms, the far field occurs at a distance from the source that is much larger than any physical dimension of the source and is much larger than λ.

The far field should not be confused with an acoustic 'free field'. The term, free field, refers to the surrounding fluid, while far field (or near field) refers to the source. In a free field, the fluid is unbounded and there are no interactions of sound with boundaries, objects, or interfaces, such as the water surface or bottom. A free field is somewhat theoretical; however, it is usually a valid assumption for sound propagation in the middle of the deep ocean, or in situations where λ is very small with respect to the distance between the source and fluid boundaries. A free field is also a good assumption in situations where sound can propagate without interference until the acoustic pressure cannot be distinguished from background noise. In a free field, p and v are related by the characteristic acoustic impedance of the fluid, which is the product of c and fluid density, ρ. This relationship can be expressed as $p = \rho c v$.

When sources are much smaller than the wavelength of sound produced, they can be modeled as simple acoustic point sources. The simplest point sources are an acoustic monopole and dipole. The former is equivalent to a pulsating sphere that produces an outgoing spherically symmetric sound wave at constant frequency in an unbounded fluid. The latter can be realized as a small rigid sphere that oscillates back and forth at constant frequency in an unbounded fluid and produces a sound wave that is not spherically symmetric. The slug flow associated with the near field falls off with the square of the distance from a monopole and with the cube of the distance from a dipole. In the far field of both monopoles and dipoles, the acoustic pressure and particle velocity are in phase and decrease with distance from the source.

There are many moving biological objects, such as the tail of a swimming fish or an insect on the water surface, that create low-frequency waves in water. However, these waves usually do not propagate as sound into the far field because they lack sufficient power. They are local hydrodynamic disturbances detectable at close range by the inner ear and/or lateral line (**see also Hearing and Lateral Line**: Lateral Line Structure, Lateral Line Neuroethology). Hydroacoustic disturbances may appear to be hydrodynamic, very close to the source, and they also propagate into the far field as sound. Examples of hydroacoustic sources include underwater turbines and ship propellers. Whole-body motion of a large swimming animal and a pulsating swimbladder (gas-filled chamber, or chambers, located in the abdomen of most all species of fish) are examples of biological hydroacoustic sources that are often modeled as an acoustic dipole and monopole, respectively.

Transmission Loss

Transmission loss is the ratio of transmitted acoustic power to incident acoustic power. It can be calculated as the difference between the sound energy level at the source and the received (or incident) sound energy level at some distance from the source. In water, sound travels much faster than the strongest ocean currents or mountain streams. These convective motions do not disrupt sound propagation in water as wind does in air, so water is considered a quiescent medium for propagation of sound. Even so, sound energy is lost during propagation because of absorption, spreading, refraction, scattering, and reflection off the surface and bottom. Absorption occurs at the microscopic level when acoustic energy is converted into heat through viscous effects. Although absorption plays a role in propagation of high-frequency signals associated with ship sonar systems and marine mammal echolocation, in the frequency range of hearing in most fishes (**Hearing and Lateral Line**: Psychoacoustics: What Fish Hear), absorption is negligible.

As a wave propagates away from a source, it usually travels radially in all directions as long as it does not encounter a change in fluid characteristics (e.g., temperature), interface with another fluid (such as air), or a solid object. This radial propagation spreads the acoustic energy of the source over larger and larger spherical surfaces that have radii equal to the distance from the source. This is called 'spherical spreading', and p decreases by one-half for every doubling of distance from the source. When the radiated acoustic energy reaches either the surface or the bottom of the water, it is generally reflected back. So, as the wave continues to propagate further from the source, acoustic energy tends to be confined between the surface and bottom and the spreading becomes cylindrical rather than spherical.

Refraction is the bending of a sound wave caused by a change in sound speed. This occurs when sound is transmitted through an interface between two media with differing sound speeds or when a sound-speed gradient is present. Sound speed increases and decreases with temperature, and vertical temperature gradients exist in bodies of freshwater and in the ocean because water layers near the surface are affected by seasonal changes and weather. Sound waves always bend toward the direction of lower sound speed, which causes sound to travel in a curved trajectory rather than a straight path. Refraction by sound-speed gradients in the ocean and large freshwater lakes causes ducting and channeling of sound. These phenomena produce acoustic convergence zones and shadow zones where sound reception is very good and very poor, respectively.

Scattering of sound underwater is analogous to scattering of light in air. One sees objects in air because light that is scattered from them is received by the eye. Likewise, objects underwater can be detected by sound that is scattered from them. Simply put, scattered sound is secondary, or reradiated, sound that would not be present if the scattering object was there. Fish scatter sound, as do most other solid and gaseous objects in the water. Scattering increases transmission loss; however, it also provides acoustic signals related to the environment that fish potentially detect and use to accomplish many necessary life functions, such as navigating in and around objects, avoiding predators, and finding prey or mates (**Hearing and Lateral Line**: Acoustic Behavior).

In many fish habitats (e.g., coral reefs), sound waves interact with the air–water interface at the surface and the sediment and substrate at the bottom. At the surface, the sound wave is nearly perfectly reflected; however, the reflected wave is out of phase with the incident wave. Therefore, p is nearly 0 Pa at the surface, but not for the reflected wave that travels downward through the fluid. At the bottom, sound is partially reflected from hard (e.g., rocky) sediments, absorbed by soft (e.g., muddy) sediments, and scattered by other types (e.g., pebbles and sand). Each surface or bottom interaction attenuates incident sound and increases transmission loss.

Standing Waves and Propagation of Sound in Shallow Water

Most fishes live either in freshwater rivers and lakes, or on the continental shelves in the ocean where maximum water depths are about 200 m. For acoustic frequencies relevant to fishes (**see also Hearing and Lateral Line**: Acoustic Behavior, and Vocal Behavior of Fishes: Anatomy and Physiology), these are shallow-water environments where sound can propagate over distances greater than the water depth only by repeatedly interacting with the surface and bottom. Thus, shallow water is a very noisy and acoustically complex environment that makes understanding the reception of sound by fishes very difficult.

At locations where the ratio of water depth to λ is less than about 100, sound does not propagate freely; instead, it becomes contained in the water column via vertical standing waves called 'modes'. For example, this occurs when the water depth is less than 300 m for sound with $f = 500\,\text{Hz}$. Each mode has a different spatial frequency (cycles per meter), resulting in a large number of vertically oriented pressure minima and maxima. This makes it difficult to predict or monitor sound pressure received by an animal. These variations also create pressure gradients that result in larger acoustic particle motions than would be expected for freely propagating sound.

Each acoustic mode propagates at its own frequency-dependent speed; however, there exists a characteristic cutoff frequency below which a mode cannot propagate. It follows that no sound can propagate at frequencies below the cutoff frequency for the mode having the lowest spatial frequency. This absolute cutoff frequency is a function of water depth and characteristics of the bottom. For example, the absolute cutoff frequency is around 100 Hz for a sandy bottom and 10 m water depth. Sound at frequencies below the absolute cutoff does exist near its source; however, it cannot propagate into the far field.

Similar to the vertically oriented modes described above, standing waves that do not propagate can exist in areas that have many hard and/or soft surfaces that essentially trap sound. These areas include ponds and lakes, inlets and bays, marinas with docks and piers, coral reefs, and underwater caves. Complex sound fields consisting of stationary standing waves are also a problem in small tanks and aquaria often used for fish-acoustics research. Prior to use in experiments, these chambers need to be carefully calibrated by measuring sound pressure at multiple locations for each frequency and temperature of interest.

Interaction of Sound with Fishes

The primary interaction of sound with fishes depends on the length of the fish with respect to λ. Most fish species hear and produce sounds at frequencies typically below 1000 Hz (**see also Hearing and Lateral Line**: Psychoacoustics: What Fish Hear). With $c = 1500\,\text{m}\,\text{s}^{-1}$, λ will be longer than 1.5 m at these low frequencies, so the majority of fishes are fairly small relative to wavelengths of sound at frequencies of importance to them. This means that when a fish encounters a sound wave, its whole body will experience the same acoustic pressure at each point in time as the wave passes. Moreover, because its body is primarily composed of water, the fish will move at approximately the same amplitude and phase as the impinging sound.

Even though the fish tends to move with the sound wave, not all of its internal organs will move together. Different tissues have different densities and characteristic acoustic impedances (ρc). Denser organs, such as bone, will not move as fast as the surrounding tissue due to inertia, while acoustic particle motion will be much larger in tissues with relatively low acoustic impedance, such as the swimbladder, because $v = (p)(\rho c)^{-1}$.

Mechanics of the Hearing Process

Fishes detect and respond to a wide variety of sounds. The exact structure of the inner ear, however, varies among species so they differ in both the range of frequencies (auditory bandwidth) and the lowest sound-pressure level (auditory threshold) that they are able to detect. The inner ear in fishes lies within the cranial cavity just lateral to the brain (**see also Hearing and Lateral Line**: Auditory System Morphology). The semicircular canals detect angular acceleration in fishes just as they do in terrestrial vertebrates (**see also Hearing and Lateral Line**: Vestibular System Anatomy and Physiology). Furthermore, the otolith organs (utricle, saccule, and lagena) serve as vestibular organs and detect the position of the head in the vertical direction relative to gravity and in other directions relative to acceleration of the body, just as the utricle and saccule do in terrestrial vertebrates. In fishes, however, the otolith organs are also involved in detection of sound (**see also Hearing and Lateral Line**: Auditory System Morphology, The Ear and Hearing in Sharks, Skates, and Rays).

Depending on the species, each otolith organ contains either otoconia or a single, dense calcareous stone (otolith) within a chamber filled with endolymph. A sensory epithelium that contains mechanosensory hair cells innervated by the eighth cranial nerve lies on the chamber wall. Each hair cell has an apical group of projections called the ciliary bundle that extends above the surface of the epithelium in which the cell lies. Between the otolith and sensory epithelium is a thin otolithic membrane that connects to both structures and helps keep them in the same position relative to each other. As fishes move with an underwater sound wave and the otoliths or otoconia are much denser than surrounding tissues, these structures lag behind the motion of the rest of the body. This creates relative motion with the sensory epithelium and causes bending of the ciliary bundles and these stimulate the underlying hair cells to send electrical signals to the brain that provide information about sound (**see also Hearing and Lateral Line**: Auditory System Morphology, The Ear and Hearing in Sharks, Skates, and Rays).

Thus, in all fishes, the otolith organs are stimulated directly by the acoustic particle motion associated with the propagating sound wave. This is referred to as the ‘direct path’ of sound to the inner ear. In fishes that have swimbladders, the otolith organs can be stimulated indirectly by particle motion created when sound-pressure fluctuations are transformed into motion by these gas-filled organs. This is referred to as the ‘indirect path’ for sound to excite the inner ear and results in an additional signal proportional to acoustic pressure.

Role of the Swimbladder

The swimbladder has several functions including respiration, provision of buoyancy, and detection of pressure changes. In addition, the swimbladder is stimulated by acoustic pressure causing its wall to move and generate secondary sound, which is again detectable through relative motion of tissues in the inner ear. Additional stimulation of the inner ear via response of the swimbladder increases auditory bandwidth and hearing sensitivity. In some species, the response of the swimbladder to sound as a function of frequency correlates with auditory sensitivity (i.e., lowest hearing thresholds occur at frequencies where the response of the swimbladder to sound is the highest). This effect, however, diminishes with increasing distance between the swimbladder and inner ear because of transmission loss associated with sound propagation through the intervening tissues.

Auxiliary and Unusual Anatomy That Enhance Hearing

Cyprinids and other otophysan species (e.g., goldfishes, catfishes, and carps) possess a series of three or four modified vertebrae, called the Weberian ossicles, that mechanically couples or connects the swimbladder to the fluids of the ear as illustrated in **Figure 2** (**see also Hearing and Lateral Line**: Fish Bioacoustics: An Introduction). The largest ossicle, the tripus, connects the anterior swimbladder chamber to the second ossicle, the intercalarium that connects anteriorly to the scaphium and, in some species, the claustrum. The scaphium and claustrum, when present, are embedded in the walls of the sinus impar, a fluid-filled canal that projects anteriorly and ultimately communicates with the saccule. Expansion of the swimbladder causes forward motion of the ossicles and fluid flow into the saccular chamber, while compression causes fluid flow out of the saccule. This increases relative motion within the saccule, provides additional stimulation of auditory hair cells, and results in lower auditory thresholds and broader auditory bandwidths in these species.

Several species have evolved a number of different mechanisms to couple gas-filled structures other than the swimbladder to the ear, thereby allowing the auditory system to detect signals proportional to acoustic pressure. Anabantids (gouramis) have a suprabranchial air-filled chamber with a membrane-type window located near the saccule. Mormyrids (freshwater elephant-nose fishes) have gas-filled chambers entirely separated from the swimbladder that are located in the semicircular canals and connected to the surface of the saccule. Hearing in several of these species indicates auditory sensitivity at frequencies up to 5000 Hz. Likewise, some sciaenid species (e.g., Atlantic croaker (*Micropogonias undulatus*) and weakfish (*Cynoscion regalis*)) having a swimbladder with a pair of anterior horns that terminate close to the ear have been found to detect higher frequencies than species lacking such structures. Some Myripristinae (soldierfishes) also have a direct connection between the inner ear and anterior projections of the swimbladder that enhances both their hearing sensitivity and bandwidth.

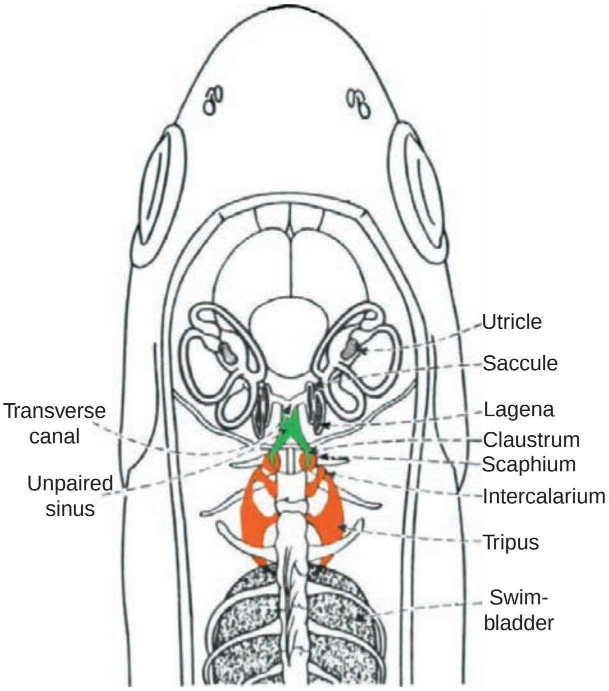

Figure 2 The Weberian ossicles connecting the anterior swimbladder with the inner ear in an otophysan fish.

At least two clupeiform species, American shad (*Alosa sapidissima*) and gulf menhaden (*Brevoortia patronus*), detect ultrasound at frequencies of 100 kHz or higher. In these fishes, the swimbladder, inner ear, and lateral line system are all linked through a pair of bony capsules in the inner ear called auditory bullae. Each bulla is divided into a gas-filled and a liquid-filled part by a membrane. A narrow duct connects the gas-filled part to the swimbladder. Transmission of sound through the membrane in the bulla creates pressure fluctuations in the liquid-filled part, which are transferred directly into the utricle. This provides additional relative motion between the utricular otolith and its sensory epithelia. The utricle is thought to play a role in the detection of ultrasound, but it is not yet understood because not all clupeids with auditory bullae have this capability.

Most auxiliary anatomical structures in fishes improve hearing at higher frequencies. Some species, however, have demonstrated enhanced sensitivity at lower frequencies that may be attributed to oversized otoliths either in the utricle or in the saccule. A larger otolith has more inertia that would increase relative motion with the sensory epithelium when stimulated by low-frequency sound.

Summary and Conclusions

Fishes live in very complex acoustic environments and yet manage to detect and use acoustic signals. There is great diversity in the structure and morphology of their inner ears, as well as other peripheral anatomical structures related to enhanced auditory sensitivity in several species. Biomechanics of the inner ear, swimbladder, and these peripheral structures correlates with the wide range of auditory thresholds and bandwidths found in many fishes.

Glossary

Audiogram A graphical representation of sound detection thresholds at the range of frequencies that are audible.

Auditory scene analysis A perceptual capacity shared by all vertebrates, including fishes, to segregate and respond independently to the individual sound sources that may be active simultaneously (e.g., the instruments of an orchestra).

Masking The reduction in audibility for one sound (termed 'signal') caused by the simultaneous presence of another sound (termed 'noise'). Masking causes the threshold for the signal to be higher (less detectable) than it normally would without the masking noise.

Otophysic connection An anatomical linkage between a gas bubble (e.g., the swimbladder) and the inner ear that brings the motions of the gas bubble, caused by sound pressure, directly to the ears.

Psychophysics A technology of experimental psychology designed to allow the investigation of the relationships between the physical nature of a stimulus (e.g., sound) and the sensations and perceptions caused by the stimulus.

Soundscape The sum of all the sounds characteristic of an environment.

Weberian ossicles A series of bones that is specially adapted as an otophysic connection between the swimbladder and the inner ear in a group of fishes known as Otophysi.

Fish Can Hear!

About 60 fish species have been evaluated with respect to their hearing abilities, and all have been shown to hear by a behavioral definition of hearing; that is, we observe them responding behaviorally to a sound source following conditioning (see below). Therefore, it has been concluded that all fishes, teleost and nonteleost, can hear. This had been controversial historically (during the early twentieth century), in part because fish have no external ears or any visible suggestion of ears.

The inner ear otolith organs (**see also Hearing and Lateral Line**: Auditory System Morphology) are stimulated directly by sound that passes through the body nearly unimpeded (**see also Hearing and Lateral Line**: Biomechanics of the Inner Ear in Fishes). Otoliths are very dense calcium carbonate stones that respond to sound (move) at a different magnitude and phase of the acoustic particle motion compared with the close-lying sensory epithelium containing sound receptor cells. The saccule is the primary auditory organ in most species.

In some fish species, additional pathways for hearing have evolved that make the animal sensitive to sound pressure as well as acoustic particle motion. These specializations include a swimbladder or other gas cavity in the head or abdomen, and mechanisms that mechanically connect the gas bladder to the ears (an otophysic connection). Vibrations of the gas bladder result from pressure fluctuations (e.g., sound pressures) impinging on the fish. These motions can be transmitted to the ears in some species where they stimulate one or more of the otolithic organs. The best known and understood of these otophysic connections are the Weberian ossicles shared by the group of fishes known as the Otophysi. The species with Weberian ossicles have extreme sensitivity to sound pressure and with hearing extending to higher frequencies (up to 2000–5000 Hz).

How Is Hearing Measured?

There are many physiological and behavioral indications that a given species can hear, but the gold standard in this field is the behavioral audiogram, or the relation between the lowest sound levels that are behaviorally detectable and the frequency of the sound. The term hearing presupposes a behavioral response because it is an ability or capacity of the whole organism to respond to sound. Various methods of behavioral analysis have been applied in hearing studies.

Psychophysics is the science that directly links the physical nature of the stimulus to the perceptions that may arise from sensory stimulation. Combined with psychophysics are the various behavior control technologies that are used to study conditioning and learning in animals. The most common ones are classical, or Pavlovian, conditioning, and instrumental avoidance conditioning. In addition, many recent experiments have used the methods for auditory evoked potentials as a partial substitute for the behavioral methods.

Classical Conditioning

Classical conditioning occurs when a previously neutral stimulus (e.g., a tone) is paired with a stimulus that elicits unconditionally a reflex of some kind (e.g., the suppression of respiration rate or heart rate). With multiple pairings of these stimuli, the previously neutral stimulus (conditioned stimulus) begins to elicit a response very much like the unconditioned reflex response. The occurrence of this response to the conditioned sound stimulus is an indication of hearing. Then the methods of psychophysics are applied to the conditioned stimulus. For example, sounds may be presented with decreasing intensity (e.g., sound pressure level) until the conditioned response fails to occur. The intensity level at which the response fails can be defined as the threshold for hearing that sound. Then, the frequency of the sound is changed and the experiment repeated. A plot of the thresholds as a function of the frequencies tested is the audiogram. It describes the weakest tones that are detectable, and the frequency range of hearing. An audiogram for the goldfish (*Carassius auratus*) is shown in **Figure 1** using these methods.

The audiogram can be interpreted as follows: at all frequencies tested, sound pressures above the audiogram line are detectable, while those levels below the line cannot be heard. The frequency range for the goldfish can be described as from 30 Hz or below to about 2500 Hz. The best frequency of hearing is about 350 Hz. One microPascal ($1\,\mathrm{Pa} = 1\,\mathrm{N\,m^{-2}}$) is the unit of sound pressure against which all sound pressure thresholds are compared. We have confidence in this audiogram because many physiological and behavioral experiments on goldfish confirm that it is specialized for detecting sound pressure (it has Weberian ossicles), and sound pressures were manipulated and measured in this experiment. The greatest sensitivity for goldfish (about 60 dB re: 1 μPa underwater) is comparable to the best sensitivity for humans in air, and many other vertebrate animals. The goldfish is the most studied of fish species in terms of hearing experiments.

Instrumental Avoidance Conditioning

A typical application of avoidance conditioning involves a free-swimming fish in a small aquarium with a partial barrier dividing the aquarium in half. A tone is presented, followed in a few seconds by a noxious stimulus (e.g., very

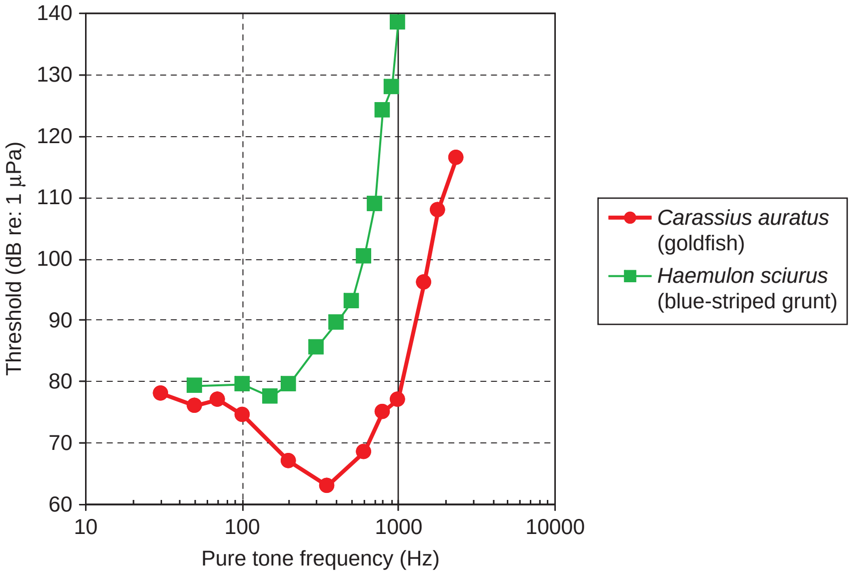

Figure 1 Audiogram for *Carassius auratus* (goldfish) estimated using classical conditioning, and audiogram for *Haemulon sciurus* (blue-striped grunt) using instrumental avoidance conditioning.

mild electric shock). The fish eventually crosses the barrier and the shock is immediately turned off. Almost immediately, the animal learns to swim over the barrier as soon as the shock is started. Then, the animal learns by trial and error that if it swims over the barrier to the other side of the tank during the tone presentation (and before shock onset), it will not get a shock. Swimming over the barrier during the tone is an indication that the fish heard the sound. Once the animal successfully crosses the barrier avoiding a shock in the majority of trials (e.g., 90%), a psychophysical procedure is implemented and thresholds are estimated as in classical conditioning. **Figure 1** shows an audiogram for the blue-striped grunt (*Haemulon sciurus*) measured by avoidance conditioning.

The blue-striped grunt is a species without any known special adaptations for hearing, and therefore we now believe that it may be sensitive to acoustic particle motion, not sound pressure. However, sound pressure was manipulated and measured in this experiment, not particle motion. Thus, this audiogram's interpretation is in doubt, because the relation between sound pressure and particle motion varies in different environments, especially in small aquaria. Nevertheless, we could describe this audiogram as extending from below 50 to 1000 Hz, with a most sensitive frequency of about 150 Hz. This audiogram is different from the goldfish audiogram of **Figure 1**, both in sensitivity and frequency range.

Auditory Evoked Potentials

The synchronous activation of many neurons in the auditory system can be monitored and recorded using surface electrodes on the animal's head. This requires extreme amplification of these minute voltages and the signal averaging of many repetitions of each stimulus. Averaged voltage waves in response to brief sound presentations are used as an indication that the sounds have activated the auditory system. The signal level is then manipulated to determine the lowest level that can still result in repeatable averaged brain waves at all effective frequencies. This results in an evoked potential audiogram, sometimes called an auditory brainstem response (ABR) audiogram. ABR audiograms are now very popular for estimating the frequency range of hearing of various species. The advantage of the ABR method is that it is rapid (usually completed in about 1 h), rather than the several days or weeks required for a behavioral audiogram. The disadvantage of the ABR audiogram is that there is no known relationship between the amplitude of these brain waves at threshold and behavioral responses; thus, the ABR thresholds themselves cannot yet be interpreted as a measure of sensitivity comparable to behavioral sensitivity. In this article, only behavioral audiograms are shown due to the uncertainty of the interpretation of ABR audiograms.

Species Variation in Hearing Ability

Figures 1–4 illustrate some of the variations in hearing abilities of fishes that have been studied. Fishes can be classified into three groups based on their hearing abilities: (1) otophysans and other species that are probably pressure sensitive, (2) species with swimbladders but without any known specializations for the detection of sound pressure, and (3) species without swimbladders without the possibility of sound pressure sensitivity. **Figure 1** illustrates two species representing the first two groups: goldfish – a pressure-sensitive otophysan – and blue-striped grunt – a nonotophysan. **Figure 2** shows the audiograms for three additional pressure-sensitive otophysans (*Cyprinus carpio* (carp), *Arius felis* (marine catfish), and *Astyanax mexicanus* (Mexican tetra)). **Figure 3**

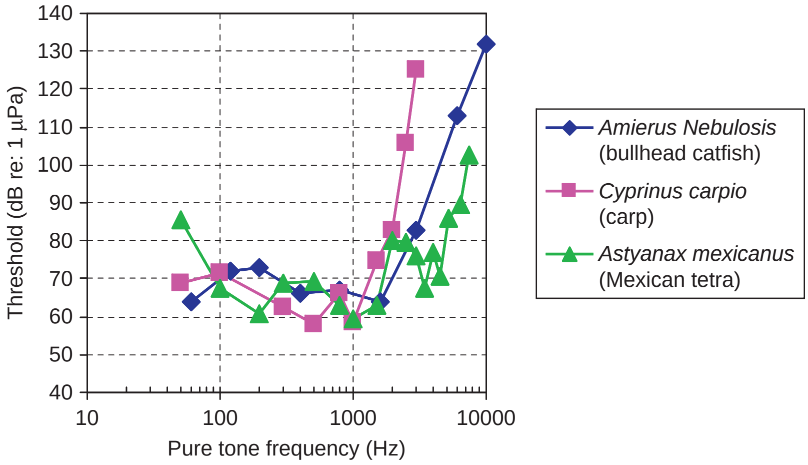

Figure 2 Sound pressure audiograms for selected Otophysi (species having Weberian ossicles).

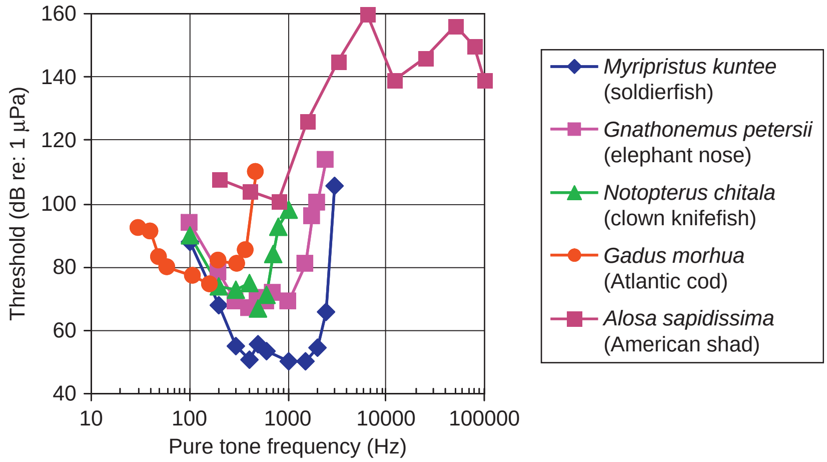

Figure 3 Sound pressure audiograms for selected species that are likely pressure sensitive due to adaptations of the swimbladder or other bubbles of air associated with the ear.

shows selected audiograms for five nonotophysan species (*Myripristus kuntee* (soldierfish), *Ganthonemus petersii* (elephant nose), *Notopterus chitala* (clown knifefish), *Gadus morhua* (Atlantic cod), and *Alosa sapidissima* (American shad)) that are likely to be pressure sensitive, but pressure sensitivity has only been experimentally confirmed for the cod. **Figure 4** shows audiograms for five species (*Pleuronectes platessa* (plaice), *Limanda limanda* (dab), *Negaprion brevirostris* (lemon shark), *Anguilla anguilla* (European eel), and *Salmo salar* (Atlantic salmon)) without swimbladders, or which have been shown to be sensitive only to acoustic particle motion in the frequency range where data are plotted. Note that **Figure 4** shows thresholds in terms of particle acceleration (dB: re: 1 nm s^{-2}). There is a group of species whose audiograms were measured in terms of sound pressure, yet it is probable that they respond only to acoustic particle motion. Thus, these audiograms (not shown) cannot be interpreted until further experiments are done.

Clearly, the otophysans (goldfish of **Figure 1**, and **Figure 2**) hear with the greatest sensitivity at the higher frequencies (up to 5000 Hz in some species). This sensitivity and high-frequency range is due, in part, to the presence of Weberian ossicles, and, in part, to adaptations of the saccular hair cells in these species to respond to the higher-frequency sounds.

Figure 3 shows audiograms for selected nonotophysan species with swimbladder specializations that probably

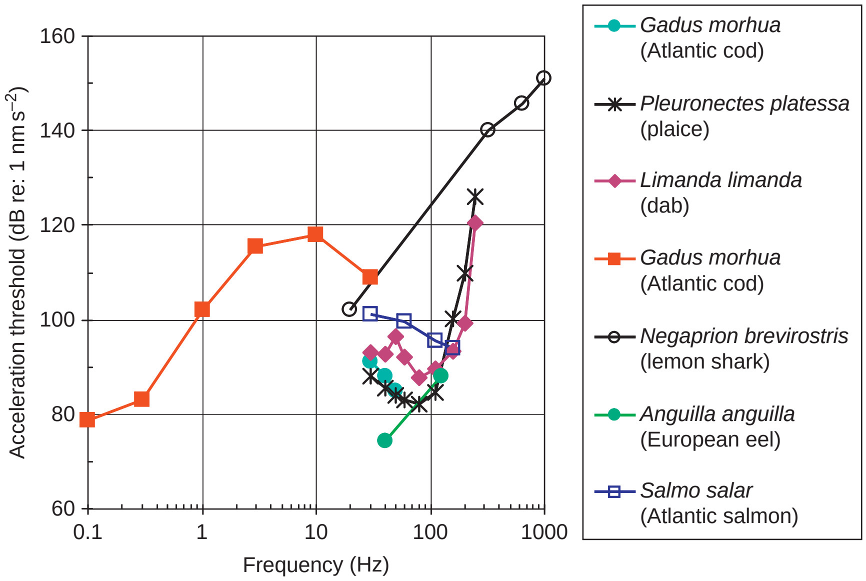

Figure 4 Selected particle acceleration audiograms for species known to be most sensitive to acoustic particle motion in the frequency range where data are displayed.

make them pressure sensitive. Unlike the Otophysi, this group exhibits significant variation in sensitivity as well as in the frequency range of hearing. The Atlantic cod has been shown to be sensitive to acoustic particle motion at low frequencies, but is pressure sensitive at the higher frequencies (above 100–200 Hz), probably due to the forward extensions of the swimbladder, near the ears. The mormyrid *Gnathonemus* sp. has a gas bladder in the inner ear to which the saccule is attached. *Notopterus* sp. and *Myripristus* sp. both have forward extensions of the swimbladder close to the ears. The American shad, *A. sapidissima*, is a herring-like fish with special adaptations of the swimbladder incorporating the utricle that has been shown to have sensitivity at ultrasonic frequencies (>20 000 Hz), but unremarkable sensitivity in the frequency range usual for fishes (<1000 Hz).

The audiograms of **Figure 4** illustrate species either without a swimbladder (*Pleuronectes* sp., *Limanda* sp., and *Negaprion* sp.), or that have been demonstrated to be sensitive to acoustic particle motion (*Salmo* sp., *Anguilla* sp., and *Gadus* sp.) in particular frequency ranges. The ordinate of this figure is in acceleration units rather than sound pressure, and illustrates the nearly constant sensitivity to acceleration at infrasonic frequencies for *Gadus* sp. Sensitivity to particle displacements at 100 Hz is similar for all the species illustrated at about 0.1 nm, or about the diameter of a hydrogen atom. This indeed is very great sensitivity.

The Determinants of Sensitivity

In addition to swimbladder and otophysic adaptations, a fish's hearing sensitivity is determined by the duration of the sound signal and the level of ambient noise present. Sound duration affects sensitivity between <10 and about 400 ms, with greater sensitivity at the longer durations. This growth of sensitivity is common in sensory systems and is known as temporal summation.

Noise is a major determinant of hearing sensitivity under most real-world and uncontrolled situations (**see also Hearing and Lateral Line**: Effects of Human-Generated Sound on Fish) for potential effects on masking of human-generated sounds in the water). For example, the detection and recognition of speech by humans depends on the levels of noise present – as noise level increases, speech becomes harder to hear, or less intelligible, and its threshold for detection becomes higher. A threshold that is determined by noise is termed a masked threshold. Masking refers to the elevation of the detection threshold for one sound (the signal) due to the presence of another sound (e.g., noise). Masking is ubiquitous, and most fishes normally hear under masking conditions in most environments. In general, masking is linear in the sense that an increment of 1 dB in the masking noise causes a 1-dB rise in the threshold for a signal.

Masking has been studied in fishes by using pure tones as signals, and white noise of varying bandwidth as maskers (**see also Hearing and Lateral Line**: Effects of Human-Generated Sound on Fish). The fundamental masking description consists of the level of a just-detectable signal in the presence of wide-band (covering a wide frequency range) noise with a flat spectrum (equal sound pressure at all frequencies). The critical masking ratio (CR) is defined as the sound pressure level in dB of the signal tone that is at threshold (just detectable in the noise) minus the spectrum level (level per Hz) in dB of the masking noise. Large critical ratios occur when the noise is relatively effective as a masker. According to the traditional theories of masking in human hearing, a masker is more or less effective depending on the frequency range of the hypothetical detection filter used to detect the pure tone signal. A filter is a system that is frequency selective, that is, it passes through (responds to) acoustic components in a given frequency range, but rejects (filters out) all other frequency components. Noise is assumed to be integrated or summed over the frequency range of the filter that is assumed to be centered at the signal frequency, so the wider (in frequency) the detection filter, the more noise is admitted, and the masking effect is greater. Therefore, a large CR suggests a wide-band detection filter, and a small CR suggests a narrow-band detection filter. These assumptions have been evaluated in masking studies on fishes and have been shown to be approximately correct.

Figure 5 plots behaviorally measured CRs for goldfish. In general, the CR at the lowest frequency (100 Hz) is about 13 dB and tends to grow linearly with signal frequency through 1000 Hz to about 24 dB. These values are well within the range reported for other vertebrate animals, including humans, and the slope of the masking effect is substantially similar for all vertebrates. The bandwidths of the hypothetical detection filters range from 21 (at 100 Hz) to 257 Hz (at 1200 Hz). All of these bandwidths are significantly narrower than the goldfish's hearing range, and suggest multiple frequency-selective detection channels in the goldfish ear. This has been

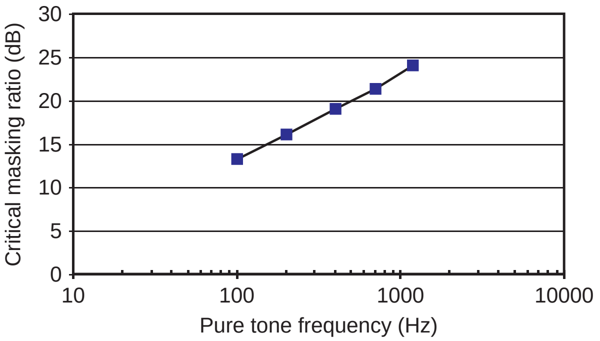

Figure 5 Critical masking ratios (CRs) for the goldfish. The CR is the threshold for the signal tone (in dB) minus the spectrum level of the masking noise (in dB).

confirmed physiologically (**see also Hearing and Lateral Line**: Physiology of the Ear and Brain: How Fish Hear).

CRs have also been measured for the Atlantic cod, haddock (*Melanogrammus aegelfinus*), marine catfish (*Arius felis*), and pinfish (*Lagodon rhomboides*). For the Atlantic cod and haddock, CRs were also measured for different spatial separations of the signal and masker noise sources. It was found that the CR can be up to 8 dB smaller (noise is less effective) when the signal source was straight ahead, and the noise source 90° to the side. Thus, fish demonstrate one feature of the cocktail party effect or the increased detectability of a masked signal when the noise source is displaced in the horizontal plane for human listeners, and suggests detection filters that are selective in the spatial domain as well as in the frequency domain.

Frequency Discrimination

One of the most important aspects of hearing by fishes (and all other vertebrates, including humans) lies in their capacities to discriminate differences between pure tone frequencies (i.e., pitch discrimination). Terrestrial animals accomplish this, in part, due to the organization of their inner ears having a basilar membrane containing sound receptor cells (as in humans and other mammals) and spatial or place mechanism for frequency analysis that appears to be lacking in fishes. So, the extent that fishes can analyze frequency probably depends on the mechanisms other than these familiar place mechanisms.

In a frequency discrimination experiment, the animal must respond one way in the presence of one frequency (F1), and another way in the presence of another frequency (F2). Then the difference (F1 − F2) between these frequencies is made progressively smaller until the animal can no longer differentiate between them (e.g., respond differently). Then this procedure is repeated at a different F1, and the relation between F1 and the smallest discriminable F1 − F2 can be described. **Figure 6** shows this relation for several species. The smallest discriminable change in frequency is plotted as a function of the F1 frequency.

Fishes have been roughly divided into two groups, the otophysans (e.g., European minnow, goldfish, and marine catfish), and the nonotophysans (e.g., *Gobius niger* (goby), *Corvina nigra* (drum), *Sargus annularis* (ringed sea bream), *Cottus scorpius* (bullhead), and *Negaprion brevirostris* (lemon shark)). These data have led to the tentative conclusion that otophysans have more acute frequency discrimination abilities than the nonotophysans. Taking the goldfish as an example, frequency discrimination acuity declines linearly with frequency, being about 3.5 Hz at an F1 of 50 Hz, to about 47 Hz at an F1 of 1000 Hz. The slope of this function and the thresholds themselves place goldfish within the range of variation seen for frequency discrimination among most terrestrial vertebrates. Fish accomplish this without a place mechanism of frequency analysis, and probably rely on a temporal code for frequency, based on the synchrony between the impulses evoked in the auditory nerve and the tone stimulus wave.

Auditory Scene Analysis

When there are multiple, simultaneous sound sources active, the human ability to segregate the sources in perception, and respond to them independently, is

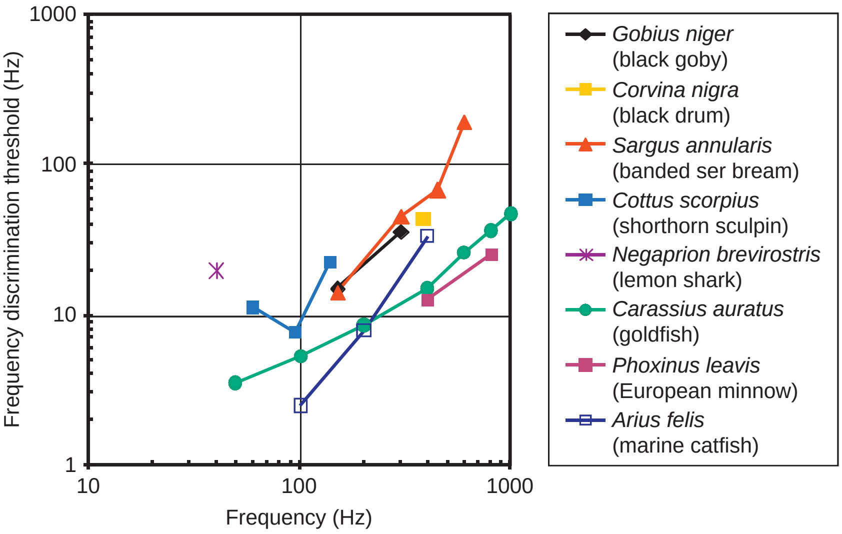

Figure 6 Frequency discrimination thresholds for all species investigated.

known as sound source segregation (**see also Hearing and Lateral Line**: Sound Source Localization and Directional Hearing in Fishes). This ability is part of auditory scene analysis (ASA), or the ability to determine the multiple sources that make up a sort of scene in perception. This scene is not necessarily spatial, requiring source localization, but is analogous to the human ability to hear out and recognize individual sound sources (e.g., instruments in an orchestra) even when source localization is not possible (e.g., when listening to a monophonic recording). Scene analysis makes it possible for two (or more) simultaneous sound sources to be heard or determined independently. This phenomenon is well known in human hearing, and has been demonstrated so far only in goldfish (plus the European starling, and some other primates). For example, goldfish can determine that two simultaneous sound sources are present, and respond to the frequency and temporal characteristics of either one, independently. It is presumed that ASA probably operates for all vertebrates and, possibly, some invertebrates. It takes place automatically, without cognition or the focusing of attention. ASA is thought to be a capacity that is necessary for hearing to have survival value, and probably evolved at the same time as hearing itself first evolved among fishes.

What Do Fishes Listen to?

This is a difficult question because we know very little about underwater acoustic ambience. Because many fish species produce sounds (e.g., vocalizations), it was long thought that their hearing was developed for the purposes of sound communication (**see also Hearing and Lateral Line**: Acoustic Behavior). Now, however, it is believed that fish listen to and make use of all the sounds that they can hear (the soundscape or the background noise of each environment), including the swimming, eating, the communication sounds of predators, prey and conspecifics, and the sounds of wind, rain, and moving water, etc. They are thought to use these sounds for soundscape orientation, the same way that humans do, to assess their environment and their place in it. To do this, the capacity for auditory scene analysis is necessary. Sound communication among fishes could only have evolved once the ability to discriminate the sound sources making up the soundscape appeared.

Glossary

Clupeid Species in the teleost order Clupeiformes, characterized by the presence of a swimbladder-derived gas-filled bulla physically connected to the utricle of the inner ear.

Lateral lemniscus Collection of axons from hindbrain auditory and, when present, lateral line nuclei that terminates mainly in the midbrain roof structure called the torus semicircularis in fish, amphibians, and reptiles, and called the inferior colliculus in mammals.

Neurogenic placodes Embryonic ectodermal thickenings that give rise to neurons and sensory cells such as the ear, lateral line and olfactory organs, and, in some cases, cranial nerves.

Nucleus A discrete population of neurons that can be recognized using histological methods such as a stain for neuronal somata (e.g., cresyl-violet), and that perform a common function (e.g., sound processing).

Otolith organ A collection of sensory hair cells in the inner ear in which the hair cell cilia are covered by a membrane covered by a calcium carbonate mass. The saccule, lagena, and utricle of the inner ear. Each has a sensory epithelium (or macula) and an otolith (or otoconia).

Otophysan A large teleost clade whose members have a series of bones (Weberian ossicles) anatomically connecting the swimbladder to the saccule of the inner ear.

Otophysic connections Anatomical linkage of the inner ear to a gas-filled structure, such as the swimbladder that brings the motions of the gas bubble, caused by sound pressure, directly to the ears.

Primitive A trait that evolved early in evolutionary history.

Primitive vertebrate feature A trait that evolved in the common ancestor of vertebrates.

Teleost The most recently evolved of all the bony fishes (Osteichthyes). Teleosts have rayed fins and a swimbladder, and include everything from goldfish to tuna to salmon.

Evolutionary Overview

Inner Ear Auditory and Lateral Line Sensory Organs

It is likely that the inner ear of the earliest jawed fishes possessed acoustic function because otic hearing organs are present in their descendents: the cartilaginous and bony fishes. Auditory function can be distributed among multiple inner ear sensory organs. Individual otolith end organs – the saccule, utricle, and lagena – may have both acoustic and vestibular roles; such bifunctionality may be the primitive vertebrate condition. In some cartilaginous fish, the macula neglecta is also acoustically responsive.

For further discussion on inner ear end organs, **see also Hearing and Lateral Line:** Auditory System Morphology, The Ear and Hearing in Sharks, Skates, and Rays, Physiology of the Ear and Brain: How Fish Hear, and Vestibular System Anatomy and Physiology.

Mechanosensory lateral line organs are a primitive vertebrate feature. These organs detect pressure gradients resulting from bulk water flow, such as occurs during swimming or the motion of conspecifics and prey. Under certain conditions, sound can also stimulate the mechanosensory lateral line, but the fundamental contribution of lateral line information to auditory processing is unknown. Convergence of lateral line and auditory inputs occurs in a number of brain areas. For further discussion on the lateral line system, **see also Hearing and Lateral Line:** Lateral Line Structure and Lateral Line Neuroethology.

Inner Ear Auditory and Mechanosensory Lateral Line Brain Circuits

The peripheral receptors of the auditory and lateral line systems (as well as in the vestibular inner ear organs) consist of sensory hair cells innervated by bipolar neurons. The anterior and posterior lateral line cranial nerves

(cranial nerves that are unnumbered) collect sensory input from lateral line mechanoreceptors on the head and trunk, respectively. Cranial nerve VIII (the octaval or stato-acoustic nerve) is an aggregate of nerve branches that collect input from each of the inner ear sensory end organs. Cranial nerve VIII enters the brain at the level of the medulla oblongata (commonly referred to as the medulla) between the entry points of the anterior and posterior lateral line nerves (**Figures 1(a)** and **1(b)**). The lateral line and octaval nerves also contain the axons of central octavolateral efferent neurons that innervate the sensory hair cells. For further discussion on octavolateral efferent neurons, **see also Hearing and Lateral Line:** Physiology of the Ear and Brain: How Fish Hear.

Embryologically, the inner ear and lateral line sensory hair cells and cranial nerves develop from, respectively, the otic and lateral line neurogenic placodes. The lateral line placodes are lost in amniotes and in those amphibians that lack a lateral line at all stages; thus, there is no apparent homolog of this system in most land vertebrates. In contrast, the otic placode is retained in all vertebrates and gives rise to evolutionarily new otic auditory organs that complement (e.g., amphibians) or functionally replace (e.g., mammals) the primitive auditory organs of fish.

The inner ear auditory and the lateral line mechanosensory nerves in jawed fish distribute information to first-order nuclei in the medulla and to areas within the cerebellum. As is the case in other vertebrates, the first-order auditory and lateral line medullary nuclei each form the beginning of a multi-component, ascending central circuit that includes additional processing areas in the medulla, as well as processing areas in the midbrain, diencephalon, and telencephalon (**Figures 1(a)–1(c)**). **Figure 2** summarizes the connections among the main components of the two ascending circuits.

The inner ear auditory and the lateral line mechanosensory systems give rise to largely separate central circuits that are similarly organized (**Figure 2**). Nuclei that receive inputs from both the sensory systems, however, are present at most levels of the brain. Remarkably, the central auditory pathways of jawed fishes and land vertebrates share a common organizational pattern (**Figure 2**) despite the evolution of nonhomologous peripheral auditory organs and, at some or all levels of the brain, auditory nuclei. The auditory pathway of the most primitive jawed fishes may have formed the substrate from which those of later radiations of fish and land vertebrates evolved. An alternative hypothesis is that the auditory pathways of different taxa follow a basal organization plan shared by the auditory and lateral line systems.

In addition to providing input to nuclei in the medulla, other connections of the two sensory systems, which are not described further, include direct inputs to granule cell

Central Anatomy of the Auditory and Mechanosensory Lateral Line Systems

First- and Higher-Order Nuclei That Project to the Midbrain Torus Semicircularis/Lateral Mesencephalic Complex

In fish, as in other vertebrates, nuclei that receive direct input from auditory fibers of the octaval nerve and from the lateral line nerves are located in the medulla oblongata (**Figures 1(b)**, **1(c)**, **2**, and **3**). Some of the neurons within these nuclei project to acoustic and lateral line regions in the midbrain torus semicircularis (TS) (bony fish)/lateral mesencephalic complex (LMC; cartilaginous fish). This connection is analogous to that from the mammalian cochlear nuclei to the inferior colliculus. In fish, axons from first-order populations course bilaterally within the lateral lemniscus to the midbrain and are joined by axons from second- or higher-order nuclei (**Figure 2**).

Octaval nuclei

Of the four, or five in the case of teleosts, nuclei that receive direct input from the octaval nerve, only the descending octaval (DO) and anterior octaval (AO) nuclei are known to process acoustic information and project to

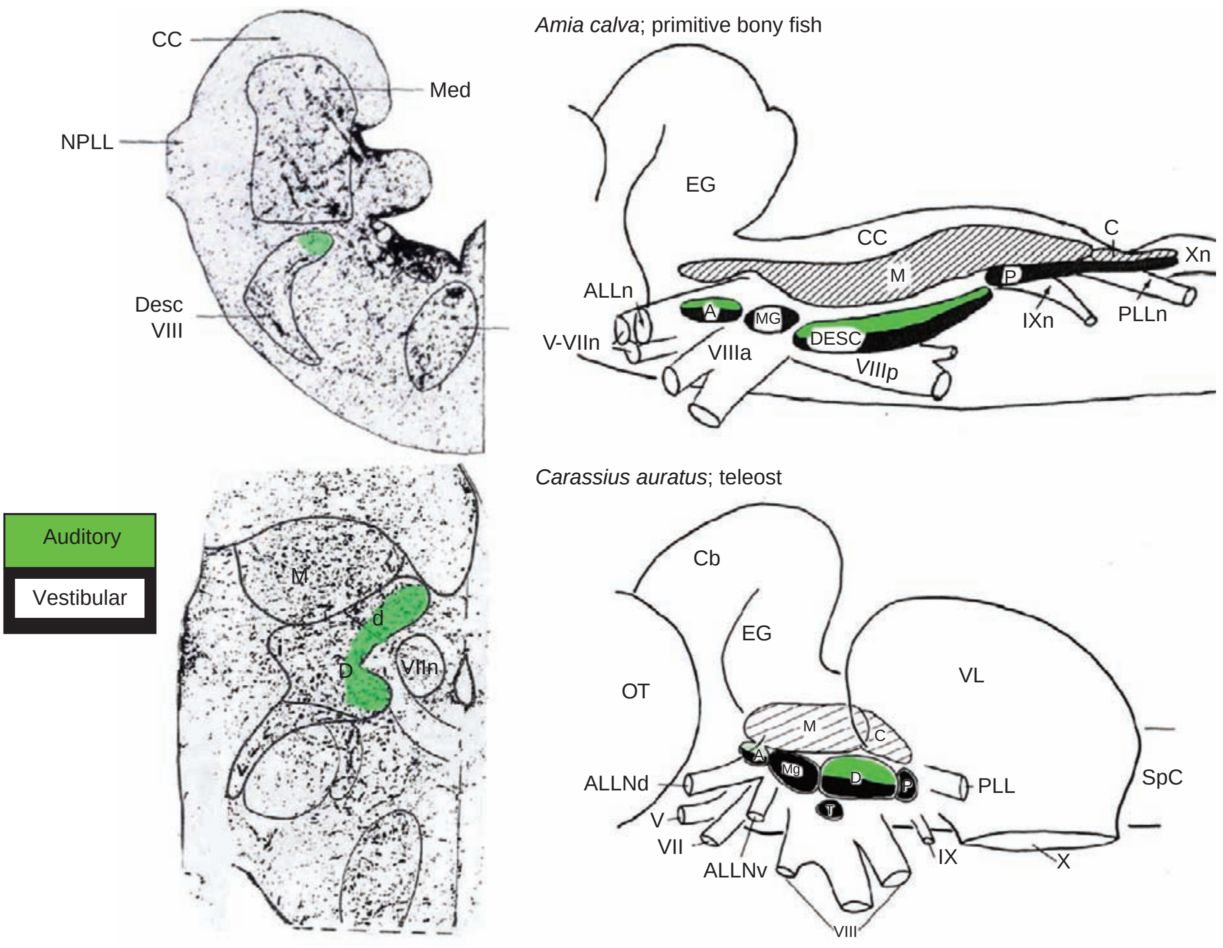

Figure 3 Right: Lateral views of the hindbrain of *Amia calva* (bowfin; top) and *Carassius auratus* (goldfish; bottom) schematically illustrate the locations of lateral line mechanosensory nuclei (diagonal lines), acoustic octaval areas (green), and vestibular octaval areas (black). Left: Transverse, cresyl violet-stained hemisections through the medulla of *Amia calva* (bowfin; top) and *Carassius auratus* (goldfish; bottom). In each species, green delineates the known acoustic region in the descending octaval nucleus. Abbreviations: A, anterior octaval nucleus; ALLn, anterior lateral line nerve; ALLNd, dorsal ramus of anterior lateral line nerve; ALLNv, ventral ramus of anterior lateral line nerve; C, nucleus caudalis; CC, cerebellar crest; D/Desc VIII, descending octaval nucleus; EG, eminentia granularis of cerebellum; IXn, glossopharyngeal nerve; MG, magnocellular octaval nucleus; M/Med, nucleus medialis; NPLL, posterior lateral line nerve; OT, optic tectum; P, posterior octaval nucleus; PLL, posterior lateral line; PLLn, posterior lateral line nerve; SpC, spinal cord; V-VIIn, trigeminal and facial nerves; VIIIa, anterior ramus of octaval nerve; VIIIp, posterior ramus of octaval nerve; and Xn, vagus nerve.

the auditory midbrain (**Figures 1(c)**, **2**, and **3**). However, neither of these nuclei are dedicated to auditory processing as each of them also has areas that receive input from vestibular organs and that have further connections to structures other than the auditory midbrain. Furthermore, it is possible that not all acoustic populations within the octaval nuclei have been discovered. Generally, octaval nerve inputs to DO and AO are ipsilateral, although in some species the octaval nerve distributes to the DO on both sides of the brain (bilaterally). The DO has commissural connections to the contralateral DO. Commissural connections are common throughout the auditory brain, as is the case in other vertebrates. For further discussion on the fish vestibular system, **see also Hearing and Lateral Line:** Vestibular System Anatomy and Physiology.

The largest first-order acoustic population resides in the dorsomedial (dm) zone of the DO (**Figures 4** and **5**). Fibers from the inner ear to the DO are distributed similarly in cartilaginous fish and most bony fish; therefore, this distribution pattern is hypothesized to reflect the primitive condition for jawed vertebrates. Inputs from the saccule, which is believed to be a prominent auditory organ in most fish species, usually provide the majority of input to DO dm zone (**Figure 4**). Fibers from the lagena and utricle overlap saccular inputs at some levels, but are largely laterally or ventrolaterally adjacent to DO dm zone (**Figure 4**). In the goldfish, some of the lagenar and utricular fibers in these adjacent areas contact long lateral dendrites of DO dm neurons, lending additional support to physiological studies that indicate auditory function in all three of the otolith organs. Based on a single cartilaginous and two bony fish species, the macula neglecta terminates largely ventral to dm zone and overlaps inputs from the utricle and posterior semicircular canal crista.

Otolith organ inputs to DO are specialized in clupeid fishes, which include taxa such as shad and herring. The clupeid utricle has a specialized acoustic pressure reception area and it is the utricle, rather than the saccule, that provides the main input to DO dm zone (**Figure 4**). The unrelated sleeper goby potentially illustrates another exception to the typical pattern of otolith inputs; in this species, otolith fibers appear to interdigitate within the dorsal descending nucleus. For additional information on this species, **see also Hearing and Lateral Line:** Physiology of the Ear and Brain: How Fish Hear.

Among fish species, there is a morphological variation in the size of dm area relative to the DO as a whole and in the relationship of dm to the cerebellar crest (CC) (**Figures 1(a)**, **1(b)**, and **5**). Species with the qualitatively largest dm zones have otophysic connections, that is, structural linkage between the inner ear and the swimbladder or other gas-filled structure. Some DO dm cells, especially in those species in which dm zone is particularly large, very likely receive descending input from CC axons. These axons, which originate largely from granule cells in the cerebellum, are known to modulate neuronal activity in the nucleus medialis (M) and may similarly

In each species, green delineates the acoustic region in the descending octaval nucleus. Bottom: Each of the diagrams corresponds to the species above it, showing the locations of neurons in the descending octaval nucleus that receive input from the saccule and project to the acoustic midbrain. The relationship of these auditory output neurons to the cerebellar crest (orange) is also shown. Abbreviations: CC, cerebellar crest; D/Desc VIII, descending octaval nucleus; d, dorsomedial zone of descending octaval nucleus; i, intermediate zone of descending octaval nucleus; M, nucleus medialis; v, ventral zone of descending octaval nucleus; and VIIn, sensory root of the facial nerve.

affect DO dm neurons. CC axons originating from a midbrain acoustic structure (the medial pretoral nucleus, MPT) may also supply DO dm zone in some species. It is possible that the CC provides little or no input to DO dm zone in species in which this zone is small.

Primitively, the dorsal portion of the AO was also acoustic, although this may not be the case in all jawed fish. Fibers from the three otolith organs usually have a distribution pattern similar to that present in the DO. The AO in clupeids has specialized anatomy and inner ear inputs.

In cartilaginous fish, the periventricular nucleus and cell plate C3 receive input from the inner ear and thus potentially receive acoustic input. These structures do not appear to be present in bony fish.

Lateral line nuclei

The lateral line nerves distribute mechanosensory input to a small nucleus caudalis and a much larger nucleus M (**Figures 1–3**). Ascending projections to the midbrain arise only from M and mainly distribute adjacent to the acoustic midbrain area.

M, which is cytoarchitecturally complex, is capped by CC axons that provide a modulatory input to at least the most dorsally located M neurons (**Figure 3**). Terminals of lateral line nerves do not appear to reach these dorsal cells, but may synapse on their ventral dendrites in addition to neurons in other areas of M. Within M, mechanosensory input carried by the posterior lateral line nerve distributes dorsally/dorsolaterally, whereas anterior lateral line fibers from cephalic mechanoreceptors distribute ventrally/ventrolaterally. M gives rise to commissural fibers that supply its contralateral counterpart, and, in addition to its major input to the midbrain lateral line area, other connections that have been reported in individual species include output to the sensory trigeminal nucleus and various octaval nuclei and input from the ipsilateral sensory trigeminal nucleus.

Cross-talk between the auditory and lateral line systems

The vast majority of fibers from inner ear auditory organs and lateral line nerves provide input exclusively to octaval and lateral line nuclei, respectively. However, smaller inputs from the inner ear to M and from the lateral line to the DO dm zone are reported in many species. Each nucleus may therefore contain areas integrating acoustic and lateral line mechanosensory information. Anatomical overlap between the two sensory systems is also present in the isthmus, midbrain, and forebrain. The functional significance of cross-talk between the two systems is not understood and may vary among species. Possibilities include sensory integration supporting sound localization, as well as the specialization of lateral line receptors that are proximate to the inner ear for sound pressure detection.

Higher-order acoustic and/or lateral line nuclei

In bony fish, the secondary octaval (SO) nucleus (**Figure 1(c)**) receives bilateral input from the DO and projects bilaterally to the auditory midbrain (**Figure 2**). The SO has up to three regions with different neuronal morphologies: dorsal, intermediate, and ventral (**Figure 6**). The dorsal and ventral regions may be universally present in teleosts; three regions are usually present in teleosts with otophysic connections. In carp and goldfish, dorsal SO neurons receive descending input from a midbrain auditory area via axons traveling in the CC. An area within SO participates in the vocal circuitry in a teleost, the midshipman *Porichthyes*. For further discussion on this topic, **see also Hearing and Lateral Line:** Vocal Behavior of Fishes: Anatomy and Physiology.

The isthmoreticular (IR) and perilemniscular (PL) nuclei both project to the auditory midbrain (**Figure 2**). The connections of IR and PL are relatively unstudied, but in goldfish PL supplies an auditory diencephalic area – the anterior preglomerular nucleus. Cell groups referred to in various studies as PL, perilemniscal, and paralemniscal may or may not be comparable. In the midshipman paralemniscal neurons project bilaterally to the lateral line area of the midbrain.

Nucleus praeeminentialis (P) receives bilateral input from M and in some species is also known to project to M. Dense input to P from the auditory midbrain was recently demonstrated in the midshipman; this may be a unique connection.

In cartilaginous fish, cell plates C1, C2, and C3 and the nucleus of the lateral lemniscus are mainly higher-order populations (C3 also receives first-order input) that process information from the acoustic or lateral line systems, or from both. It is unknown whether or not any of these populations are homologous to any nuclei in bony fish.

Acoustic and Lateral Line Mechanosensory Areas in the Midbrain TS/LMC

The TS of bony fish (**Figures 1(c)** and **7**) and the LMC of cartilaginous fish are the presumed homologs of the mammalian inferior colliculus. Acoustic-processing areas are adjacent to lateral line mechanosensory areas. The TS of bony fish is known primarily from studies in teleosts and includes an auditory portion – nucleus centralis (NC) – and a lateral line mechanosensory portion – nucleus ventrolateralis (VL) (**Figure 7**). As at lower levels of the brain, anatomical and physiological studies indicate some overlap of the two sensory systems. In certain bony fish species, the boundary between NC and VL is readily apparent only as a result of tract-tracing or via electrophysiological recording. Similarly, the LMC of cartilaginous fish has clearer subdivisions in some species than in others. The LMC includes a lateral line mechanosensory mediodorsal nucleus and a medioventral nucleus that is thought to be acoustic. Relatively, little is known about the connections of the LMC compared with those of the bony fish TS.

In bony fish, NC receives auditory ascending input – much of it bilateral – from the DO dm, AO, SO, IR, and PL (**Figure 2**). The ascending outputs of the NC course

to diencephalic nuclei (**Figure 2**) that are generally considered to be auditory; many of these nuclei have descending projections to NC. Some species also have an MPT that receives input from NC. In addition, NC projects to the deep, multisensory layers of the optic tectum and to lower-level acoustic populations in the medulla. Additional connections of NC that may be species specific have been reported.

The VL is the lateral line processing toral area (**Figure 7**). M provides the major ascending input into VL (**Figure 2**); in some species, it may also receive input from other structures at lower levels of the brain, such as the paralemniscal neurons. VL also has reciprocal connections with the optic tectum, primarily its deep layers, and projects ipsilaterally to P.

Acoustic and Lateral Line Mechanosensory Areas of the Forebrain

Forebrain acoustic and lateral line areas have been systematically studied in few species of bony fish. Nonparallel terminology makes species comparisons across the literature daunting. Interestingly, a comparative study of various otophysan species suggests many connectional variations. The following information is drawn primarily from the most recent publications describing forebrain connections in two distantly related teleost groups: the otophysans goldfish (*Carassius*) and carp (*Cyprinus*) and the batrachoidid midshipman. Only major connections are described.

In goldfish (*Carassius*), carp, and midshipman, three areas in the diencephalon are associated with the auditory system, the lateral line mechanosensory system, or both: subdivisions within the preglomerular complex (PG), the central posterior nucleus (CP), and the anterior tuber/tuberal nucleus (AT) of the hypothalamus (**Figure 1(c)**). The posterior thalamic nucleus (PTH) in midshipman may have unique lateral line inputs.

In goldfish and carp, the PG, CP, and AT project to or receive input from specific pallial and subpallial telencephalic areas (**Figures 1(c)** and **2**): the medial division of area dorsalis of the pallium (Dm), the lateral division of area dorsalis of the pallium (Dl), and, within the subpallium, area ventralis dorsal nucleus (Vd), area ventralis ventral nucleus (Vv), and area ventralis supracommissural nucleus (Vs). Based on overall patterns of connectivity, there are two major hypotheses about how Dm and Dl can be compared to regions of the tetrapod pallium. One view holds that Dm and Dl are similar to the tetrapod amygdala and hippocampus, respectively. An alternative view is that Dm and Dl are homologous to isocortical areas.

Connections of preglomerular complex

The PG (**Figure 1(c)**) is composed of several divisions, some of which are further parsed into subnuclei. Two recent studies recognize nucleus preglomerularis anterior (PGa) as an auditory area, but apply slightly different nomenclature to auditory and lateral line regions within nucleus preglomerularis lateralis (PGl).

The strong connections of the NC to the PGa and to the caudal subnucleus of the nucleus preglomerularis lateralis (cPGl; nomenclature of Northcutt), and the connections of PGa and cPGl to the Dm likely comprise the major ascending auditory pathway into the pallium (**Figure 2**). Comparative studies suggest that acoustic processing in Dm may be characteristic of all bony fish. While Dm also receives inputs from the lateral line (including electrosensory input, when present) and gustatory systems, there is evidence suggesting that Dm includes modality-specific subregions.

The PGl-v (ventral part of the rostral subnucleus of nucleus preglomerularis lateralis; nomenclature of Northcutt) receives lateral line input from VL and AT, and presumably visual input from the optic tectum. Terminal zones of rPGl-v axons distribute in Dm and Dl.

Connections of central posterior nucleus

The CP (**Figures 1(c)** and **2**) is reciprocally connected to NC and VL. It is also connected to other forebrain areas that receive auditory and lateral line inputs. CP has a major ascending output to the subpallium (**Figure 1(c)**) – Vd, Vv, and Vs – and a rather minor output to the pallium – Dm.

Connections of anterior tuber of the hypothalamus

The hypothalamus (**Figures 1(b)**, **1(c)**, and **2**) gets input from NC, and in at least some species from VL. In all/most species, auditory and lateral line inputs distribute to a nucleus or region in the AT. In goldfish, AT receives inputs from two other acoustic structures, MPT and PGa, as well as from the suprachiasmatic nucleus. AT projects to a region of the PG – the rPGl-v; the latter nucleus projects to Dm and Dl. Dm gives rise to a strong projection back to AT.

Summary

The similarity of central lateral line and acoustic pathways in fish may be the result of common developmental processes, or rules that organize the location and connectivity of the central components of the two sensory systems. It can be hypothesized that shared developmental processes among fishes and between fish and land vertebrates may underlie the fundamentally similar organization of the acoustic pathways in all vertebrates, despite striking differences in the identity of peripheral auditory receptors and in the anatomical details of central auditory populations.

Glossary

Auditory plasticity The ability of the auditory system to make structural and functional changes.

Auditory transduction The transformation of acoustic stimuli into electrical signals by sensory hair cells in the ear.

Coefficient of synchronization A parameter to describe the strength of phase locking of a neuron, ranging from 0 (random firing) to 1 (perfect phase locking).

Inter-spike interval histogram A histogram of the distribution of inter-spike intervals in time, showing the temporal response pattern of a neuron.

Octavolateral efferent The process of a neuron in the brain that projects to octavolateral organs such as the inner ear and lateral line; this output from the brain alters the sensitivity and thus regulates octavolateral inputs to the brain.

Otolithic afferent The process of a ganglion neuron that conveys the sensory input from an otolithic organ (the lagena, saccule, or utricle) to the brain.

Period histogram A histogram of the distribution of spike rates over the stimulus period. A peak in the period histogram indicates phase locking, whereas no peak indicates a random response.

Peri-stimulus time histogram A histogram of the spike rate over the stimulus duration, showing the temporal response pattern of a neuron. It is also called a post-stimulus time histogram.

Phase locking A temporal response feature of a neuron that fires spikes at the same phase per cycle of a pure tone.

$Q_{10\ \mathrm{dB}}$ A ratio of the characteristic frequency over the frequency bandwidth at 10 dB above the lowest threshold; it represents the sharpness of a tuning curve.

Rate-level function A plot of the spike rate vs. the stimulus level of a neuron that is used to reveal the neural coding of stimulus intensity.

Threshold The lowest stimulus level that evokes neural activity.

Torus semicircularis A major octavolateral nucleus in the midbrain of fishes.

Tuning curve A plot of the threshold vs. the stimulus frequency for a single neuron, showing its characteristic frequency (the most sensitive frequency), the best sensitivity (the lowest threshold), and its sharpness of tuning ($Q_{10\ \mathrm{dB}}$).

Introduction

Hearing is an important sense in fishes. The fish ear contains three otolithic organs (the saccule, utricle, and lagena), and these play a key role in the ability of fishes to hear and maintain balance. In the majority of fishes that have been examined, the saccule is considered the major auditory organ, whereas the lagena and utricle may play a minor role in hearing. The otolithic organ of fishes is a fluid-filled sac composed of a sensory epithelium attached to a calcareous otolith via an otolithic membrane (**Figure 1**) (**see also Hearing and Lateral Line**: Auditory System Morphology).

The sensory epithelium has many sensory hair cells, each of which has an eccentrically placed kinocilium and a cluster of stereocilia. The height of stereocilia decreases as the distance they are located from the kinocilium increases. Thus, each hair cell is morphologically polarized. Hair cells in otolithic organs are innervated by otolithic ganglion neurons, and these ganglion neurons convey auditory and vestibular inputs to the brain for central processing (**see also Hearing and Lateral Line**: Auditory/Lateral Line CNS: Anatomy). In addition, the brain has octavolateral efferent neurons that receive sensory inputs and project to octavolateral organs such as the ear and the lateral line. The octavolateral system in fishes includes octavolateral organs as well as octavolateral nuclei in the brain.

The ear functions in hearing and balance; the lateral line system mainly detects net water movement over the fish body (**see also Hearing and Lateral Line**: Lateral Line Neuroethology). Very few studies have

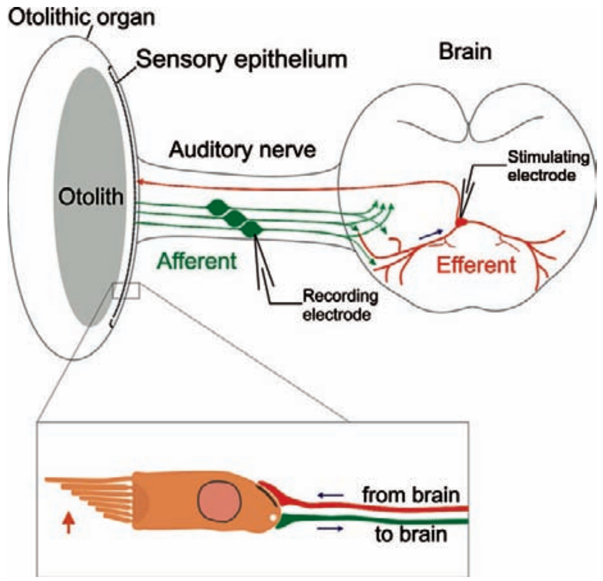

Figure 1 A schematic drawing of the auditory system of fishes, showing an otolithic organ that is innervated by auditory ganglion neurons (green) and an octavolateral efferent neuron (red). Auditory afferents send encoded acoustic information to the brain whereas the auditory efferent projects to hair cells in the otolithic organ. A metal electrode is used to stimulate the octavolateral efferent neuron in the brain while acoustically evoked neural responses from an auditory ganglion neuron are recorded by a microelectrode. The enlargement of the sensory epithelium shows a sensory hair cell with its morphological and functional polarization indicated by the arrow near the ciliary bundle. Adapted from Tomchik SM and Lu Z (2004) Morphology and physiology of otolithic organ efferents. *Society for Neuroscience* Abstract 530.4.

been conducted on auditory physiology of major fish groups, such as lampreys, sharks, and sturgeons, that have a sensory epithelium or otolithic organs and are most likely able to detect the particle motion mode of sound. This article focuses primarily on the physiology of the auditory portion of the octavolateral system in teleost fishes including the sensory hair cells, auditory afferents, major auditory nuclei in the brain, and auditory efferents.

Auditory Transduction

The first step of auditory processing in fishes is auditory transduction, the transformation of acoustic energy into an electrical signal, such as a receptor potential, by sensory hair cells in the ear. When a sound wave reaches an otolithic organ, it sets the otolithic organ in motion. Due to a significant difference in tissue density between the sensory epithelium and otolith, the epithelium tends to move along with the sound wave while the otolith tends to remain at rest (**see also Hearing and Lateral Line**: Auditory System Morphology, Biomechanics of the Inner Ear in Fishes). This relative movement between the sensory epithelium and otolith generates a shearing force that bends the ciliary bundles of hair cells.

When hair cell ciliary bundles are bent from the stereocilia toward the kinocilium, hair cells are activated via the depolarization of their cell membranes. However, when the ciliary bundles are bent in the opposite direction, hair cells are inhibited via hyperpolarization of their cell membranes. Therefore, sensory hair cells in the inner ear of fishes are functionally, as well as morphologically, polarized. When hair cells are activated, they release a chemical called a neurotransmitter. The neurotransmitter binds to its receptor in the membrane of the otolithic ganglion neurons, leading to depolarization of the neuron. If the depolarization reaches a certain membrane potential, the neuron fires action potentials (also called spikes). The spikes travel along afferents of the auditory ganglion neurons to convey encoded acoustic information to the brain for central processing.

Afferent Coding of Sounds

Intensity Coding

Sound intensity (level) is an important physical property of sound. How do fishes tell a loud sound from a weak one? First, look at how individual auditory afferents respond to sounds at different sound levels. The relationship between neural activity and sound level can be explained using a rate-level function. As shown in **Figure 2**, auditory afferents do not fire spikes when the sound level is too low, but do begin to fire spikes as sound intensity reaches a certain level called the threshold, which is defined as the lowest sound level that can evoke a neural response. Above threshold, the firing rate increases with sound level until the maximum firing rate is reached. The sound intensity corresponding to the

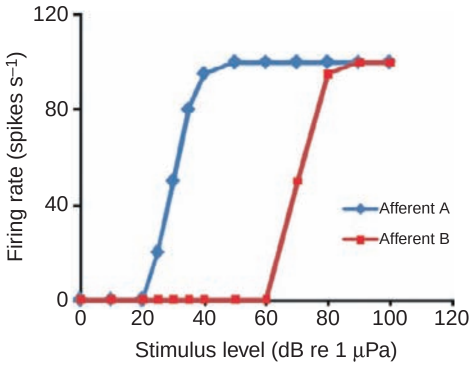

Figure 2 Schematic drawings of rate-level functions of two auditory afferents (A and B) with different thresholds and saturation levels. Firing rates of each auditory afferent increase monotonically with stimulus level in a range between threshold and saturation.

maximum firing rate is called the saturation level. Auditory afferents are unable to increase their firing rate beyond the saturation level. Within the linear portion of a rate-level function between threshold and saturation, neural firing rate is correlated with sound level. Therefore, sound intensity is encoded in the firing rate by auditory afferents. This firing rate is sent to the fish brain for processing to extract the sound intensity information.

Each fish otolithic organ nerve (the saccular nerve) is a collection of afferents and efferents (**Figure 1**). Afferents are sensory fibers that convey inputs from the otolithic organs to the brain, whereas efferents are motor fibers from the brain that project to the otolithic organs. Auditory thresholds vary remarkably among individual auditory afferents. For example, afferent A in **Figure 2** is more sensitive than afferent B because afferent A has a lower threshold (i.e., 20 dB re 1 μPa) than afferent B (60 dB re 1 μPa). Afferent A is useful for encoding sound intensity between 20 and 40 dB re 1 μPa, whereas afferent B is good for encoding sound between 60 and 80 dB re 1 μPa. In other words, individual auditory afferents of fishes often have a hearing dynamic range of about 20 dB. By pooling all auditory afferents together, the auditory nerve is capable of encoding sound levels over a 100-dB range. The sum of the properties of all auditory afferents accounts for the ability of fishes to detect sound intensity (**see also Hearing and Lateral Line**: Psychoacoustics: What Fish Hear).

Frequency Coding

Sound frequency provides animals with information about the nature of a sound source, such as a prey or a predator. Frequency analysis is one of the important functions of the auditory systems in animals. Compared with terrestrial vertebrates, fishes possess a primitive ability to analyze sound frequency.

Any natural sound in the world is a complex sound, which is a sum of many simple sounds (i.e., pure tones). Frequency selectivity of auditory afferents has been studied most thoroughly in teleost fishes such as the goldfish (*Carassius auratus*) and oyster toadfish (*Opsanus tau*). The frequency selectivity of single auditory afferents can be illustrated with a tuning curve. A tuning curve is a plot of thresholds at different sound frequencies (**Figure 3**). Three parameters from a tuning curve are used to describe frequency-response properties of auditory afferents. The best sensitivity (BS) refers to the lowest of thresholds at sound frequencies tested, which indicates how sensitive an auditory afferent is – the lower the BS, the higher the sensitivity of an auditory afferent. The characteristic frequency (CF) of an auditory afferent is the stimulus frequency at BS. $Q_{10\ \mathrm{dB}}$ is defined as CF over the frequency bandwidth at 10 dB above BS and reveals the sharpness of tuning of an auditory afferent.

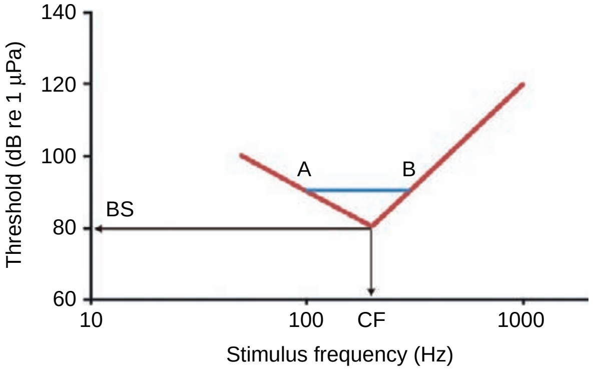

Figure 3 Schematic drawing of a tuning curve of an auditory afferent. BS = 80 dB re 1 μPa. $Q_{10\ \mathrm{dB}}$ = CF/FBW = 1, where CF = 200 Hz and FBW = 200 Hz. FBW is the frequency bandwidth at 10 dB above the BS, which is indicated by the length of AB.

In general, compared with terrestrial vertebrates, auditory afferents of fishes are broadly tuned to relatively low frequencies up to several hundred hertz. It is known that tonotopic organizations (also called tonotopy) are present in most nonfish vertebrates. Tonotopy refers to the spatial representation of sound frequencies in a structure of the auditory system such as the basilar membrane of the cochlea (the hearing organ) in mammals. Auditory afferents innervating hair cells in the basilar membrane are tuned to specific frequencies that correspond to the resonant frequencies of the basilar membrane at the innervating sites. Tonotopy has not been well investigated in fishes. Although some studies provided evidence of a crude tonotopic organization in the goldfish saccule as well as the carp's midbrain, the existence of tonotopy needs to be verified in other fish species.

Temporal Coding

A sound wave is often plotted in time domain (i.e., a function of displacement of medium molecules over time). Temporal coding refers to a neural coding that is based on the timing of spikes, or intervals between spikes. For example, fish auditory afferents are capable of firing spikes that are locked at a certain phase of the cycle of a pure tone; this is called phase locking. Temporal response properties of auditory afferents can be illustrated using the peri-stimulus time histogram (PSTH), inter-spike interval histogram (ISIH), and period histogram (**Figure 4**). PSTH is a histogram of spike times over the duration of a sound presentation. The spike time is the time interval between the beginning of the stimulus and the time at which a spike occurs. Fish auditory afferents often have a sustained temporal response pattern with little adaptation (see the PSTH in **Figure 4**).

Fish auditory afferents tend to phase-lock to tonal stimulation, showing many peaks with a regular inter-peak

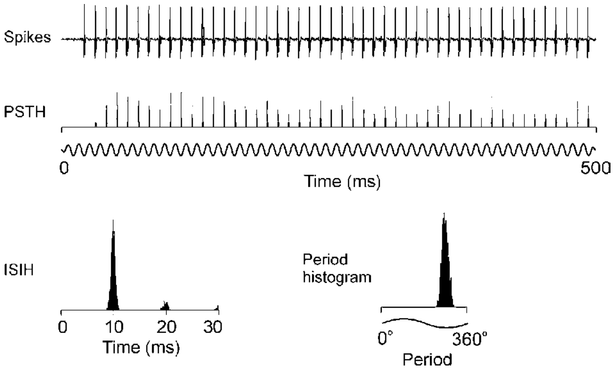

Figure 4 Phase-locking response pattern of an auditory afferent to a 500-ms pure tone at 100 Hz, showing a sweep of spikes, peri-stimulus-time histogram (PSTH), inter-spike interval histogram (ISIH), and period histogram. The histograms were constructed from neural responses of the auditory afferent to 50 presentations of the tone. Modified from Lu Z, Xu Z, and Buchser WJ (2003) Acoustic response properties of lagenar nerve fibers in the sleeper goby, *Dormitator latifrons*. *Journal of Comparative Physiology A* 189: 889–905.

interval over the sound duration in the PSTH. The distribution of time intervals between spikes can be illustrated using the ISIH. For example, in the ISIH shown in **Figure 4**, the major peak occurs at 10 ms, corresponding to the period of the 100-Hz pure tone used. In other words, the information of sound frequency is encoded in the temporal pattern of spikes, the inter-spike interval. The small peak at 20 ms in the figure indicates that the afferent sometimes fired one spike every two stimulus periods. The phase-locking feature of auditory afferents is often displayed with the period histogram, which illustrates the spike time distribution over the stimulus period (see **Figure 4**). A peak in the period histogram indicates that the afferent is locked around a certain phase. The strength of phase locking of auditory afferents can be assessed with the coefficient of synchronization, *R*. *R* ranges from 0 (no phase locking, a flat distribution of spike times in the period histogram) to 1 (perfect phase locking, a vertical line at a phase of the stimulus cycle).

There are several temporal response characteristics of auditory afferents in fishes. Most otolithic afferents are phase locked to tonal stimulation, and the strength of phase locking varies with stimulus level and frequency. Above threshold, phase locking increases with stimulus level until saturation (1 spike every stimulus cycle). At a given stimulus level, phase locking decreases as stimulus frequency moves away from CF. Some auditory afferents of fishes are capable of firing two spikes per stimulus cycle, particularly at stimulus frequencies that are equal or less than 100 Hz. The ISIH of this response pattern shows a major peak at half the stimulus period, and the period histogram has two peaks that are separated by 180°. This double phase locking appears to result from the fact that an auditory ganglion neuron may innervate two hair cell groups that are oriented in opposing directions from one another.

Auditory Plasticity

Auditory plasticity refers to the ability of the auditory system to make structural and functional changes. It is another common feature shared by all vertebrates. Although auditory plasticity has not been thoroughly investigated in fishes, a few studies have demonstrated changes in hearing sensitivity during the development. For example, the auditory sensitivity of juvenile plainfin midshipman fish (*Porichthys notatus*) is about 10–15 dB lower than that of adults. An increase in auditory sensitivity during the development has also been shown in the bicolor damselfish (*Pomacentrus partitus*).

Auditory plasticity can also occur in adulthood. The frequency response of saccular afferents of adult female midshipman varies with seasonal reproductive activity. Specifically, saccular afferents are tuned to higher frequencies in gravid females during the summer than in nonreproductive females during the winter (**see also Hearing and Lateral Line**: Vocal Behavior of Fishes: Anatomy and Physiology). In the summer, midshipman males swim to the shallow water of intertidal zones to build nests and vocalize to attract conspecific females. The advertisement call of males is a sound with multiple frequency components. The fundamental frequency of the midshipman's advertisement call is about 100 Hz, and the second harmonic, 200 Hz, is the most dominant frequency of the mating call. Saccular afferents of summer gravid females are more broadly responsive to the second and third harmonics of the advertisement call, than those of nonreproductive and winter adult midshipman females. This indicates that summer reproductive females are better fit to encode the male's mating call than winter adult females and nonreproductive juveniles. There is strong evidence that this auditory plasticity in the plainfin midshipman fish is mediated by sex hormones.

Central Representation of Sounds

Frequency Tuning

As described above, fish auditory afferents have crude frequency selectivity, that is, they are quite broadly tuned. How is the information of stimulus frequency processed in the brain? Data of frequency selectivity have been collected from the torus semicircularis (a major octavolateral nucleus in the midbrain) and the central posterior nucleus (a major auditory nucleus in the diencephalon) of the goldfish (**see also Brain and Nervous System**: Functional Morphology of the Brains of Ray-Finned Fishes and **Hearing and Lateral Line**:

Auditory/Lateral Line CNS: Anatomy). The $Q_{10\ \mathrm{dB}}$ of auditory neurons in the torus semicircularis is significantly higher than that of saccular afferents, whereas the $Q_{10\ \mathrm{dB}}$ of auditory neurons in the central posterior nucleus is similar to that of saccular afferents. These results indicate that frequency tuning is sharpened at the midbrain, and becomes broad again at the diencephalon. The enhanced tuning at the midbrain is most likely due to a unique inhibitory process in the brain. Evidence has shown that inhibitory side bands appear to sharpen frequency tuning at the level of hindbrain or midbrain. However, the strength of frequency tuning does not continue to increase at higher levels of the brain. It is hypothesized that the auditory midbrain and diencephalon play different roles in frequency analysis. The auditory midbrain contributes to analytic listening (i.e., breakdown of a complex sound into simple components); the auditory diencephalon plays an important role in synthetic listening (i.e., integration of sound components).

Temporal Response Patterns

In contrast to the sustained temporal response pattern with phase locking observed in auditory afferents, various temporal response patterns have been found for auditory neurons in the brain. They include onset, bursting, chopper, pauser, and buildup, which resemble those observed in the mammalian cochlear nucleus. These temporal response patterns have not been observed in auditory afferents, suggesting that they are response patterns unique to the brain. Although phase locking, even strong phase locking, is found in the brain, the percentage of phase-locked auditory neurons tends to decrease along the auditory pathway from the periphery to the brain. It appears that strong phase locking at the auditory periphery is converted into distinctive temporal responses with little phase locking in the brain.

Transformation from the Peripheral Code to a Central Code

Central auditory processing of natural sounds has been reported in several teleosts. For example, the waveform of the advertisement call (or hum) of male plainfin midshipman fish is similar to a 100-Hz pure tone. Like those of other teleosts, saccular afferents of the midshipman are phase locked to fine tonal structures of the mating call. Once this phase-locking information is conveyed to the brain, the brain transforms the peripheral phase-locking code into a new central code. Experimental results indicate that auditory neurons in the torus semicircularis of the midshipman do not show strong phase locking to individual tonal components of the male advertisement call. Instead, they are responsive to the frequency difference of concurrent hums. In the fish natural habitat, males with nests are located not far from one another. Thus, the sound received by a midshipman female is frequently a concurrent signal that is composed of two or more hums. The concurrent signal is often a beat because frequencies of two hums differ by only a few hertz. Auditory midbrain neurons of midshipman females are able to encode the frequency of the beat. Therefore, the peripheral phase-locking code is transformed into a beat frequency code in the fish midbrain.

Another example of central auditory processing of natural sounds involves the mormyrid fish (*Pollimyrus adspersus*), a weakly electric fish that also uses sound in communication. It has been documented that mormyrid males produce sounds such as grunts, moans, and growls to court conspecific females. These courtship sounds consist of click trains with inter-click intervals ranging from 5 to 50 ms. Auditory afferents of the mormyrids fire spikes that are time-locked to individual clicks but show no significant relationship to any inter-click intervals. This time-locked information at the auditory periphery is converted into a new code in the brain that enables the fish to extract temporal information of clicks of courtship sounds. Evidence shows that auditory neurons in the midbrain of this species are selectively responsive to the inter-click intervals that are consistent with those of courtship sounds. Therefore, temporal features of the courtship sounds are extracted in the midbrain of the mormyrid fish.

Role of Octavolateral Efferents

Like other vertebrates, fishes have an auditory system that consists of both afferent and efferent pathways as illustrated in **Figure 1**. In addition to the afferent pathway, octavolateral efferent neurons in the brain innervate auditory, vestibular, and lateral line organs to regulate their responses. Although the octavolateral efferent system has not been well investigated in fishes, results of some recent studies shed new light on the structure and function of the system. There are up to three octavolateral efferent nuclei in the brain of fishes, depending on the species. For example, the sleeper goby (*Dormitator latifrons*) has a single efferent nucleus that is centered on the midline of the medulla and is composed of 13–29 densely packed cell bodies. Each efferent neuron has bilateral processes that are thought to receive multiple sensory inputs such as auditory, vestibular, visual, somatosensory, and lateral line. Efferent fibers form several branches to project to multiple octavolateral organs including otolithic organs, vestibular ampullae, and lateral line neuromasts.

Compared with auditory afferents, octavolateral efferents have distinctive response properties. First, octavolateral efferents have higher spontaneous activity than otolithic afferents. Second, they are not phase locked to tonal stimulation. Third, all octavolateral efferents have low-pass tuning curves with CFs lower than 20 Hz. Fourth, octavolateral efferents have shallow rate-level functions without saturation up to 50 dB above threshold. Finally, they are omnidirectionally sensitive to sounds whereas most otolithic afferents are directionally selective.

How does efferent activation affect afferent responses from octavolateral organs in fishes? Early studies showed that (1) efferents that synapse on hair cells in auditory and lateral line organs tend to inhibit spontaneous and evoked activity of afferents and (2) efferents that go to vestibular organs or synapse on afferent terminals in auditory organs appear to have primarily excitatory or mixed effects on the afferent responses. The results of a recent study on the sleeper goby show that efferent stimulation inhibits the response of auditory afferents to a tone by reducing the signal-to-noise ratio in quiet conditions. However, when masking noise is added, efferent stimulation can increase the signal-to-noise ratio of auditory afferent responses. These results indicate that efferent feedback can help fishes extract a sound from a noisy environment.

Summary

Fishes possess an auditory system that enables them to process fundamental information of sound. The fish auditory system is part of the octavolateral system that plays an important role in hearing, balance, and detection of water movement. For fish hearing, sensory hair cells in the otolithic organs transduce sounds into spikes, and otolithic organ afferents convey spikes to auditory nuclei in the brain where spikes are analyzed to extract the information of sound such as intensity and frequency. At the auditory periphery, sound intensity is encoded in the spike rate whereas sound frequency is encoded primarily in the inter-spike interval. Peripherally encoded frequency and temporal information is analyzed in the brain so that biologically relevant information of sound can be extracted. Some fish auditory responses change with developmental and environmental factors. In addition, auditory efferent neurons in the brain receiving indirect auditory input innervate the inner ear to regulate the auditory input to the brain. These essential auditory processes observed in fishes appear to be shared by higher vertebrates, including humans.

Glossary

Acoustic particle motion Motion of the medium associated with an acoustic disturbance.

Auditory scene analysis Process by which humans and other vertebrates are able to hear out and determine the various sources of sound that make up a given mixture of sources impinging on an organism, such as the individual musical instruments making up an orchestra. This process makes use of the perceptual ability of source segregation.

Otophysan fish Having bones (Weberian ossicles) that link the swimbladder to the ear.

Phonotaxis Movement of an organism relative (positive or negative) to a sound source.

Sound pressure The increase (and decrease) in the density of a medium associated with an acoustic disturbance.

Source segregation The perceptual ability to hear and determine individual sound sources from the mixture of multiple sources in the environment.

Introduction

The underwater acoustic environment can be noisy and complex. To make sense of their world, fishes must assign the sounds they hear to appropriate sources and not confuse sounds that originate from independent sources. It is easy to demonstrate that humans have this ability because, with eyes closed, they can identify a number of separate sound-producing objects around them. This is known as source segregation. This ability has been shown in a number of vertebrate groups, including mammals, birds, and fishes.

Source segregation is a fundamental component of auditory scene analysis, which is the parsing of the acoustic ambience into specific, independent sources. By definition, everything in the scene is significant to the extent that the components of noise, for example, must be segregated from biologically relevant sounds for communication signals to be properly interpreted. It is likely that all organisms that hear, from insects to humans, are capable of source segregation.

An important component of source segregation is sound source localization. Sound source localization gives the acoustic scene a spatial dimension. Surprisingly, it is still unclear whether or not fishes can locate sound sources in this sense. It seems logical that they do, but empirical and theoretical work on this topic is contradictory. All experiments to date that are consistent with sound source localization abilities in fishes could be interpreted as a more restricted capacity of discriminating between sources at different locations (and distances), and not necessarily knowing where the sources are located in an absolute sense.

This article provides an overview of underwater sound and the function of fish ears (for more detailed descriptions, **see also Hearing and Lateral Line:** Auditory System Morphology, Biomechanics of the Inner Ear in Fishes, and Psychoacoustics: What Fish Hear).

Underwater Sound

A thorough treatment of acoustics is beyond the scope of this article but can be found in **Hearing and Lateral Line:** Biomechanics of the Inner Ear in Fishes. However, for this article, it will be necessary to understand some important differences between sound pressure and acoustic particle motion. Sound pressure is a measure of the fluctuations in the density of the medium due to the presence of sound. Sound pressure is what most terrestrial ears sense and it is measured using a microphone or hydrophone. Particle motion is the movement of the particles that make up the media when sound is present. This movement is described in terms of particle displacement, velocity, or acceleration (**see also Hearing and Lateral Line:** Biomechanics of the Inner Ear in Fishes). An important distinction between pressure and particle motion is that pressure is scalar while particle motion is a vector. That is, pressure at any one point is a single number that represents magnitude. Particle motion is a vector quantity, meaning that it is a number composed of two parts, a magnitude and a direction. The difference between a scalar and a vector is that of knowing that a car is moving at the speed of 100 km h^{-1} (scalar) versus knowing that this car is moving at the speed of 100 km h^{-1} due north (vector).

When a disturbance or motion occurs, energy is radiated away from the source in the form of pressure and particle motion. As one moves away from the source, pressure and particle motion decay at different rates. In what is known as the near field, or close to the sound source (**see also Hearing and Lateral Line:** Biomechanics of the Inner Ear in Fishes for a more complete description), the amplitude of the particle motion decreases more rapidly with distance than the amplitude of the pressure. In air, particle motion decays within short distances of the source and it is rarely experienced by terrestrial animals. In water, the wavelengths are longer because water is denser than air. Consequently, the near field underwater is larger than in air and particle motion remains high farther from the source. Far from a sound source, the particles of the media still move to cause pressure fluctuations. The particle motion in the far field is radial to the source and proportional to the sound pressure amplitude. The range of the near field and far field depends on the type of sound source and the signal wavelength, which is determined by the frequency of the signal and the speed of sound in the medium (for a quantitative description of sounds fields, **see also Hearing and Lateral Line:** Biomechanics of the Inner Ear in Fishes).

The Physics of Fish Ears

The ears of all fishes consist of otolith-containing or otoconia-containing end organs (**see also Hearing and Lateral Line:** Auditory System Morphology) that function as inertial accelerometers. As accelerometers, the otoliths are set in motion by the motion of the medium. More precisely, the body of the fish moves with the same displacement, direction, and phase as the water because fish tissue has about the same acoustic properties as water. Otoliths and otoconia are denser than water and, therefore, move with smaller amplitude and lag in phase relative to body of the fish (**see also Hearing and Lateral Line:** Biomechanics of the Inner Ear in Fishes). The result is relative movement between the otolith and the macula (sensory epithelium) that contains the sensory hair cells (**see also Hearing and Lateral Line:** Auditory System Morphology). Hair cells are inherently directionally sensitive and their axis of best directional sensitivity varies along the macula (**Figure 1**; **see also Hearing and Lateral Line:** Auditory System Morphology and Biomechanics of the Inner Ear in Fishes). This is the basic mechanism by which all fish ears are thought to function, and it is, presumably, how fishes would get directional information about a sound source.

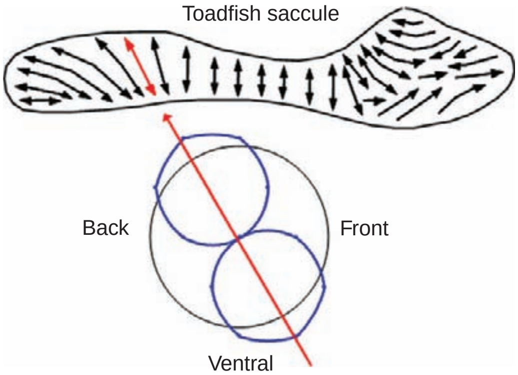

Figure 1 Movement of the otolith in one direction maximally activates only a portion of the hair cells on the macula. Top: Orientation pattern of hair cells on the saccular macula (**see also Hearing and Lateral Line**: Auditory System Morphology). The red arrow shows the group of hair cells maximally activated by the movement of the otolith along the axis indicated by the red arrow in the lower part of the figure. Bottom: The directional response pattern of a nerve cell and hair cell (blue line) with a directional orientation (best axis) equal to the red arrow. This cell will respond best when the direction of particle motion is along the pathway indicated by the red arrow. It will not respond when the motion is 90° to the arrow. Hair cells and nerve cells from different locations on the macula will respond best when the particle and respective otolith motion is along the lines of their respective black arrows.

Some fishes have specialized morphological adaptations that enable them also to detect sound pressure. To effectively sense the pressure component of sound, fishes make use of gas-filled structures such as swimbladders because the gas is compressible and will change volume in a sound field. Such specialized fish species have their gas bladders in close proximity to the ear and/or specializations such as the Weberian ossicles in otophysan fishes (e.g., goldfish (*Carassius auratus*), zebrafish (*Danio rerio*), and catfish (*Ictalurus punctatus*)) that link the swimbladder to the ear (**see also Hearing and Lateral Line:** Auditory System Morphology). The ears of these fishes are stimulated in proportion to the sound pressure level, and sound pressure may be the more relevant component for their hearing.

Behavioral Evidence for Directional Hearing and Sound Source Localization

The first experiments to address sound source localization by fishes were carried out in 1935 on the European minnow (*Phoxinus laevis*). Pioneers Karl Von Frisch and his student Sven Dijkgraaf attempted to train minnows to go to one feeding station randomly selected among four within a lake. The feeding station at which the fish would receive food was marked by a sound emitted at that station prior to feeding. When the fish failed to discriminate between feeding stations, it was concluded that *Phoxinus* could not localize sound sources. Von Frisch convincingly explained these negative results by pointing out that the European minnow was a pressure-sensitive otophysan fish. Otophysans were thought to respond exclusively to sound pressure, via the Weberian ossicles connected to the swimbladder. As previously mentioned, sound pressure at any single point contains no information about the direction of sound propagation. Thus, it was thought that otophysan fishes were unable to perceive direction and were therefore incapable of sound source localization. At that time, no other modes of fish inner ear stimulation, such as the detection of particle motion, were known so it was believed that no fishes were capable of localizing sound sources.

Since then, the behavioral capacity for directional hearing by fishes has been demonstrated in a number of teleost species using psychoacoustic discrimination techniques. Direction-dependent masking was found in several species, including haddock (*Melanogrammus aeglefinus*), pollack (*Pollachius pollachius*), ling (*Molva molva*), and Atlantic cod (*Gadus morhua*). Classic experiments of the 1970s used cardiac conditioning techniques, which measure changes in heart rate in response to an auditory stimulus, to measure the detection thresholds of fishes for a pure tone signal in the presence of a white-noise masker. Masked thresholds were measured as a function of the angular separation of the signal and masking noise sources in the horizontal and vertical planes. It was found that the signal became more detectable or that it was detected at lower signal-to-noise ratio when the angular separation between the signal and noise source was greater than 20° in the horizontal plane and 16° in the vertical plane (i.e., a minimum audible angle (MAA) of 20° horizontal, and 16° vertical). In the early 1980s, it also was found that Atlantic cod could discriminate sound source distance. Experiments showed that cod could discriminate between pure tones emitted alternatively from two aligned underwater speakers at different distances. The cod's ability to discriminate distance was thought to be based on the distance-dependent phase angle between sound pressure and acoustic particle acceleration within the near field of the sound source. Overall, these discrimination experiments provided strong evidence that fishes are well able to discriminate between sound sources in three-dimensional space, but they did not demonstrate that fishes could correctly locate the sound sources.

Some of the best behavioral evidence of sound source localization by fishes comes from a series of conditioning experiments on the Ballan wrasse (*Labrus berggylta*) and Atlantic cod. In these free-field experiments, fishes were conditioned to make a response (turn and orient in the direction of the sound source) whenever the source changed location (**Figure 2**). The sources were separated by angles ranging from 7° to 71° in the horizontal plane, and the results showed that the fish could detect the spatial changes in source location with a MAA of 22°. These experiments also showed that fishes could detect the direction of sound propagation and that this ability required two intact inner ears. Although these experiments clearly demonstrated the ability of fishes to detect spatial changes in the sound source, it could still be argued that the experiments did not demonstrate that fishes could correctly determine the location of sound sources. Nevertheless, these experiments stood as the best evidence for sound source localization by fishes.

Recently, the plainfin midshipman fish (*Porichthys notatus*) was shown to exhibit phonotaxis by approaching

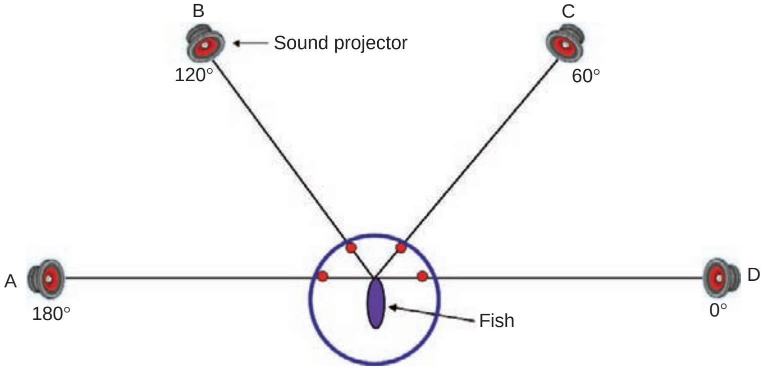

Figure 2 Diagram of four alternative choice experiments that investigated directional hearing in Atlantic cod (*Gadus morhua*). Fish were housed in a netted cage while a stimulus tone of 75 Hz was played from one of four sound projectors (A–D) at different directions. The fish were free to move in the cage and trained to orient toward the food dispenser (red dot) that was in line with the active sound projector.

a sound source that was broadcasting a version of the male's advertisement call (a continuous, multiharmonic signal with a fundamental frequency of ~90 Hz). In these experiments, gravid female midshipman fish were observed to approach and contact the sound source when released about 100 cm away from the source. These fish took (primarily) direct pathways to the source and were evidently capable of sound source localization, but how did they do it?

Theories of Directional Hearing and Sound Source Localization

The work of the 1970s and 1980s was in stark contrast to the thinking of the early 1960s when Willem van Bergeijk suggested that directional hearing in fishes was entirely dependent upon the lateral line system. In the then dominant acoustico-lateralis hypothesis, van Bergeijk posited that the lateral line and auditory system functioned as a single system that could compute sound source location in the near field. Because van Bergeijk assumed that ear-mediated hearing in fishes only processed sound pressure using the swimbladder as a pressure-to-displacement transformer, he asserted that directional hearing by means of a fish ear was not possible in either the near or far fields. The experiments that surgically eliminated the cod's ear, however, showed that both ears are needed for directional detection at a distance from the source, much like that of terrestrial vertebrates.

Terrestrial animals generally use the differences between the sounds arriving at the two ears (acoustic cues) to compute sound source direction, at least in the horizontal plane. These cues consist of time of arrival differences at the two ears (interaural time differences or ITDs), and also the sound level differences at the two ears (interaural level differences or ILDs) caused by the sound shadowing by the head. Fishes cannot use these acoustic differences because: (1) the speed of sound is over 4 times greater in water than in the less dense air, making ITDs very small; (2) the closeness of the ears further reduces ITD cues; and (3) there is a minimal sound shadow caused by the head because the fish's entire body moves with the sound, making ILDs also very small.

So, it is thought that to the extent that fishes can locate sources using sound, the brain must have access to other information. This information arises within the otolithic ears themselves, and in their direct response to acoustic particle motion. Because hair cells are directional receivers and their orientation varies along the macula, the axis of particle motion can, in general, be established by determining which hair cells were stimulated. In the horizontal plane, all the hair cells of the right and left ears respond best when the axis of particle motion is parallel to the orientation of the ear within the head (**Figure 1**). Each ear is maximally activated by particle motion along different axes. The cue is not caused by acoustic level differences arriving at the ears, but by differences in the responses of the ears themselves to particle motion. In other words, the ears themselves are directional and respond best to different axes of particle motion. The brain may calculate the axis of particle motion by calculating the ratios of right and left ear activation. This process has been called vector detection and is the basis for all current models of directional hearing and sound source localization by fishes.

Vector Detection and the Phase Model

Fishes probably can resolve the particle motion vectors using their two ears and the diversity of hair cell directions. However, as Arie Schuijf has pointed out, this does not entirely solve the problem of sound source localization. The axis of particle motion could be resolved by vector detection, but which end of the axis points toward the source? This question has been termed the 180° ambiguity problem. A solution is possible if fishes obtain independent information about the phase of the sound pressure waveform and the particle motion waveform. Using this information, the direction to the sound source could be computed and the 180° ambiguity resolved. Discrimination experiments found that accurate discrimination was no longer possible when the phase relationship between pressure and particle motion was experimentally reversed. This finding supports the idea that localization of sound sources depends on vector detection using particle motion, followed by phase comparison of the pressure and particle motion waveforms.

However, there are still problems that this theory, the so-called phase model, cannot solve. One is that sharks and other elasmobranches seem to be able to locate sound sources in the near and far fields, yet they probably do not detect sound pressure because they lack a swimbladder or other gas bubble associated with the ears (**see also Hearing and Lateral Line:** The Ear and Hearing in Sharks, Skates, and Rays and **Chondrichthyes**: Physiology of Sharks, Skates, and Rays). Another problem for the phase model theory is that particle motion vectors only point to and away from monopole sound sources. A monopole source is like an underwater bubble of gas that expands and contracts with pressure fluctuations. It is thought that most underwater sound sources are not monopoles, but are dipoles or other types. Dipoles are like a vibrating sphere without volume changes. They produce a sound field in which the particle motion vectors do not always point toward and away from the source, and thus would present confusing particle motion vectors to fishes. One possible solution is that fishes do not know where the sound source is in the way that human listeners (or, presumably, other terrestrial animals) do. For example, fish may sample from multiple locations and then swim in the direction that is loudest.

Brain Mechanisms Underlying Sound Source Localization

Peripheral neural encoding of directional information has been investigated in a few species. In these species, Atlantic cod, oyster toadfish (*Opsanus tau*), plainfin midshipman (*P. notatus*), and sleeper goby (*Dormitator latifrons*) responses from the auditory nerve (individual auditory saccular nerve cells) tend to show perfect directionality (**Figure 3**). It is perfect in the sense that response strength is proportional to the axis of stimulation in only one direction. Nerve cells differ considerably in their best-axis vector, likely because individual saccular nerve cells may contact hair cells that are oriented only in one direction. In other words, each hair cell orientation seems to have a private line to the brain. In some fishes (e.g., the sleeper goby), the afferent neurons from all of the otolithic organs to the brain are sufficiently sensitive to respond to particle motion associated with biologically relevant sounds. This suggests that the brain may be able to use information from all the otolithic organs in the computation of sound direction.

Representation of directional acoustic information in the central nervous system has been studied in three species (goldfish, oyster toadfish, and rainbow trout (*Oncorhynchus mykiss*)). Directional information in the oyster toadfish is present in the descending octaval nucleus (DON) of the brainstem (medulla oblongata; **see also Brain and Nervous System:** Functional Morphology of the Brains of Ray-Finned Fishes and **Hearing and Lateral Line:** Auditory/Lateral Line CNS: Anatomy and Physiology of the Ear and Brain: How Fish Hear). This is the first auditory nucleus that receives input from both ears, and many of the DON cells are more directionally selective than the saccular nerve cells. Directional selectivity in the DON appears to be enhanced by excitatory–inhibitory interactions within the brainstem, but it is not clear if the processing is based on monaural or binaural inputs, or a combination of both. Some recent evidence for binaural computation has been found. In DON cells of the oyster toadfish, some of the best axes of stimulation could not have been obtained from saccular afferents located on the same side of the head as the recorded DON cells.

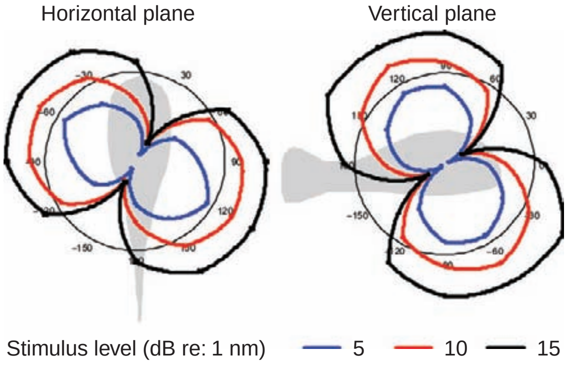

Figure 3 The directional response patterns of one nerve cell of the oyster toadfish (*Opsanus tau*). The left panel shows that the best azimuthal direction is about 60° to the left front, and the right panel shows the best elevation is about 120° (up and to the back). Data are shown for three stimulus levels. Note that the cell responds best to one particular axis of particle motion, but cannot determine as to which end of the axis points toward the sound source.

Directional sensitivity continues to improve at the level of the midbrain in the torus semicircularis (TS). The distribution of best-axis vectors of acoustic particle motion in oyster toadfish TS is much wider than the comparable distribution of best-axis vectors in the saccular nerve cells. The greater range could be due to input from otolithic end organs other than the saccule, or alternatively, due to input from saccular nerve cells from both ears. In either case, all axes of acoustic particle motion are represented in the TS. In contrast to the oyster toadfish, recordings from the TS of the goldfish, a pressure-sensitive otophysan fish, show a narrow distribution of the best axes that is similar to the distribution of best-axis vectors of the saccular nerve cells. Interestingly, the broad distribution of best-axis vectors of the lagenar and utricular afferent nerve cells is not reflected in the properties of the goldfish TS. This lack of diverse best-axis vectors may indicate poor directional hearing in the goldfish and other pressure-sensitive otophysans, just as von Frisch and Dijkgraaf originally reasoned.

Summary and Unresolved Issues

Fishes have available to them a great deal of acoustic information, and fishes that make the best use of that information would, presumably, have the greatest survival and reproductive advantages. The process of making sense of the soundscape is known as auditory scene analysis, and scene analysis requires the ability to segregate information coming from different sound sources. In turn, the fundamental components of sound source segregation are the ability to identify objects emitting sounds, and the ability to estimate where those objects are located. While there is general confidence that at least some species of fishes can accomplish sound source localization, we are ignorant of many aspects of this ability, and this situation presents a whole set of unanswered questions.

Perhaps first among the questions is whether and how fishes like the European minnow and goldfish (and all other species that are primarily pressure sensitive) accomplish sound source localization. Input to the ears is dominated by the swimbladder's response that is proportional to pressure, but a vector detection mechanism based on particle motion from the external source seems to be required for localization. Where does this motional input come from? How can the phase model that requires both pressure and motional inputs be used in species lacking a swimbladder such as elasmobranchs and flatfish? Do fishes perceive the location of sources as human listeners do, or do they merely have a behavioral strategy for approaching sources? In discrimination experiments with multiple sources, fishes are able to discriminate between them, but do they perceive their absolute location or do they merely understand that the sources are somehow different? What is the role of the lateral line system in sound source localization in the near field?

These and other questions remain unanswered. Although we are fairly certain that the axis of particle motion is determined using a vector detection strategy, we are still without a complete account of sound source localization that is generally accepted.

Glossary

Ambient noise The combination of sound from natural sources.

Audiogram A graphical representation of sound detection thresholds at the range of frequencies that are audible.

Auditory threshold The average sound pressure level that is just audible to a subject under quiet conditions.

Background noise The prevailing combination of ambient (natural) noise and man-made noise.

Infrasound Sound that is lower in frequency than 20 Hz, the normal limit of human hearing.

Masking A blocking of the detection of one sound by another.

Mitigation Taking action to minimize the effects of noise.

Noise Unwanted sound; also refers to a sound with a random waveform containing energy across a broad range of frequencies.

Noise-exposure criteria The thresholds set to protect animals from sounds that may harm them.

Particle motion The back-and-forth motion of the component particles of the medium that accompany passage of a sound; it can be expressed as particle displacement (nm), velocity ($\mathrm{nm\,s^{-1}}$), or acceleration ($\mathrm{nm\,s^{-2}}$).

Sound-exposure level (SEL) A measure of the energy of a sound and it depends on both amplitude and duration; the SEL is the time integral of the instantaneous squared sound pressure normalized to a squared reference pressure over a 1-s period (expressed as dB re 1 $\mu\mathrm{Pa}^2\,\mathrm{s}$).

Sound-pressure level (SPL) The fluctuation in pressure above the hydrostatic pressure that characterizes passage of a sound (expressed as dB re 1 μPa).

Soundscape The totality of sounds at a given location.

Ultrasound Very high frequency sound, generally above 20 kHz.

Introduction

Many of the sounds detected in seas, lakes, and rivers are entirely natural. The sounds of falling rain, breaking waves, cracking ice, bubbles, spray, and turbulence provide a continuous but a varying background of noise. Less frequently, earthquakes, volcanic eruptions, and lightning strikes generate intense sounds, traveling over great distances. Sounds from marine mammals, fish, and crustaceans add to the ambient noise. Snapping shrimps and chorusing fish can contribute significantly over a wide band of frequencies, which may mask communication signals from other animals (**see also Sensory Systems, Perception, and Learning**: How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling). Together with the sound of wind-driven waves, these biological sounds may dominate ambient noise levels.

In recent years, humans have added to sea noise. Sounds from shipping, underwater explosions, seismic exploration, offshore construction, and sonars of various types have raised the level of background noise. Typical sound levels at different frequencies from different sources are shown in **Table 1**.

There is concern over the effects of these extraneous sounds upon fish and other aquatic animals. It is known that very intense sounds may kill or injure fish. At lower levels, sound may impair their hearing, affect their ability to orient, or make their vocalizations difficult to detect. It may evoke changes in behavior that may affect spawning migrations or disrupt foraging and feeding, with effects at the population level. Do these sounds have a significant effect upon the fitness of aquatic organisms, affecting their welfare and their survival? If so, how might we reduce them or mitigate their impact?

Sound Sources

Sounds generated by human activities form a significant part of the total underwater background noise. Sound is

Table 1 Characteristics of a number of underwater sound sources

Sound	*Source level (dB re 1 μPa at 1 m)*	*Bandwidth (Hz)*	*Major amplitude (Hz)*	*Duration (ms)*
Explosion (TNT, 1–100 lbs)	272–287 peak	2–1000	6–21	~1–10
Percussive pile driver	185–260 peak	20 to >20 000	40–1000	50
Vibrating pile driver	173–185 rms	10–10 000	100–1500	Continuous
Dredging	168–186 rms	30 to >20 000	<500	Continuous
Drilling	145–190 rms	10–10 000	<100	Continuous
Operating wind turbine	114–130 rms		<200	Continuous
Small ships	160–180 rms	20 to >10 000	>1500	Continuous
Large ships	180–190 rms	20 to >10 000	>1000	Continuous
Low-frequency sonar	215 peak	100–500		600–1000
Medium-frequency sonar	223–235 peak	2800–8200	3500	500–2000
High-frequency sonar	235 peak	Variable		5–10
Seismic air-gun array	260–262	10–1000	10–120	30–60

used for our benefit in underwater communication, navigation, fish finding, research, and sub-sea exploration. However, many sounds are an incidental by-product of other activities, such as commercial fishing, the transportation of goods, drilling for oil and gas, aggregate extraction, the dredging of shipping channels, and the construction of piers and harbors.

Man-made sounds can be continuous or they may be transient or impulsive. Propeller and engine noise from a ship continues for as long as the ship is on the move, although it may change in level and quality as the ship maneuvers. Sounds from some industrial activities, such as drilling or dredging, may be generated for long periods, although they may greatly vary in amplitude with time. Other sounds from activities, such as percussive pile driving, or seismic surveying, are intense but transient. The sounds are intermittent, although they may be repeated many times. Continuous sounds from sources such as ships raise the baseline of ambient underwater noise over wide areas, while transient or impulsive sounds occur less often. It is possible that in many areas, chronic exposure to moderate levels of noise has more significant biological impact than an occasional exposure to extremely loud sounds. Certainly, it is important to distinguish between long-term exposure to noise that affects habitat quality and masks natural sounds, and short-term acute exposure to intense sounds that may evoke a short-term response and which, in some cases, may result in injury or death.

Sound is a back-and-forth disturbance of the component particles of a material medium. As an object vibrates, some of its kinetic energy is transferred to the surrounding gas or liquid. The consequent vibration of particles close to the object is in turn coupled to more distant particles, so that a traveling sound wave is transmitted away from the source at a speed dependent on the density and elasticity of the medium. The passage of the sound wave involves both compression and motion of the medium. The compression wave is observed and measured using an instrument sensitive to pressure variation – a microphone or hydrophone. The particle motion within the medium is more difficult to monitor. It is usual to specify a sound by the sound pressure alone, and to estimate the particle motion, if required, from a knowledge of the acoustic properties of the medium.

The range of sound pressures encountered in water is enormous, and sound levels are therefore specified on a logarithmic scale as decibels (dB) relative to a specified reference level. In water, the reference pressure is 1 μPa. In air, a different reference level is used, so that dB levels in air and water cannot be compared directly. Besides, sound travels much faster in water.

As sounds are variations in pressure with time, they can be described by the different frequency components they contain. Humans can detect or hear sounds over a frequency range extending from 20 Hz (cycles per second) to 20 kHz (20 000 Hz). However, there are many different types of sound. Some are short or transient like a crash or bang, others are long or continuous, like the sound from a boat engine. Some sounds have a tonal or musical quality, while others are rough and unpleasant. The frequency spectrum describes the full range of frequencies within a sound.

Ship noise is very pervasive in some parts of the ocean. It emanates from engines and other machinery, rotating shafts, propellers, and the interaction of water with the hull. The motion of the ship through the water may create low-frequency pressures and water displacements around the ship. Much of the noise from a ship results from cavitation – the collapse of air spaces created by the rotating propellers. Individual ships have their own noise signatures and can be detected over distances of kilometers. Ship noise is greatest close to ports and shipping lanes, and it has become greater as the number of ships on the high seas has increased. In shallow coastal waters, the soundscape may be dominated by sound from small boats fitted with outboard motors.

Construction and industrial activities, both onshore and offshore, may generate significant noise in lakes and rivers, as well as in the sea. These activities include pile driving, dredging, drilling, the use of explosives in construction and decommissioning, the operation of offshore wind farms, and activities at oil- and gas-production facilities. Percussive pile driving may produce especially intense sounds. With this activity, a post, sheet, or tube made of steel or reinforced concrete is driven into the seabed to support a superstructure such as a jetty or a wind turbine. The head of the pile is struck repeatedly, driving it downward until the pile has reached the required depth. The insertion of each pile may take minutes or hours, depending on the size of the pile and the substrate conditions, and there could be many piles. Pile driving generates short pulses of sound with most of the energy concentrated at frequencies below 1000 Hz. Close to the pile, the peak sound pressures associated with each strike may be very high. In addition, compressive, shear, and surface waves are generated within the substrate that may result in large particle accelerations close to the seabed. The use of explosives both in construction and in the removal or decommissioning of structures such as oil platforms also produces very high peak sound levels. The sounds from these activities can travel great distances (tens of kilometers).

Dredging of ports and harbors as well as the extraction of sand and gravel from the seabed create continuous but rather variable levels of sound at low frequencies. Vibrating pile drivers, in contrast to their percussive counterparts, produce continuous sound, so do trawling by commercial fishing vessels, the drilling of oil and gas wells, and tunneling beneath the seabed. Noise is also generated by the operation of offshore wind farms and by oil and gas platforms, although the levels produced during operation are generally lower than those during the construction phase.

Other activities deliberately produce underwater sound. Seismic surveying for oil and gas involves the generation of a low-frequency pulse of sound (with most of the energy in the range 10–120 Hz) that travels through water to enter the seabed. A receiver array detects the returning sound. By analyzing the reflections, it is possible to identify the properties of the seabed, the underlying geology, and the presence of oil and gas deposits. The surveys are conducted from a ship towing an array of air guns. Each air gun produces a short intense pulse of sound that is focused downward by the configuration of the array. Surveys may cover a wide area and last for several weeks.

Sonar is used to measure depth, to map the seabed, to detect fish, to track subsurface vehicles, or to search for military targets. Sonars operate at a range of sound frequencies and are classified as low- (<1 kHz), mid- (1–10 kHz), and high-frequency (>10 kHz) sonars. High-frequency sonars may be detected by only a few fish species, but mid- and low-frequency sonars may operate well within the range of frequencies that can be detected by fish (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays and Psychoacoustics: What Fish Hear). Mid-frequency sonars are perhaps the most common and most relevant to fish, as they are used by many navies to search for submarines. They may have high source levels and generally produce long sound pulses in which the frequency changes.

Other sources of underwater sound include high-frequency acoustic-harassment devices (generally operating above 20 kHz) that are intended to scare marine mammals away from fishing nets, acoustic beacons (used for navigation purposes), and even the underwater components of sonic booms generated by aircraft flying above the sea surface.

Sound travels almost 5 times faster in water than it does in air. Underwater sounds are generally measured using hydrophones sensitive to sound pressure; however, in some cases, particle motion may also be required (because many fish are sensitive to particle motion rather than sound pressure). In a free sound field, particle motion can be estimated, but close to acoustic boundaries the relationship becomes complex and it is necessary to measure particle motion directly. Particle motion can be expressed as particle displacement, particle velocity, or particle acceleration. As motion is a vector, its direction is important. The amplitude of a sound diminishes and its frequency characteristics change with distance from the source. The output from most sources is usually described by the source level – the sound-pressure level (SPL) at 1 m. This is obtained by fitting measurements made at different distances to a model that describes the rate at which sound diminishes with distance. Estimating the sound levels that reach a fish can be difficult, especially if the sound is to be described in terms of particle motion. Yet, it is the sound reaching the fish that is significant. The metrics used to describe and evaluate the impact of sounds include the root mean square (rms) pressure (or particle acceleration), peak sound pressure, received energy (received sound-exposure level (SEL)), rise time, duration, frequency range, roughness, duty cycle, and directionality.

Impacts on Fish

Sound is important to fish. Fish depend on sound to communicate with one another, detect prey and predators, navigate from one place to another, and avoid hazards. Fish larvae use sound to settle in suitable habitats. An important additional function of hearing is auditory-scene analysis – the ability of animals to break down the overall sound field into separate elements to analyze the world around them and assign different components to particular sources (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays, Psychoacoustics: What Fish Hear, and Vocal Behavior of Fishes: Anatomy and Physiology).

Our current knowledge of the impact of underwater sound on fish is fragmentary. In particular, knowledge of the auditory capabilities of fish is limited and relies, with a few notable exceptions, on experiments carried out in the laboratory (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays and Psychoacoustics: What Fish Hear). The presentation of measured sound stimuli to fish under experimental conditions presents major difficulties. Fish are generally most sensitive to low frequencies that are difficult to reproduce with precision, and many fish are sensitive to particle motion that has to be estimated from the measured sound pressures, and in many cases it is not estimated at all. Many of the thresholds and audiograms presented (**see also Hearing and Lateral Line**: Psychoacoustics: What Fish Hear) are unreliable and must be treated with great skepticism. For most fishes, there are no empirical data to describe their hearing characteristics.

Several general conclusions can be drawn from the few audiograms available for fish. Fish are sensitive to a rather restricted range of frequencies compared with birds and mammals. Even the most sensitive fish have relatively poor hearing above 2–3 kHz. There are one or two exceptions: some fishes do appear to be sensitive to very high amplitude, high frequency sounds, including the ultrasonic frequencies generated by some sonars. However, fish are generally most sensitive to relatively low frequencies, including sounds in the infrasonic range (less than 20 Hz).

It is evident that the unaided fish ear is sensitive to particle acceleration and is most responsive to low frequencies. Increased sensitivity and extension of the range to higher frequencies are found in those fish with gas-filled spaces close to or connected with the ear. These fish are sensitive to sound pressure. They include carp (freshwater fish of the order Cypriniformes), which have a connection between the swimbladder and the inner ear (**see also Hearing and Lateral Line**: Auditory System Morphology). At their most sensitive frequencies, fish may not be limited by their absolute sensitivity but by the level of ambient noise, even under relatively quiet sea conditions (**see also Hearing and Lateral Line**: Auditory System Morphology).

There is a hierarchy of ways in which sound affects fish. At one extreme, fish may die when they are exposed to very high energy sounds, for example, close to an explosion or pile driver. In other cases, high-level sounds may injure internal organs. Fish may show temporary hearing loss and damage to the sensory hair cells of the inner ear following exposure to high levels of both continuous and interrupted sound. Lower-level sounds may disrupt behavior patterns, or mask the detection of biologically important sounds. However, in many cases, sounds may simply be detected by fish at a distance without any overt change in behavior. It is possible to think in terms of overlapping zones of impact away from the source, with death and injury occurring at close range, while at extreme distances the animal barely hears the sound (**Figure 1**).

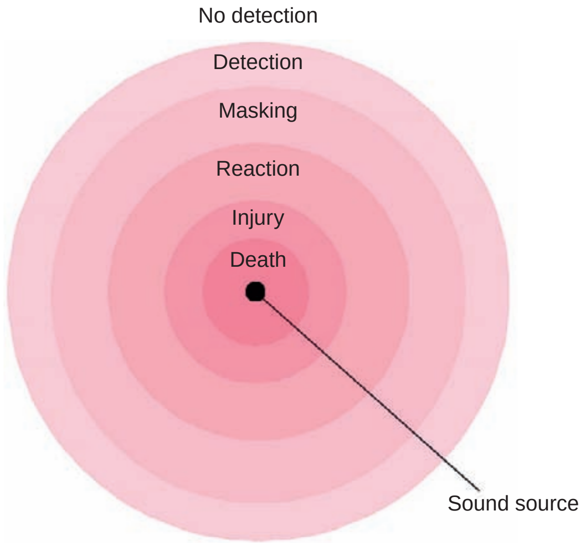

Figure 1 Zones of impact from a sound source. Note that the zones overlap one another.

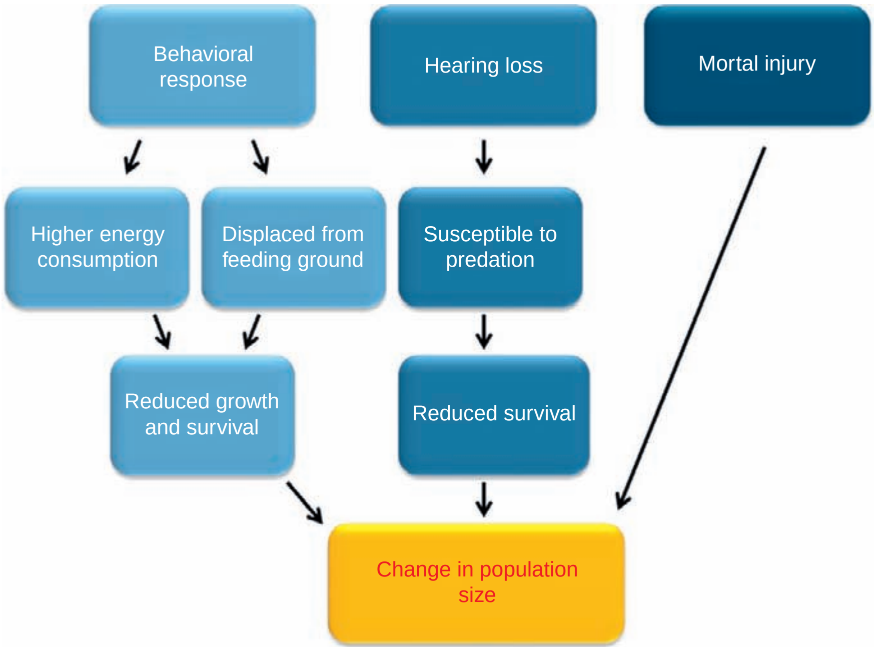
Studies of fish behavior in response to sounds are difficult to perform. Many factors may influence the results. A careful case-study approach must be adopted, based on well-designed experiments. A great range of impacts has been observed from fish in response to underwater sound. Some fish have shown changes in swimming behavior and orientation, including startle reactions. Schools of pelagic fish dive in response to the firing of seismic air guns, while demersal fish flee from a seismic source across the sea floor. The horizontal and vertical distributions of both pelagic and ground fish change after several days of air-gun operations. Fish cease critically important activities, such as feeding and sound production. Catches in sea fisheries decrease both during and after seismic surveys. Some of the behavioral effects are short term, diminishing after the initial presentation of the sound. Others are longer term and result in fish consistently avoiding a sound source.

So far it has not been possible to grade the magnitude of their response according to the level and characteristics of the sound. Distinctions have been made between involuntary startle reactions, changes in behavior, and outright avoidance, in an attempt to separate inconsequential behavior from significant responses, but the reactions of fish to sounds are often species specific and depend upon the context. We should perhaps not be too concerned about how fish behave in response to sounds. Rather, we should ask what significance this behavior is likely to have for their survival. Will the behavior itself be costly in terms of energy loss or risk to fitness? Will the behavior result in the longer-term impairment of survival through displacement from a preferred area, or will the fish be denied access to a key habitat (**Figure 2**)? From a conservation perspective, the impact of extraneous



Behavioral response
Hearing loss
Mortal injury
Higher energy consumption
Displaced from feeding ground
Susceptible to predation
Reduced growth and survival
Reduced survival
Change in population size

Figure 2 From a conservation standpoint, it is the impact of sound exposure upon survival which is critical, rather than the immediate response.

sounds on individual fish is less important than their impact on populations and ecosystems, either alone or in combination with other stresses such as commercial fishing. There have been attempts to develop predictive models, based on studies of the disruption to individuals, and examining effects on key life functions such as feeding, growth, reproduction, and migration. However, such models are still in their infancy.

Regulation and Mitigation

Man-made underwater sound becomes significant when it causes harm to living fish. If a man-made sound affects the survival of fish or their ability to reproduce, then it may be important to regulate, eliminate, or reduce noise production. Regulation usually involves the setting of standards or criteria defining the levels of sound that cause a specified degree of response. In setting noise-exposure criteria, it is necessary to have regard to the particular animal or animals being exposed, and their particular sensitivity to sound. It is difficult to extrapolate from one species to another, especially for fish, which are the most diverse of vertebrates. It is also necessary to have some knowledge of the noise levels to which the fish will be exposed, specified by appropriate metrics. A level can then be set which, if exceeded, will constitute a breach in a regulation.

Acute noise-exposure criteria can be used to regulate particular sources, or to place restrictions on the technology that generates the noise. It is perhaps easiest to set these noise-exposure criteria based on the SPL that will result in the death of fish. There has been research into the levels of impulsive sound from explosions that cause lethal injury. It is clear that physical injury from a transient pressure wave is related to the peak-pressure level, the rise time, and the period that the peak pressure acts upon the body. In general, smaller fish are generally more vulnerable than larger fish, and fish with gas inclusions, such as the swimbladder, are more vulnerable than those without.

On the basis that impulsive sounds can harm fish, several regulatory authorities have set standards for the use of pile drivers on the coast and in rivers. One example for pile driving stipulates that SPLs must be maintained below 150 dB rms with reference to 1 μPa for a minimum of half the impacts or strikes; and peak SPLs must be maintained below 180 dB re 1 μPa for all strikes in areas of potential fish presence. The setting of these standards often has been done in an arbitrary way. In particular, a peak value of 180 dB re 1 μPa seems to have gained wide acceptance as an upper limit, without clear justification or critical appraisal. Some researchers have emphasized that several factors, including the total energy, the peak sound pressure (or particle acceleration), and the duration, are important in causing damage rather than the sound pressure *per se.* They have estimated the SEL that results in the death of half the exposed fish based on data for exposure to a single explosive sound and have applied this figure to pile driving for fish of differing size, which gives SEL limits ranging from 195 to 198 dB re 1 μPa^2 s. A dual-criteria approach has also been suggested that includes an interim single-strike criterion for SEL combined with an interim criterion for peak sound pressure. It recommends that criteria for pile driving should be set at an SEL level of 187 dB re 1 μPa^2 s, and a peak SPL of 208 dB re 1 μPa in any single strike. It is important to realize, however, that such criteria are based on very limited data with respect to noise-induced injury. In particular, there are very few data on the cumulative effects of repeated exposure. Measurements of the impact upon fish of large particle accelerations are also lacking.

Some researchers have emphasized that it is important in specifying a level to measure the sound by passing it through a filter that approximates the audiogram of the species. This procedure excludes sound at frequencies that the fish is unable to detect. The approach is not entirely valid because injuries may be inflicted on the fish at frequencies outside its hearing range, and especially by steep rise times and high peak values that are associated with wide bandwidth sounds.

For many fishes that are sensitive to particle motion, the expression of exposure in terms of sound pressure may not be appropriate. The particle acceleration ($m\,s^{-2}$), the acoustic intensity (in $W\,m^{-2}$), or even acoustic intensity over time ($J\,m^{-2}$) is more relevant.

It is much more difficult to decide on noise-exposure criteria for fish based on behavioral responses rather than on temporary hearing loss, injury, or death. Fish are very diverse in their behavior and their responses are often species specific and context dependent. It has been said that sounds that are more than 90 dB above the hearing threshold may cause a strong avoidance response and are therefore especially likely to be harmful. Others have suggested that SPLs of 150 or 160 dB re 1 μPa should be regarded as those at which avoidance behavior is triggered. There are few data to support these assertions and the figures chosen are entirely arbitrary. Much more evidence must be gathered before any simple rule of thumb can be established.

For chronic exposure to moderate-level sounds, where there is no single source but many, quite different criteria must be set. Here, the main problem is the masking of sounds by background noise, as there is considerable overlap between man-made noise and the sounds important to fish. Masking can shorten the range over which sounds can be detected and individuals communicate. There is a dearth of information on long-term trends in ocean noise. Routine monitoring of background noise levels is now underway at a number of experimental sites. It has been suggested that maximum levels should be set for especially sensitive marine sites to protect the natural soundscape.

Besides these regulatory measures, there are a number of options for mitigating the effects of noise. A technique commonly applied with marine mammals is to establish a safety zone for the noise-making activity, ensuring that there are no vulnerable animals within the affected zone. Outside the zone, the sound levels are unlikely to pose harm. With fish, unlike sea mammals, it is not always possible to determine whether there are fish present within the zone of harm, and this procedure is less useful. Other mitigation measures involve attenuation of the sounds themselves. A bubble curtain placed around a pile driver will reduce the sounds transmitted into the water, but not into the substrate. Bubble curtains are certainly successful in reducing the peak amplitude of sounds from pile driver by up to 10 dB, and they also reduce the high-frequency content of the sound. However, they do not reduce the energy transmitted at the lower frequencies to which fish are sensitive. Moreover, fish close to the seabed may respond to the substrate vibrations. Other physical measures that can be effective include placing an absorbent pad between the driven pile and the hammer, and reducing the peak level and the rise time. Raising the level of repeated sounds gradually, to allow fish to escape before the loudest sounds are transmitted, is another measure that is thought to reduce the impact of a sound source and is applicable to both pile driving and seismic surveys.

Perhaps the most effective mitigation measures involve the imposition of spatial and seasonal restrictions to avoid exposure of sensitive species and habitats to noise. Thus, noise-producing activities may be limited to periods and locations when fish are not breeding, migrating, or engaging in other sensitive activities.

Glossary

Amplitude The maximum pressure deviation from ambient pressure in a sound wave.

Decibel (dB) A logarithmic scale for comparing signal parameters such as sound pressure, particle velocity, voltage, current, etc.

$$\text{Number of decibels} = 20\log_{10}(a_1/a_0),$$

where a_0 and a_1 are the two signal parameters being compared. Decibels are used in acoustics for sound pressure levels and other measurements.

Frequency The number of wave cycles in a time interval (measured in Hz = 1 cycle s^{-1} or kHz = 1000 cycles s^{-1}).

Interpulse interval Time between two pulses in a sound.

Oscillogram A graph produced from an oscilloscope or sound analysis software that records the pressure of a sound wave along a time axis.

Period The time it takes for one cycle of a sound wave to pass by a point.

Power spectral density The total sound power of a 1-Hz-wide band centered at a given frequency in a sound.

Pulse train A set of sound waves, each pulse due to a single set of sonic muscle contractions, or a single contraction for some species.

Sound pressure level A measurement of the sound pressure in decibels comparing the measured sound pressure (a_1 in the decibel formula above) to a reference pressure (a_0 in the decibel formula above). Underwater sound measurements use 1 μPa as the reference pressure.

Spectrogram (also sonogram) A graph representing the sound frequency and intensity variation over time; useful in identifying fish species by their sounds. Most spectrograms are displayed as two-dimensional plots in which the horizontal (x) axis is time (in s), the vertical (y) axis frequency (in Hz), and the color (z) axis is power spectral density (in dB).

Introduction – Fish Behavior and Underwater Sound

Because the underwater world is often dark and turbid, fishes have evolved to take advantage of sounds (**see also Behavior and Physiology**: Linking Fish Behavior and Physiology: An Introduction). Fishes can hear sounds, some better than others, within a frequency range of 10–1000 Hz for most species. Some fishes can hear much higher frequencies, up to 4000 Hz (or ultrasound >20 kHz in some Clupeids) (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays and Psychoacoustics: What Fish Hear). Hearing provides fishes with the ability to analyze their auditory scene – their local (~1 m) and long-distance (~10 m to 1 km) acoustic environment (**see also** Biomechanics of the Inner Ear in Fishes).

Fishes also produce sounds in the same frequencies as they hear for communication (**see also Hearing and Lateral Line**: Psychoacoustics: What Fish Hear). Fishes have evolved specialized sound production mechanisms including stridulation of bones and teeth or contraction of sonic muscles to drive gas-filled swimbladders (**see also Hearing and Lateral Line**: Vocal Behavior of Fishes: Anatomy and Physiology). Recordings of many fish sounds can be played at the 'Relevant websites' listed at the end of this article. It appears that sounds are produced by some of the most primitive fishes (i.e., various species of sturgeons (Acipenseridae) and the reedfishes or bichirs, gray bichir *Polypterus senegalus* and West African bichir *P. retropinnus* Polypteridae)) for the purposes of intraspecific communication. Sound production in fishes has also evolved more than once and has become important for communication in codfish (Gadidae), drumfish (Sciaenidae), toadfishes and midshipmen (Batrachoididae), and many other species. Sound production is used by fishes to communicate along with chemical, tactile, and visual signals (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior and Behavioral Assessment of the Visual Capabilities of Fish).

Fishes produce two different types of sounds: (1) pulsed sounds, in which the sonic muscles contract once to produce each pulse and (2) tonal sounds, in which the sound-producing muscles contract repeatedly to cause a steady-state vibration of the swimbladder. Pulsed sounds, such as the knock produced by silver perch, *Bairdiella chrysoura* (Sciaenidae) (**Figure 1**), have frequencies that depend on the physical properties of the sound-producing mechanism (sonic muscles and swimbladder), and will vary with the size of the individual fish. Tonal sounds, such as the boop produced by oyster toadfish, *Opsanus tau* (Batrachoididae) (**Figure 2**), have frequencies that depend on the vocal pacemaker and muscle contractions, and do not vary with the size of the fish.

The distance that fish sounds travel depends on the loudness of the sound, the loudness of the background noise at the same frequencies as the sound, and the water conditions (e.g., depth, temperature profile, and bottom type). Most sound communication among fishes occurs over short distances, less than 10 m. Although the knock of an individual silver perch can be detected at a maximum distance of 316 m in quiet conditions, the biologically relevant propagation distance is closer to 2 m, especially when background sounds are loud from other fish that are calling nearby. However, the combined sounds of aggregations of fish in the open ocean can be detected by hydrophones at distances of 1–8 km. Conversely, the maximum detection distance can be significantly shorter (<1 m) in shallow streams and ponds where turbulence, wave noise, bottom depth, and the shore limit the sound propagation distances.

Scientists use hydrophones (underwater microphones) to record fishes in the wild and when held captive in aquaria to identify the sound-producing species involved (**Figure 3**). Hydrophones have been attached to remotely operated vehicles (**Figure 4**), submarines, and autonomous sound-recording equipment to capture short- and long-term variations of acoustic fish behavior. Sound recordings are then correlated with biological measurements (size, sex, spawning condition, and gamete production) taken at the same time.

What Species Make Sound?

Many fishes make sounds, including (in addition to the families already noted above) catfishes (multiple families in the order Siluriformes), sculpins (Cottidae), Siamese fighting fishes (Osphronemidae), sea robins and gurnards (Triglidae), pearlfishes (Carapidae), elephant-nose fishes (Mormyridae), damselfish (Pomacentridae), wrasses (Labridae), grunts (Haemulidae), porgies (Sparidae), seabasses and groupers (Serranidae), sunfish (Centrarchidae), cichlids (Cichlidae), and gobies (Gobiidae). This is not an exhaustive list of

sound-producing fish families, and at least 700 species are known to make sounds; many species likely to produce sounds have not been studied (**see also Hearing and Lateral Line**: Psychoacoustics: What Fish Hear).

Why Do Fishes Make Sound?

Fishes produce sound for a variety of reasons. These include: (1) incidental sounds produced while swimming and feeding and (2) sounds produced intentionally for communication during aggression, predatory attack (alarm calls), feeding, reproduction, and possibly produced for echolocation. Examples of each type of sound are provided in the subsections below.

Incidental Sounds

Some sounds are incidental and are produced by body movements such as swimming. Anecdotal evidence suggests that these hydrodynamic sounds can be detected by prey fish avoiding predatory fishes. Many fishes are also known to produce sounds incidentally during feeding. These feeding sounds can be simple, like the scraping of teeth on coral as parrotfish, *Sparisoma* sp. and *Scarus* sp. (Scaridae), feed on algae. Other fishes produce sounds when chasing or capturing prey. For example, seahorses, *Hippocampus* sp. (Syngnathidae), make clicking sounds as their skull hits vertebrae when catching prey. Margate, *Haemulon album* (Haemulidae), make both pop and burst

sounds depending on their feeding mechanism. Popping sounds are made as the fish propels its body forward after plankton, while burst sounds accompany the act of expelling sand from their mouth and opercular openings after a benthic feeding.

Intentional Sounds

Aggressive sounds

There are many examples of fish sounds used in aggressive interactions between individuals of the same species or in territory defense. When several grey gurnard, *Eutrigla gurnardus* (Triglidae), are given food in a laboratory, there is a significant increase in both visual and acoustic displays, with different sound types indicating feeding, fighting, and warning (**Figure 5**). These signals prevent other fish from feeding in the same area. Bicolor damselfish, *Stegastes partitus* (Pomacentridae), are well known for their acoustic and visual displays when approached by an intruder (e.g., SCUBA diver). Bicolor damselfish produce popping sounds with an increasing repetition rate as the intruder approaches their nest. If the intruder is not deterred by the acoustic and visual displays and continues to approach, the damselfish engages in physical battle, biting, and even ramming the intruder.

Alarm calls

Alarm calls denote behaviors alerting conspecifics to predators in the area. For example, longspine squirrelfish, *Holocentrus rufus* (Holocentridae), grunt or make staccato sounds when an intruder, such as another longspine squirrelfish, a bluestriped grunt, *Haemulon scirus*

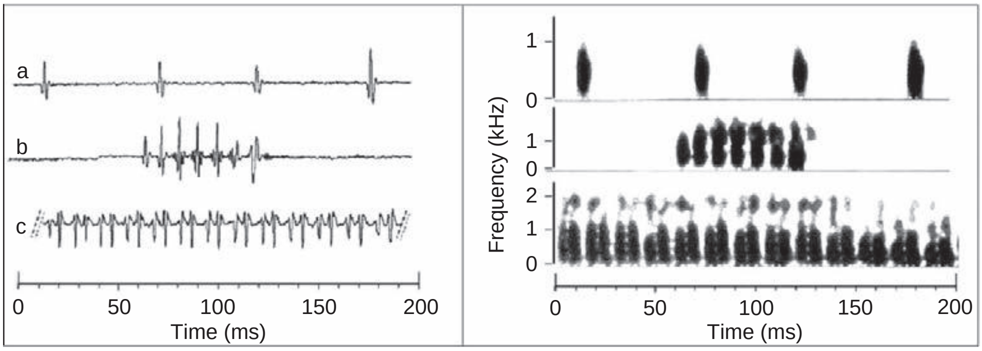

Figure 5 Oscillogram (left) with spectrogram (right) representation of the three types of acoustic signals emitted by grey gurnards *Eutrigla gurnardus* (Triglidae): (a) knocks (feeding); (b) grunts (fighting); and (c) growls (warning). Modified from Amorim MCP, Stratoudakis Y, and Hawkins AD (2004) Sound production during competitive feeding in the grey gurnard. *Journal of Fish Biology* 65: 182–194.

(Haemulidae), a mullet, *Mugil* sp. (Mugilidae), or a spotted moray eel, *Gymnothorax moringa* (Muraenidae), enters their territory. Longspine squirrelfish produced longer staccatos when spotted moray eels were introduced experimentally into their territories compared with the introduction of nonpiscivorous mullet and grunt, suggesting that the longer staccatos may be an alarm call. These squirrelfish alarm calls have been recorded when moray eels and groupers hunt together cooperatively on reefs. These alarm sounds are examples of altruistic behaviors that may facilitate escape behaviors for closely related individuals.

In contrast, longspine squirrelfish have been observed to become silent when the low-frequency (<10 kHz) component of bottlenose dolphin, *Tursiops truncatus*, echolocation sounds was played back. Similarly, a chorus of silver perch (**Figure 6(a)**) was silenced by the sounds of their predator (**Figure 6(b)**). This acoustic avoidance effect was demonstrated by playback experiments using bottlenose dolphin signature whistles, which caused a drop in silver perch sound production of 15 dB (**Figure 6(c)**), but this did not happen when a control sound (700-Hz tone) was played back (**Figure 6(d)**). It is unclear if warning sounds were produced by the silver perch and longspine squirrelfish prior to the silences in these cases.

Spawning/advertisement call

The most well-described fish calls are associated with spawning and reproductive behavior. Sound production, when associated with spawning, is common in turbid water or dark environments, and often occurs during nocturnal spawning events. Generally, only male fishes make spawning sounds as advertisement calls. Acoustic signals may be the mechanisms for female fishes to locate spawning-ready male conspecifics, especially in dark waters. Nocturnal sound production by males is commonly associated with pelagic eggs produced by females in field hydrophone surveys of fishes in the family Sciaenidae: silver perch; weakfish, *Cynoscion regalis*; spotted seatrout, *C. nebulosus*; and red drum, *Sciaenops ocellatus* (**Figure 7**).

In aquarium observations, male red drum used acoustic, visual, and tactile cues during courtship. Males call females with increasingly rapid sounds as spawning approaches, first with two to four short pulse trains, then with rapid drum rolls. When a female responds to the sounds of a male, she begins swimming off the bottom. The male then uses visual (e.g., color change) or tactile (nudging near the female's vent) cues to initiate egg release.

When white seabass, *Atractoscion nobilis* (Sciaenidae), were observed with underwater video and hydrophones in semi-natural oceanic enclosures, a single female spawned with multiple males (up to nine individual males), while the males made sounds variously described as drum rolls, thuds, and a chanting chorus of sounds. During courtship, the males would swim alongside the female with their vents in close proximity to the female's vent (**Figure 8(a)**), making low-frequency (30–200 Hz) pulse trains of sounds (**Figure 9(a)**), some of which were identified as drum rolls and thuds (**Figure 9(b)**). The female exhibited vertical color bars during courtship and spawning, which provided a visual cue to the males

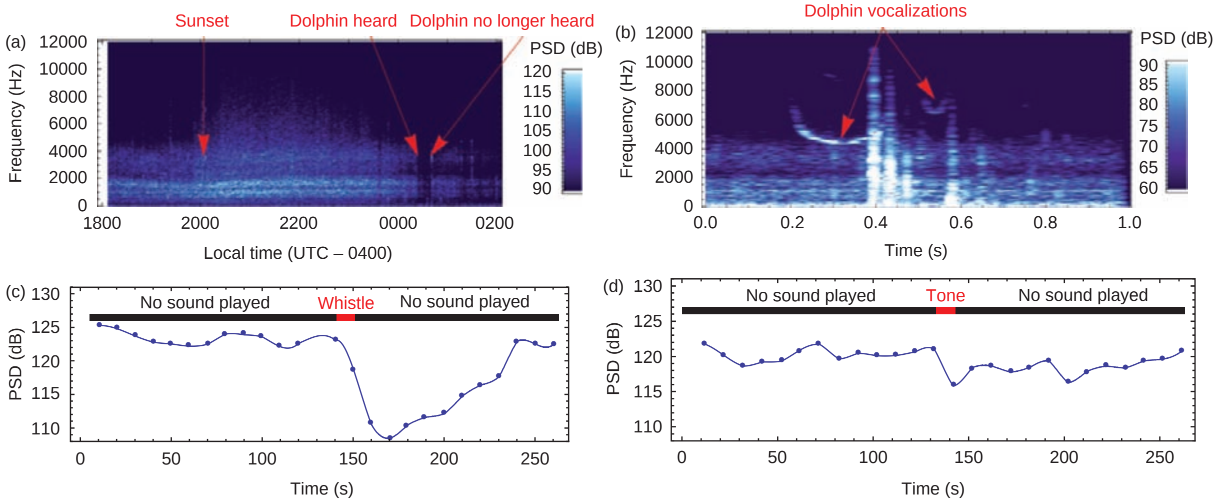

Figure 6 Silver perch, *Bairdiella chrysoura*, acoustic avoidance of bottlenose dolphin, *Tursiops truncatus*, whistles. Power spectral densities (PSDs) given in dB re 1 $\mu Pa^2\ Hz^{-1}$. (a) Composite sonogram showing a silver perch chorus with a sudden quiet period at time 00:24 (24 min after midnight). (b) Sonogram of bottlenose dolphin whistles recorded during the silver perch quiet period in (a). (c) Variation of silver perch loudness, measured by the peak of the power spectrum between frequencies 950 and 1200 Hz, before and after a bottlenose dolphin whistle was played through an underwater speaker. (d) Same measurement as (c) before and after a 700-Hz tone was played through an underwater speaker. Reproduced from Luczkovich JJ, Daniel HJ III, Hutchinson M, et al. (2000) Sounds of sex and death in the sea: Bottlenose dolphin whistles silence mating choruses of silver perch. *Bioacoustics* 11: 323–334.

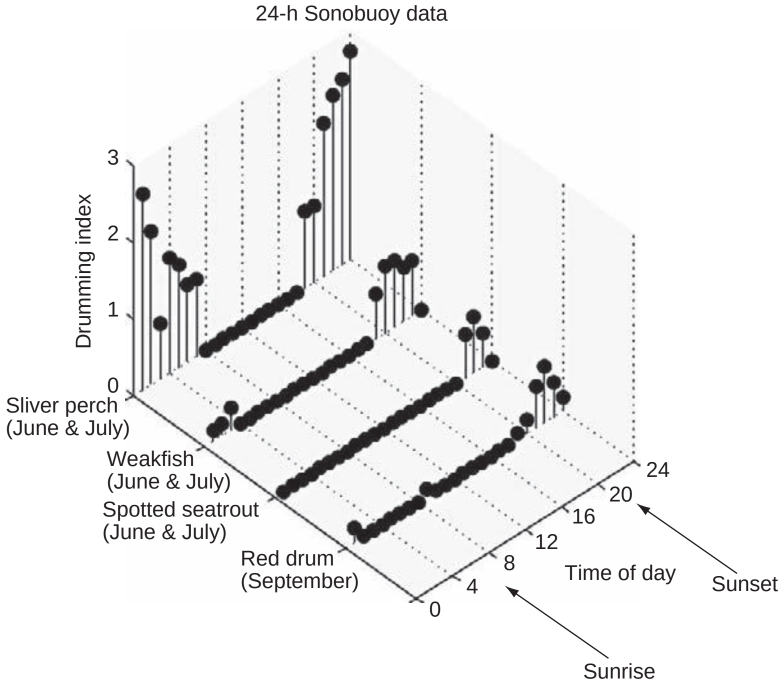

Figure 7 An index of sound production during spawning (drumming index) showing nocturnal and seasonal sound production patterns exhibited by silver perch, *Bairdiella chrysoura*; weakfish, *Cynoscion regalis*; spotted seatrout, *C. nebulosus*; and red drum, *Sciaenops ocellatus*, in Pamlico Sound, North Carolina, USA. An index of 0 corresponds to no fish sound detected, 1 to an individual call detected, 2 to several individual calls detected, and 3 to a chorus of sounds too loud to distinguish individual calls. Reproduced from Luczkovich JJ, Pullinger RC, Johnson SE, and Sprague MW (2008) Identifying sciaenid critical spawning habitats by the use of passive acoutics. *Transactions of the American Fisheries Society* 137: 576–605.

indicating the willingness of the female to spawn. During spawning, a long trail of gametes was observed as the spawning pack swam toward the surface producing a continuous chant (**Figure 9(c)**) during gamete release (**Figure 8(b)**). In this sciaenid species, sound production was made before and during spawning events, and the sound was continuous and loudest during the gamete release.

Female fishes may be able to interpret acoustic signals as a measure of male fitness and use the sounds to choose an appropriate male to fertilize the eggs. The best-studied example of mate choice based on sound production is the plainfin midshipman, *Porichthys notatus* (Batrachoididae). Each summer on the US Pacific coast, plainfin midshipman migrate from deep water to tidepools in the intertidal zone to mate. Males produce a tonal humming sound of 100 Hz with duration lasting from a few minutes to hour-long calls to attract mates. Laboratory experiments have demonstrated that the females are attracted to recorded 100-Hz hums played back alternatively through two underwater speakers. Playback experiments using artificial humming sounds of the same frequency also attract females. When presented with pure tones of various frequencies near the hum frequency, female midshipman showed a preference for 100-Hz tones.

Male damselfishes (Pomacentridae) produce sounds to warn competing males to keep away from their territory and to initiate courtship behavior with a female. In the bicolor damselfish (*Stegastes partitus*), sound playback experiments on a natural reef using males' recorded chirp sounds demonstrated that males use the sound as a warning to other males to keep out. Territory holders can discriminate between neighboring males based on sounds, which carry size-related information (larger damselfish have lower-frequency chirps). Females can also discriminate between males' chirps of different frequencies, choosing the largest males. Male Hawaiian dominos, *Dascyllus albisella*, had significantly longer pulse durations during mating events than when males only were present. During mating, males also complete a signal jump in which they swim upward and then move up and down while producing pulses of sound. Signal jumps differ in interpulse interval, period, pulse duration, and amplitude compared with male aggressive encounters. Signal jumps are related to male vigor and fitness, allowing females to assess a mate using both visual and auditory cues.

Researchers have observed and recorded spawning haddock, *Melanogrammus aeglenus* (Gadidae), in aquaria. Males were observed to participate in several complicated behavioral acts during spawning and courtship, many of which have specific sounds associated with them

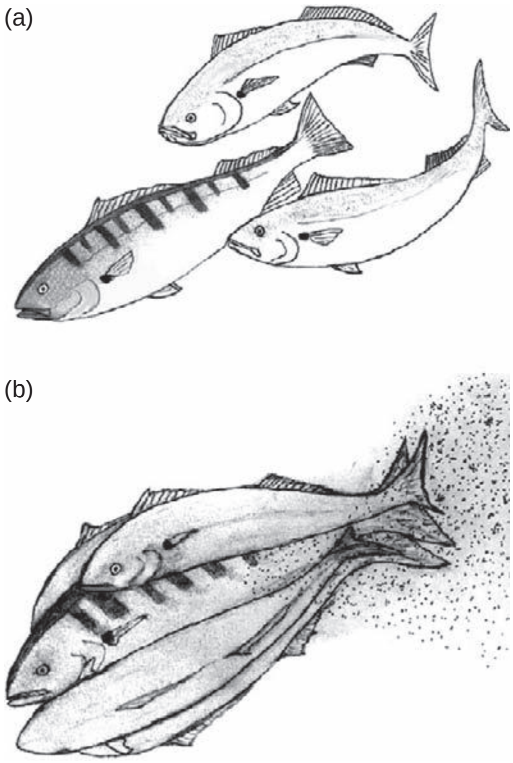

Figure 8 Illustrations of (a) two courting white seabass, *Atractoscion nobilis*, males shadowing and nudging a darkly barred gravid female and (b) a spawning pack of four males and a barred female simultaneously releasing gametes during a broadcast spawning event. Reproduced from Albers SA and Drawbridge MA (2008) White seabass spawning behavior and sound production. *Transactions of the American Fisheries Society* 137: 542–550.

(**Figure 10**). Researchers hypothesized that the associations of distinct sounds with these complicated behaviors are because haddock spawn at depths of over 100 m, where there is little light. Thus, the sounds enhance the visual displays.

Other examples of fishes that produce sound during courtship and mating include the parrotfish, groupers, hamlets, and gobies. In the butter hamlet, *Hypoplectrus unicolor* (Serranidae), both members of a spawning pair are simultaneous hermaphrodites, and both make sounds. The butter hamlet individual acting in the male spawning role (producing spermatozoa) produces an initial courtship sound, a series of 500-Hz pulses. The other individual, acting in the female role (producing eggs), also produces a sound during egg release, which is a frequency-modulated downward sweep (between 600 and 200 Hz), followed by a longer broadband sound (350–1350 Hz). Individuals will then immediately reverse in their mating roles, making the appropriate sounds for their sex role. In striped parrotfish, *Scarus iseri* (Scaridae), group spawning occurs in association with sound production. A spawning rush or upward swimming group of 5–30 individuals of both the sexes produces a low-frequency (30–1200 Hz) broadband sound during the entire spawning event. Grass gobies, *Zosterisessor ophiocephalus* (Gobiidae) are sound producers, having grunting and staccato sounds associated with territorial defense, courtship, and reproduction. Males produce these sounds prior to mating. The frequencies (~330 Hz) of these transient sounds are inversely related to fish size.

Navigation and echolocation

Fishes may use sounds, produced by themselves or other species, as a way of finding their way around. For example, there is evidence that more larval damselfish and cardinalfish (Apogonidae) are attracted to artificial reefs that have sounds of reef animals (fishes, snapping shrimp, and urchins) played through underwater speakers than are attracted to control sites that do not have reef sounds. Larval reef fishes also swim toward the sounds of a coral reef played back through a speaker. Because coral reef sounds can be heard by larvae over a long distance (~100 m), planktonic larval fishes can possibly use sounds as a navigation cue to locate suitable settlement habitats.

It has been suggested that fishes make sounds as a way of learning about the environment around them from the echoes that reflect from the bottom or objects in the sea (**see also Hearing and Lateral Line**: Sound Source Localization and Directional Hearing in Fishes). For example, the sea catfish, *Arius felis* (Ariidae), has been shown experimentally to find its way through a maze with transparent walls, never hitting the walls and all the while making popping sounds; individuals that had been muted by surgically cutting their sonic muscles did not make sounds and did not easily navigate the maze, bumping into the transparent plastic walls (**Figure 11**). Blinded sea catfish were also able to navigate the maze, but did so while making sounds. Deep-sea fishes (families Macrouridae and Moridae) have sonic muscles, unusual inner ear structures with large otoliths, and can produce sounds at great depths (3900 m), loud enough to be detected near the surface by a hydrophone. Sound production by these deep-sea fishes may be used to echolocate in total darkness. Whether fishes actually use sound in this way remains speculative, but is an area of considerable interest.

Sound Production and Ontogeny, Sex Differences

Although fishes produce sounds, this does not occur equally at all life stages or in both sexes. Most studies have identified mature males producing sound, but not females or juveniles. For example, in the drumfish family, weakfish, and spotted seatrout, males produce advertisement calls associated with spawning, but females and immature males do not have enlarged drumming muscles

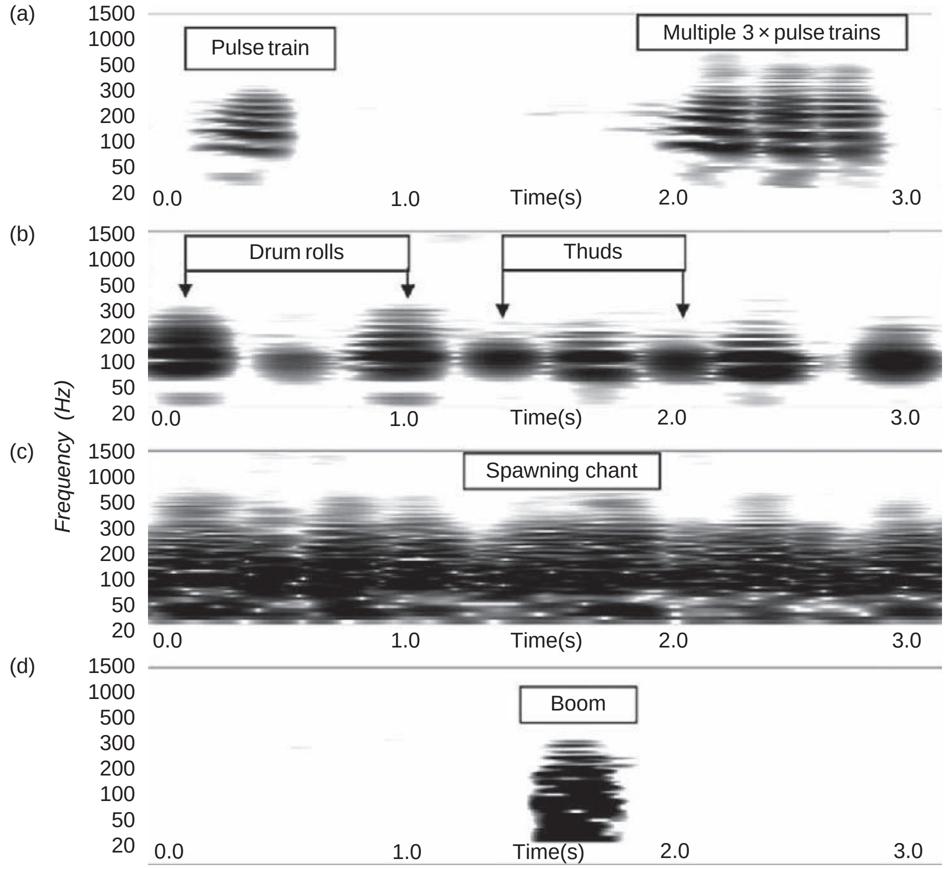

Figure 9 Sonograms displaying: (a) white seabass, *Atractoscion nobilis*, courtship sounds, including single and multiple (33) pulse trains; (b) drumroll and thud sounds produced in rapid succession at the beginning of a spawning event; (c) spawning chant of continuous, overlapping drumroll and thud sounds; and (d) hydrodynamic boom. Sounds recorded from fish held in a net pen in Catalina Harbor, California. Reproduced from Albers SA and Drawbridge MA (2008) *Transactions of the American Fisheries Society* 137: 542–550.

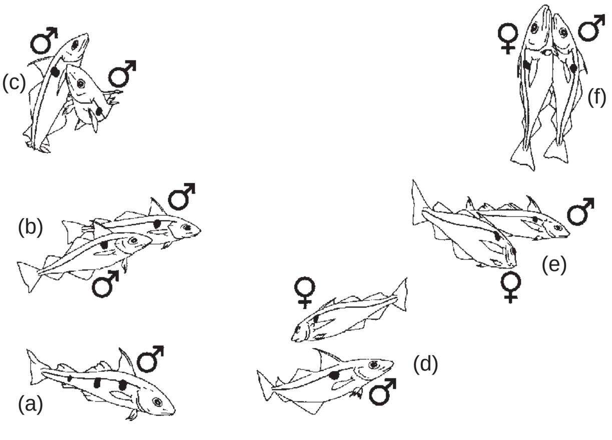

Figure 10 Behavior shown by haddock during courtship: (a) solitary display by a male; (b) lateral display by one male to another; (c) circling of two males in lateral display; (d) lateral display by a male to a female; (e) flicking by a male to a female; (f) mating embrace between male and female, with synchronous release of eggs and milt. From Hawkins AD and Amorim MC (2000) Spawning sounds of the male haddock *Melanogrammus aeglefinus*. *Environmental Biology of Fishes* 59: 29–41.

that are necessary for sound production. This is an example of sexual dimorphism.

In other species (including striped cusk-eel, *Ophidion marginatum* (Ophidiidae), Atlantic croaker, *Micropogonias undulatus* (Sciaenidae), grey gurnards, multiple species of toadfish, midshipmen, and haddock), both sexes produce sound, although differences in anatomy and sound characteristics are apparent. For example, both male and female croaking gouramis, *Trichopsis vittata* (Osphronemidae), produce sounds, but the sounds differ in loudness and spectral characteristics when mating and in agonistic encounters. Female croaking gouramis initiate courtship by producing low-intensity purring sounds, the only species documented to do this.

Sound production in juvenile fishes has not been well studied. Juvenile Lusitanian toadfish, *Halobatrachus didactylus* (Batrachoididae), can produce territorial sounds when they have reached 38 mm in standard length. Atlantic croakers have been shown to have sonic muscles at a standard length of 45 mm and the ability to produce sounds prior to maturity. It has been shown that sounds become louder and lower in frequency as these fishes

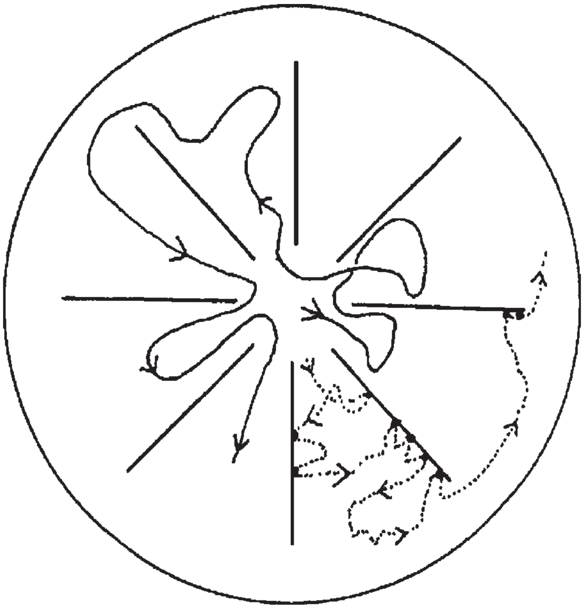

Figure 11 The maze-swimming behavior of sea catfish, *Arius felis*, a normal, sound-producing individual (solid line), and one of a group of eight muted individuals (dashed line). Reproduced from Fig. 6 in Tavolga WN (1976) Acoustic obstacle detection in the sea catfish (*Arius felis*). In: Schuijf A and Hawkins AD (eds.) *Sound Reception in Fishes*, pp. 185–204. Amsterdam: Elsevier, with permission from Elsevier.

grow. There are also differences in the rates of pulsing between juveniles and adults of the same species. These acoustic differences by different life stages may be indicative in changes of behavior (e.g., fighting vs. mating) for these species.

Sound production can vary within a species and sex. Two types of males occur in plainfin midshipman (types I and II), each having different vocal patterns and reproductive strategies. Type I males make the 100-Hz humming sound as an advertisement call to attract females to a spawning nest. Type II males do not make these humming advertisement sounds. Both types of males produce grunts, which are used in agonistic encounters. Instead of initiating courtship behaviors through the hums, type II males will instead employ a sneaker strategy in that they enter the nest of a type I male and spawn with the female, while the type I male is engaged in territorial defense with another type I male. Thus, sound production in midshipman depends upon genetic factors and the physiological state of the males (types I and II, spawning or fighting). Grass gobies also exhibit differences in sound production associated with the alternative reproductive strategies of males: small sneaker males had small dorsal fins, higher frequency (415 Hz), and quieter sounds, while large territory defenders had elongated second dorsal fins, lower-frequency sounds (299 Hz), and louder (by 10 dB) sounds.

Sound Production as a Fishery Management Tool

Scientists have used hydrophones and sound recorders to locate spawning grounds by documenting fishes making sound in the natural environment. Many such studies have been done in association with routine biological sampling, such as egg and larval fish collections using plankton nets, or adult fishes captured by trawl nets and angling. The results of such studies suggest that economically important fishes in the families Sciaenidae, Serranidae, and Gadidae make sound primarily in spawning periods and that sounds can be used as a proxy for spawning behavior. Pelagic egg abundance and sound production of fishes are correlated, both increasing during the mating period. For example, weakfish along the US Atlantic Coast has been shown to increase its sound production during mating periods in May through July each year, when their gonadal development stages are greatest. In addition, the drumming muscles in the male weakfish were also highly developed at that time, due to increased blood levels of testosterone. These results suggest that spawning activities are associated with sound production by male weakfish.

Conclusion

Sound production plays an important role in the survival, social organization, mating success, and navigation capabilities of fishes in dark and turbid aquatic environments. There is a need for more studies linking sound production and specific behaviors in species known to make sound and many more undescribed sound-producing species. Various types of sounds (pulsed and tonal) are produced in association with specific behavior by over 700 species of fishes. Different sounds are produced at different maturity and life stages, with pulsed sound frequencies declining as an individual gets larger. Although most sound producers are males, in some species both sexes make sounds that differ in characteristics.

New technologies based on digital sampling hydrophones connected to automated sound recorders are being used to assess variation in sound production during the day and seasonally, allowing spawning times to be determined remotely. Use of passive acoustic monitoring, combined with active sonar and traditional methods of sampling, can help assess habitat use, size of individuals, and the spawning stock size for economically important sound-producing species and improve fisheries management practices. Scientists now regularly listen to fishes and can identify the species making the sound, their size, and something about their natural behaviors, even when the conditions prevent visual observations. The use of sound by fishes is essential for their survival; humans now appreciate this importance and use it as an aid in conservation of fishes.

Glossary

Extrinsic drumming muscles A sound-generating muscle that is not entirely attached to the swimbladder, but has its origin on other skeletal structures such as ribs, vertebral processes, or tendons.

Intrinsic drumming muscles A sound-generating muscle that is entirely attached to the swimbladder.

Pectoral girdle/pectoral fin tendons The pectoral girdle connects the anterior appendage (fin or forelimb) to the axial skeleton. Some fishes vibrate a pair of tendons attached to pectoral fin to generate sounds.

Pectoral spine First-enhanced fin ray in catfishes which is used for defense when locked in a perpendicular position and for sound production when rubbed in a groove of the shoulder girdle.

Sonic/vocal motor nuclei Clusters of motor neurons whose cell bodies (somata) form a motor nucleus (not to be confused with the nucleus inside of a cell) that is located in the hindbrain and/or spinal cord of the central nervous system.

Introduction

The diversity of vocalizations and vocal organs among fishes is discussed first, followed by a focus on how sound-producing muscles and the central nervous system (CNS) determine the physical properties of vocal behaviors. Historically, the sound-producing systems of fishes were only referred to as sonic. These systems are also referred to here as vocal, and the associated behaviors as vocalizations, because of the development of the vocal control systems in similar regions of the CNS in both fishes and other vertebrates (see section Vocal Neuron Control).

Vocalizations

Fishes vocalize in various behavioral contexts such as when they are caught, defending territories such as nests, when advertising nest sites, and during courtship and mating (**see also Hearing and Lateral Line**: Acoustic Behavior and **Sensory Systems, Perception, and Learning**: How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling). We estimate that approximately a third of all living fish species vocalize. Given the approximately 30 000 or more species of living fishes, there are more vocal species among fishes than among either mammals or birds. The vocalizing species identified so far belong to the bony fishes that include two major clades known as Actinopterygii and Sarcopterygii (also includes tetrapods). The majority of vocal fish are actinopterygians and include the basal groups of African bichirs (Polypteridae) and sturgeons (Acipenseridae) and the more recently evolved teleosts that comprise the vast majority of actiniopterygians. Jawless (Cyclostomata – lampreys and hagfish) and cartilaginous (Chondrichthyes – sharks, skates, rays, and chimaeras) fishes that are more primitive than bony fishes are not known to vocalize.

The vocalizations of fishes, like those of other vertebrates, vary in their spectral (frequency content) and temporal (e.g., duration and call rate) properties. As discussed in more detail in the next section, most fishes produce sound either by vibrating fast-contracting muscles attached to gas-filled swimbladders or by vibrating some part of the pectoral girdle or fins. Swimbladder or drumming sounds are usually brief (on the order of milliseconds), with the primary energy only a few hundred hertz (**Figures 1(a) and 1(b); Figures 2(a)–2(c)**). Each sound pulse results from a single contraction of the swimbladder muscles. Multiple sound pulses make up a single call that can vary widely in duration and energy content at one or more frequencies. Multi-harmonic signals have a tonal quality with energy peaks at a fundamental

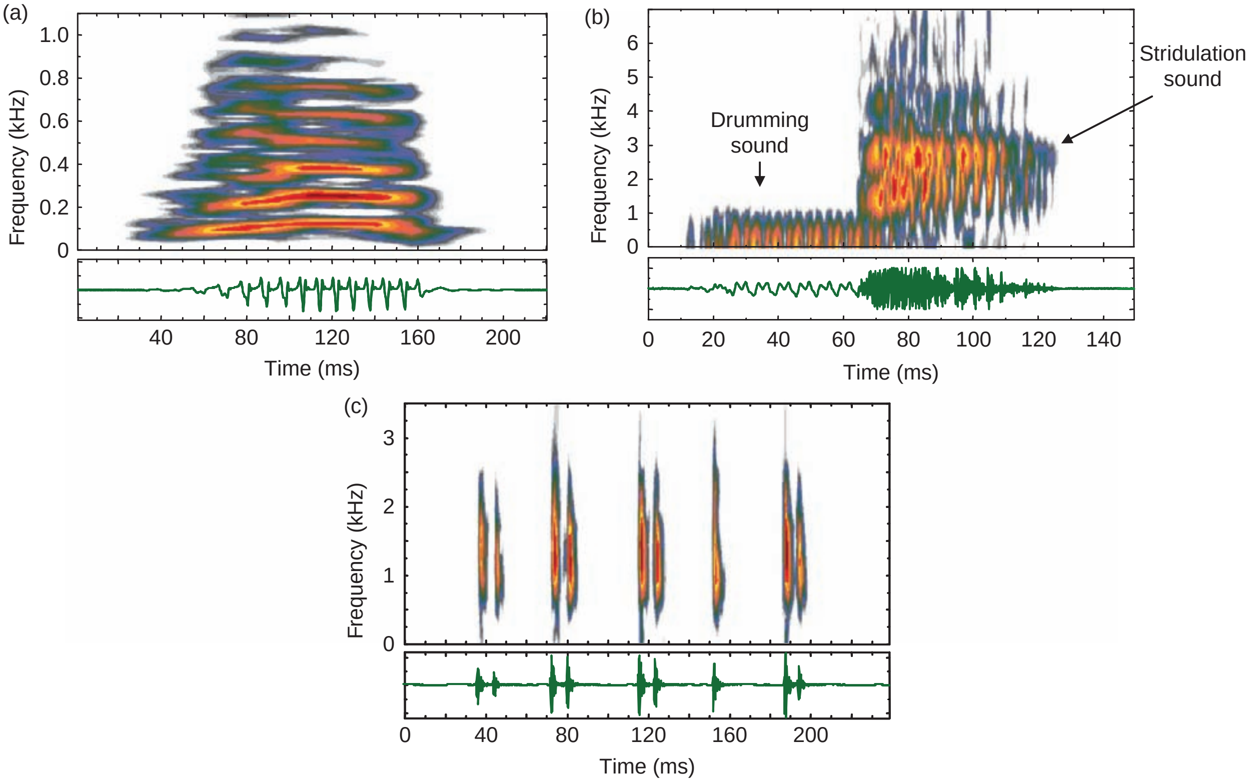

Figure 1 Sonagrams (or spectrograms, above) and waveforms (or oscillograms, below) of vocalizations emitted by various fish species and various sound-generating mechanisms. The sonogram or spectrogram displays the amount of sound energy at each of the frequencies that comprise the call (top) and an oscillogram trace shows the time-varying waveform. (a) A low-frequency multi-harmonic sound produced by drumming muscles in a piranha (*Pygocentrus nattereri*). The main sound energy is concentrated at approximately 200–300 Hz (red color; sound sample, **Sound Clip 1**). (b) A sound produced by a long-whiskered catfish (*Pimelodus blochii*). In the second part the sound, energies are found up to several kilohertz (sound sample, **Sound Clip 2**). (c) A croaking sound emitted during agonistic behavior in a croaking gourami (*Trichopsis vittata*) (sound sample, **Sound Clip 3**).

frequency and at harmonics that are integer multiples of the fundamental (**Figure 1**(**a**); (**Sound Clip 1**); **Figures 2**(**a**) and **2**(**b**)). Some swimbladder drumming sounds are referred to as nonharmonic signals because energy is spread over a broad range of frequencies rather than being concentrated in discrete energy bands; hence, these signals are often referred to as broadband (**Figure 2**(**c**)).

The vocal repertoire of the plainfin midshipman (*Porichthys notatus*), a species that belongs to a larger group of vocal fish known as toadfishes (Batrachoididae), exemplifies the range of call types produced by fishes (**Figure 2**; **Sound 4–6**). During the breeding season, nesting males emit long-duration, multi-harmonic hums that can last for more than 1 h and are used to attract females to their nest. Males also produce very brief, broadband grunts that last for about 100 ms during agonistic encounters. Grunts are often produced in succession to form grunt trains. Males also produce agonistic growls that are essentially a mix of hums and grunts.

The calls of species that vibrate the pectoral fins (stridulation) are generally pulsatile, but typically have a higher frequency content than swimbladder-associated sounds. Pectoral sounds are broadband, with their primary energy close to or greater than 1 kHz. Swimbladder/drumming and pectoral/stridulation sounds may be produced in series or simultaneously as by some catfish (**Figure 1**(**b**); **Sound Clip 2**); Croaking gouramis (*Trichopsis vittata*, Osphronemidae) generate a series of high-frequency double pulses called croaks (**Figure 1**(**c**); **Sound Clip 3**) Long (150–200 ms) and loud croaks are produced by both sexes when defending territories, while brief, lower-intensity sounds are emitted by females prior to mating.

Vocal Organs

The main group of sound-generating mechanisms among fishes involves the swimbladder. The swimbladder (**see also Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes) can be vibrated in numerous ways by a pair of muscles variously called drumming, sonic, or vocal muscles.

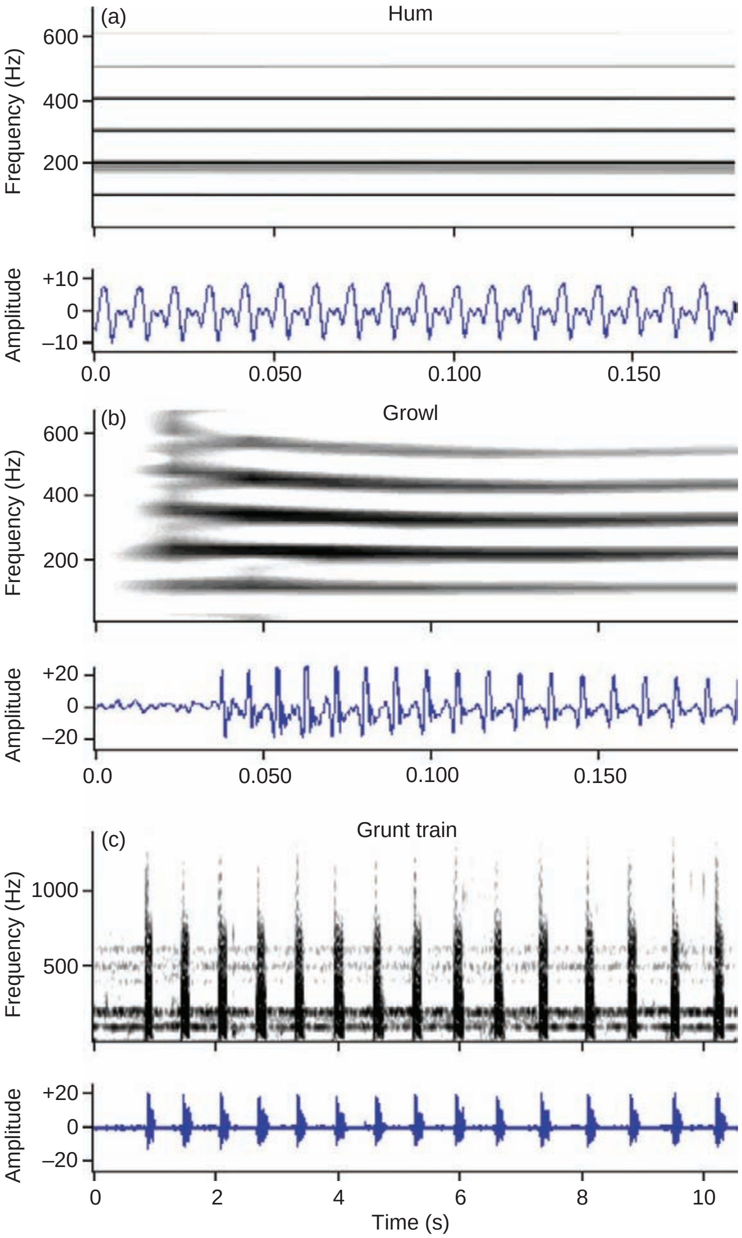

Figure 2 Male plainfin midshipman fish (*Porichthys notatus*) produce three major classes of vocalizations – hum, growl, and grunt train. (a) This hum has a fundamental frequency of 102 Hz with several harmonics (sound sample, **Sound Clip 4**). (b) The growl begins with a grunt region followed by a hum-like region (sound sample, **Sound Clip 5**). (c) The grunt train shows a series of grunts (sound sample, **Sound Clip 6**). Recordings by Marchaterre, MA, Cornell University. From Bass AH and Clark CW (2003) The physical acoustics of underwater sound communication. In: Simmons AM, Fay RR, and Popper AN (eds.) *Acoustic Communication*, pp. 15–64. New York: Springer, with kind permission of Springer Science+Business Media.

Drumming muscles, which are among the fastest contracting striated muscles known among vertebrates, vibrate swimbladders at high rates (50–250 Hz). Based on the origin and insertion of these muscles on parts of the musculoskeletal system, several types of swimbladder mechanisms may be distinguished.

Drumming muscles often have a direct connection to the swimbladder. Intrinsic drumming muscles are entirely attached to the walls of the swimbladder, as found in toadfishes (**Figure 3(a)–3(c)**). Extrinsic muscles originate on a part of the musculoskeletal system other than the swimbladder, but insert either directly or indirectly via tendons or bones on the bladder. For example, the tigerfish (*Terapon jarbua*, Terapontidae) has muscles originating on the medial surfaces of the dorsal part of the shoulder girdle (supracleithra) connected to the skull, and inserting dorsally on the anterior half of the swimbladder (**Figure 4**). The pimelodid catfish (*Pimelodus* sp., Pimelodidae) has muscles

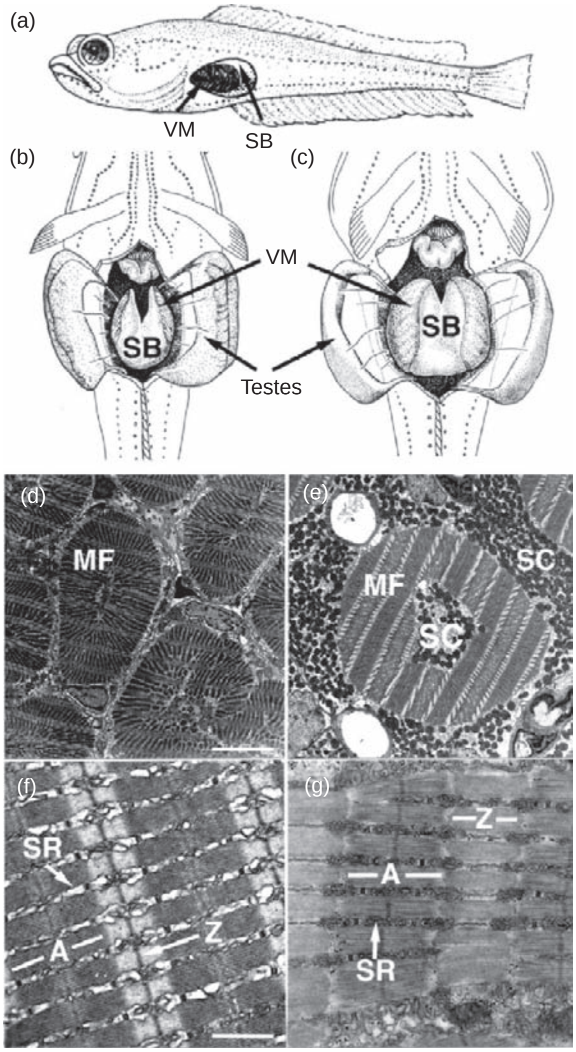

Figure 3 Intrinsic, swimbladder drumming muscles differ between male morphs in the midshipman fish, *Porichthys notatus*. (a) Drawing of a side view shows the location of the swimbladder (SB) with attached vocal muscles (VM). (b, c) Drawings of ventral views with the VMs attached to the SB in a type II, sneaker male (b) and a type I, humming male (c). (d–g) The fine structure of the vocal muscle in type II (d, f) and type I (e, g) males as viewed with an electron microscope. (d, e) As shown in cross section, the muscle fibers of type II (d) and type I (e) males are tubular in shape and include a large region of myofibrils (MF). The myofibrils of type II males are surrounded by a thin band of sarcoplasm (SC) that contains nuclei and mitochondria. The fibers of type I males have a ring of myofibrils with central and lateral zones of SC filled with mitochondria. (f, g) As viewed along the length of a single muscle fiber of a type II (f) and a type I (g) male, the width of Z-lines and the degree of branching of the sarcoplasmic reticulum (SR) are greater in type I males. Scale = 6 μm in (d) and (e), and 0.8 μm (f) and (g). New York: Academic Press. (d–g) Modified from Bass AH and Marchaterre MA (1989) Sound-generating (sonic) motor system in a teleost fish (*Porichthys notatus*): Sexual polymorphism in the ultrastructure of myofibrils. *Journal of Comparative Neurology* 286: 141–153.

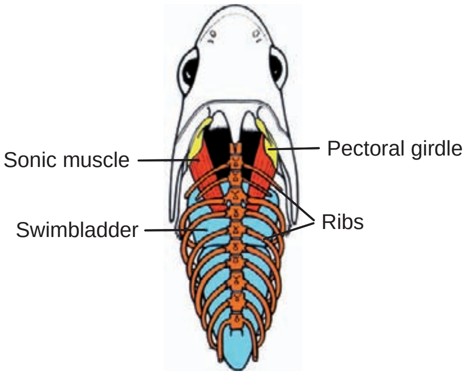

Figure 4 Line drawing of dorsal view showing sound generating mechanisms in the tiperperch (*Terapon jarbua*). The sonic/vocal muscle originates at the pectoral (shoulder) girdle and inserts on the dorsal surface of the swimbladder immediately beneath the anterior ribs. Contractions of the muscle results in sound production. Modified from Zupanc GKH (1982). *Fische und ihr Verhalten*. Melle: Tetra Verlag

originating on a lateral process of the vertebral column and inserting on the swimbladder ventrally (see **Figure 5**(**d**)).

In other cases, sound-producing muscles lack any direct connections to the swimbladder. There is a wide range of such indirect mechanisms. The muscles in black and red piranha (*Serrasalmus rhombeus and Pygocentrus nattereri*; Characidae) originate on the second rib and insert on a broad tendon that surrounds the swimbladder ventrally, similar to the band that wraps around a horse to hold a saddle in place (**Figure 6**). In the unrelated drums and croakers (Sciaenidae), drumming muscles originate on the body wall lateral to the swimbladder and insert on a broad tendon surrounding the dorsal part of the swimbladder. In the jaraqui (*Semaprochilodus insignis*, Prochilodontidae), a close relative of piranhas, the swimbladder is vibrated via large muscles extending between the ribs, allowing these fish to produce loud evening choruses in the Amazonian river system where they live. Several catfish families have bony plates called elastic springs that vibrate the swimbladder. In thorny (Doradidae) and upside-down (Mochokidae) catfishes, drumming muscles pull a disk-shaped elastic spring forward (**Figures 5**(**a**) **and 5**(**b**)), extending the bladder. In sea catfishes (Ariidae), the elastic spring is concave-shaped and pointed (**Figure 5**(**c**)).

The second major group of vocal mechanisms in fishes depends on vibration of either the pectoral/shoulder girdle or the modified pectoral fins. In sculpins (Cottidae), a group that lacks a swimbladder, the entire shoulder girdle is vibrated by muscles extending from the skull to the dorsal edge of the shoulder girdle. Several catfishes possess an enhanced first pectoral fin ray known as the pectoral spine. The friction process of the base of the pectoral spine is rubbed in a groove of the shoulder girdle (**Figure 7**(**a**)) that results in a series of pulsed, high-frequency, stridulatory-like sounds (**Figure 1**(**b**)). Croaking gouramis generate a pair of

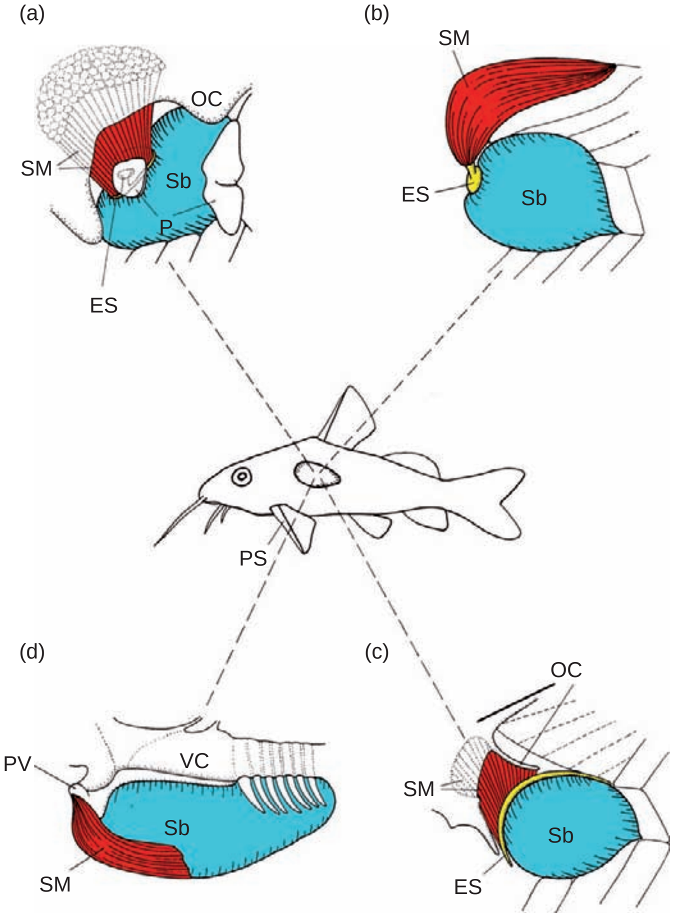

Figure 5 Diversity of sonic/vocal muscles associated with the swimbladder in catfishes. (a) In thorny catfishes (Doradidae), the sonic muscles (SM) originate at the occipital bone (OC) and insert on a bony plate (elastic spring ES) that touches the swimbladder (Sb). The ES is connected via a tendon to a dermal plate (P). (b) In upside-down catfish, the sonic muscle originates in the dorsal musculature and inserts on a small, round ES. (c) In sea catfish, the ES is a broad and pointed bony plate which surrounds the swimbladder dorsally and anteriorly. (d) In pimelodid catfishes, the sonic muscles originate on a process (PV) of the vertebral column (VC) and insert on the swimbladder ventrally. PS, pectoral spine. Modified from Ladich F and Fine ML (2006) Sound generating mechanisms in fishes: A unique diversity in vertebrates. In: Ladich F, Collin SP, Moller P, and Kapoor BG (eds.) *Communication in Fishes*, vol. 1, pp. 3–43. Enfield, NH: Science Publishers.

sound pulses using two enhanced pectoral fin tendons that are stretched during the forward movement (abduction) of the fin and plucked over enhanced bases of fin rays (**Figure 7(b)**). When pectoral fins are beaten alternately, a series of double pulses called croaking sounds are emitted.

Though less well studied, sound also can be produced by other musculoskeletal adaptations. For example, the clownfish (*Amphiprion*, Pomacentridae) makes sounds when the mouth is rapidly shut by a sonic ligament, followed by the collision of teeth. Seahorses (Syngnathidae) generate clicking sounds by rubbing posterior head and neck bones against each other.

There is no clear evolutionary relationship between fish systematics and the diversity of sound-producing mechanisms. Sonic/vocal organs are either a characteristic of an entire order such as the intrinsic drumming muscles in toadfishes, or can occur in only three species in one genus within a suborder, such as tendon plucking in croaking gouramis.

Sexual Dimorphisms in Sound-Producing Muscles

Sound-producing muscles vary in development between sexes. They may be similarly developed in both sexes such as in the croaking gourami (*Trichopsis vittata*), can be much smaller in females such as in the pygmy gourami *T. pumila*, or can be completely absent in one sex such as in the females of several species of drumfishes. The descriptions of sex differences in pectoral mechanisms are few.

Sexual dimorphisms in drumming muscles are best known for the intrinsic muscles among toadfishes (**Figures 3(a)–3(c)**), as exemplified by midshipman fish that have two types of males. Territorial males, known as type I males, build nests under rocky shelters in the intertidal zone from where they produce long-duration, hum advertisement calls to attract females (**Figure 2(a)**). A second group of males (type II) either sneak or satellite spawn. Although neither

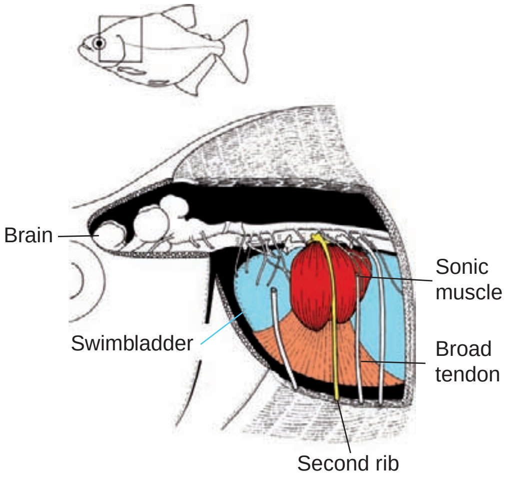

Figure 6 Line drawing of lateral view showing swimbladder region of a black piranha (*Serrasalmus rhombeus*) (insert) and the sonic/vocal muscle in more detail (lower drawing). The sonic muscles originate dorsally at the second rib and insert ventrally at a broad tendon surrounding the swimbladder ventrally. Figure 7 Line drawings of pectoral sound-generating mechanisms. (a) Stridulatory mechanism in catfishes. This lateral view of the left pectoral girdle in a pimelodid catfish shows the shoulder girdle (SG), the enhanced first fine ray (PS, pectoral spine) and the dorsal friction process (FP) with a series of ridges. (b) Pectoral tendon plucking mechanism in the croaking gourami. Contraction of the sonic muscle (SM) results in stretching of both enhanced tendons (ET) and abduction of fin rays (FR). Adapted from Ladich F (2004) Sound production and acoustic communication. In: van der Emde G, Mogdans J, and Kapoor BG (eds.) *The Senses of Fishes: Adaptations for the Reception of Natural Stimuli*, pp. 210–230. New Delhi: Narosa Publ. House.

type II males nor females generate hums, they generate grunts (which type I males also produce, **Figure 2(c)**). The sound-producing muscles of the humming, type I male are sixfold larger than those of females and type II males (e.g., **Figures 3(b)** and **3(c)**). The tubule-shaped muscle fibers have alternating bands of overlap and nonoverlap between thick and thin filaments that gives a striated appearance like other skeletal muscles (**Figures 3(d)–3(g)**). Only type I males have enlarged central and peripheral zones of sarcoplasm (muscle fiber cytoplasm) that are densely filled with mitochondria, clearly adapted to providing energy during their long bouts of humming (**Figures 3(d) and 3(e)**). Type I male muscle fibers differ in other anatomical traits that likely reflect biomechanical adaptations related to humming (see **Figures 3(f)** and **3(g)**).

Vocal Neuron Control

Fishes, like other vertebrate groups, have a vocal control system in the CNS (**Figure 9(a)**). Muscle contraction is evoked by excitation from clusters of nerve cells (motor neurons) that form a sonic or vocal motor nucleus (not to be confused with the nucleus inside of a cell). The sonic/vocal motor nuclei (VMNs) are bilaterally symmetrical; each nucleus elicits the contraction of the sonic muscle on the same side of the body.

There are three major patterns of organization for the VMN of fishes. The first pattern, like that found among all toadfishes (**Figure 9(b)**), has the VMN positioned in the posterior hindbrain and/or anterior spinal cord. A second pattern shows the VMN forming a column along the ventral border of the hindbrain and spinal cord. In contrast,

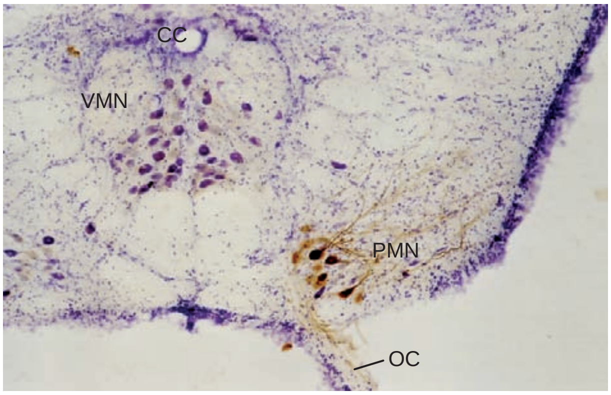

Figure 8 Photomicrograph of neurons (brown) and fibers in brainstem of the mochokid catfish, *Synodontis nigromaculatus*, showing the location of vocal motor neurons. Nonlabeled, swimbladder vocal motor neurons (VMN) are on the midline below the central canal (CC). Labeled pectoral spine motor neurons lie within the ventrolateral motor column (PMN). Axons of the PMN exit the brain via the occipital nerve (OC). From Fine ML and Ladich F (2003) Sound production, spine locking, and related adaptations. In: Arratia G, Kapoor BG, Chardon M, and Diogo R (eds) *Catfishes*, vol. 1, pp. 249–290. Enfield, NH: Science Publishers.

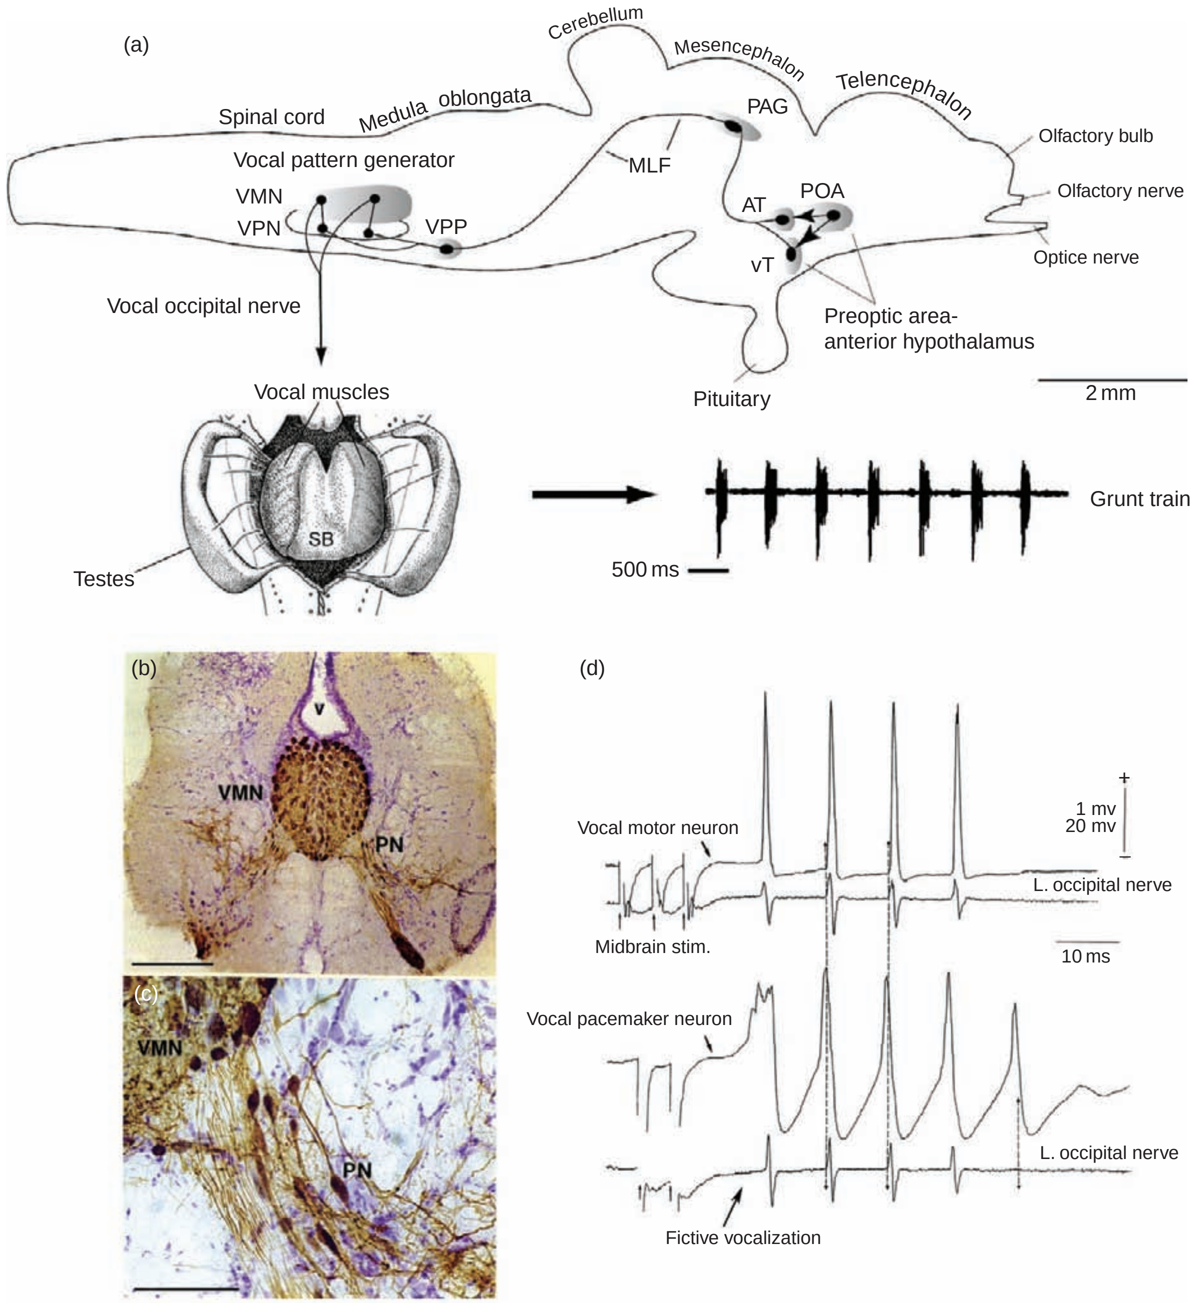

Figure 9 Vocal pattern generator in the midshipman fish, *Porichthys notatus*. (a) Side view of the brain showing vocal network. Solid dots represent the somata of neurons, and lines represent connections between neuron populations (nuclei). Two connected dots indicate reciprocal connections. (a) Nuclei in the preoptic area (POA) and anterior hypothalamus (ventral tuberal nucleus (vT); anterior tuberal nucleus (AT)) send axons to the periaqueductal gray (PAG) in the midbrain. The PAG connects to the vocal pattern generator that extends between the posterior hindbrain and anterior spinal cord, and consists of vocal prepacemaker (VPP), pacemaker (VPN), and motor (VMN) nuclei. VMN axons innervate, via occipital nerve roots, the vocal swimbladder muscles. The arrow points to a grunt train that is produced by a type I male when defending his nest (see **Figure 2**). (b, c) Morphology of the vocal pattern generator. Following application of a compound known as biocytin to the cut end of the nerve that innervates a single vocal muscle, both VMNs and the adjacent pacemaker neurons (PN) are labeled (v, fourth ventricle). Scale = 300 μm in (b)' and 75 μm in (c). (d) Vocal neuron physiology. Shown here are intracellular recordings from single vocal motor and pacemaker neurons following electrical microstimulation in the PAG (see (a)'). Each trace is the average of four. Both intracellular records from neurons (top) and intracranial records (bottom) from the left occipital nerve are shown. The nerve records are referred to as fictive vocalizations because they directly determine the fundamental frequency and duration of natural calls. The fictive call evoked here equals a single grunt. Small arrows at the beginning of the lower traces indicate the beginning of electrical microstimulation that evokes a fictive call. The highly synchronous discharges of the occipital nerve are aligned (vertical lines) with the intracellular recordings to show the similar timing in the firing of pacemaker and motor neurons. Timescale and direction of polarity for all electrical records are indicated. (a) From Forlano PM, Marchaterre MA, Deitcher DL, and Bass AH (2010) Distribution of androgen receptor mRNA expression in vocal, auditory and neuroendocrine circuits in a teleost fish. *Journal of Comparative Neurology* 518: 493–512. (b, c) Adapted from Bass AH, Horvath BJ, and Brothers, E (1996) Nonsequential developmental trajectories lead to dimorphic vocal circuitry for males with alternative reproductive tactics. *Journal of Neurobiology* 30: 493–504. (d) Adapted from Bass AH and Baker R (1990) Sexual dimorphisms in the vocal control system of a teleost fish: Morphology of physiologically identified cells. *Journal of Neurobiology* 21: 1155–1168.

catfishes, such as mochokids and pimelodids with two sound-generating mechanisms, have both a midline nucleus associated with a swimbladder mechanism and a far ventral nucleus associated with a pectoral spine mechanism (PMN, **Figure 8**). A third pattern, found in piranhas and a few other taxa, shows swimbladder muscles innervated solely by spinal motor neurons (not shown).

The vocal motor system has been best studied in toadfishes that have an expansive VMN (**Figures 9(a)** and **9(b)**). The VMN is controlled by other CNS nuclei that together form a vocal motor network. Premotor neurons, called pacemaker neurons (PNs) because they determine the firing rate of motor neurons, are adjacent to the VMN (**Figures 9(b)** and **9(c)**). PNs receive input from a prepacemaker nucleus (VPP, **Figure 9(a)**) that is turned on by other vocal nuclei (**Figure 9(a)**, see legend for abbreviations). Together, VPP and PN directly determine the duration and fundamental frequency of vocalizations.

Studies of larval midshipman and toadfish show that the vocal premotor–motor circuit develops in a segment-like region across the hindbrain–spinal transition. A phylogenetic analysis shows that this pattern is highly conserved between fish, as well as in all the other major lineages of sonic vertebrates – amphibians, reptiles, birds, and mammals (including primates). Thus, the vocal basis for acoustic communication appears to have evolved from an ancestrally shared, developmental compartment originating prior to the evolutionary origin of the group of fishes that gave rise to tetrapods.

Concluding Comments

Fish, like all other major groups of sound-producing animals, vocalize in a wide range of social contexts including territory defense and mate attraction. Fish make sound mainly by vibrating muscles attached to either the swimbladder or parts of the pectoral skeleton. Unlike terrestrial vertebrates, they do not produce sounds with a vocal organ that involves the vibration of membranes in an airflow as in the larynx of amphibians, reptiles, and mammals or the syrinx of birds. However, the muscles used for these functions, like the neural systems used to control sound frequency and duration, have similar evolutionary developmental origins among fishes and terrestrial vertebrates. Given that sound production is widespread among the more than 30 000 species of fish, the work reviewed here represents studies of a very small sample size. There remains much to learn about how and why this remarkably successful group of vertebrates makes and uses sound to reproduce and survive.

Glossary

Cupula A gelatinous structure covering the hair cells of a neuromast.

Innervation The nerves that carry information to or from a sense organ or muscle.

Mechanosense A sense that encodes a mechanical stimulus.

Neuroethology The combined study of behavior (ethology) and its neural basis.

Neuromast The functional unit of the lateral line consisting of a patch of hair cells, supporting cells and the overlying cupula. Motion of the cupula relative to the sensory cells results in stimulation of the lateral line.

Papillate Describing neuromasts that are located on small skin protuberances.

Rheotaxis Orientation to water currents.

Introduction

In his history of lateral line studies, the great Dutch twentieth-century physiologist Sven Dijkgraaf distinguishes two senses of the phrase 'the function of a sense organ'. The first is the function of the sense organ in the life of the animal as a whole. How does it serve in the quest for food or mates? The second relates to the functional properties of the sense organ itself and its ability to detect and code specific aspects of the stimulus. Although the structural features of a sense organ provide useful insight into function, full characterization requires direct recording of the electrical responses of the sense cells and their afferent nerve fibers. These fibers transmit sensory information from the sense organs to the brain in the form of action potentials that propagate along the nerve. The frequency and temporal pattern of these events represent the output of the sense organs, the input to the brain, and the sensory code for whatever has been sensed. Although electro- or neurophysiology is essential for our understanding of how a sensory system works, Dijkgraaf rightly points out that, neurophysiology does not give conclusive evidence that any particular applied stimulus and observed response has biological relevance. A biologically relevant understanding of a novel sensory system requires a combined approach of neurophysiology and behavior (ethology), which has become the field of neuroethology (**see also Hearing and Lateral Line:** Psychoacoustics: What Fish Hear).

To illustrate these issues, consider being faced with an alien animal (**Figure 1**). The ventral surface of the body has a recognizable mouth and nostrils, but otherwise is covered with numerous pin-sized holes from which canals disappear into the body, and a series of complex subepidermal canals that can be revealed by injection with blue ink. What is the function of these structures? How could one find out?

When these structures were first discovered, they were considered to be the mucus-producing organs. It was not until their innervation was described and examined electrophysiologically, that the sensory nature of these structures was revealed. Neurophysiological characterizations alone, however, proved inconclusive, as these structures responded to many different things, including tactile, thermal, chemical, and electrical stimuli. It took detailed behavioral studies to effectively delineate the function of these structures, which turned out to be a part of not one, but two separate sensory systems: an electrosensory system that senses weak electrical currents (**see also Detection and Generation of Electric Signals:** Morphology of Electroreceptive Sensory Organs) and a mechanosensory lateral line that senses water movement. The discovery process itself, more thoroughly documented on the electrosensory side, is a beautiful illustration of how powerful combined neurophysiological and behavioral approaches can be in elucidating function.

A neuroethology approach thus provides the best insight into how an unfamiliar sensory system such as

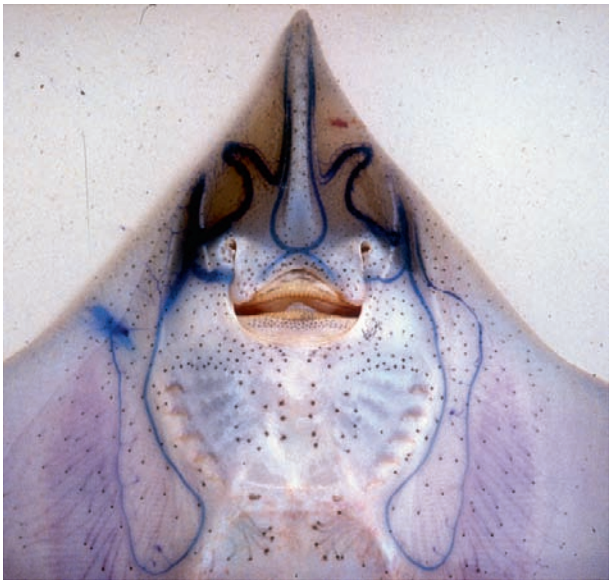

Figure 1 Ventral surface of a skate (*Raja nasuta*). Lateral line canals are injected with blue ink (injection site visible on left side of the figure). Electrosensory pores are pigmented in this species. Note the distribution of both systems around the mouth.

the lateral line provides biologically useful information, and how this information is processed by the brain to guide behavior. Neuroethologists also recognize that function is often best revealed in animals with peculiar (to humans) behavioral and sensory adaptations. For example, a lot has been learned about the neuroethology of the lateral line by studying nocturnal fish with visual limitations and other surface-dwelling species that feed on surface insects. At the same time, it is important to recognize that all fish possess a lateral line, so this sense is likely to provide important (if yet unrevealed) contributions to many aspects of fish behavior. At the most basic level, biological behavior is all about mating, feeding, and moving about safely (and cheaply) in between times. Hydrodynamic information encoded by the lateral line has been shown to play a critical role in each of these behaviors. However, we will concentrate on movement and feeding, as covered in separate sections below.

Movement and the Response Characteristics of Lateral Line Submodalities

If a fish sits facing into a slow uniform flow, or glides in still water, there is a uniform and predictable flow of water over the body. As described in **Hearing and Lateral Line:** Lateral Line Structure, there is a submodality of the lateral line (superficial neuromasts (SNs)) that is anatomically suited to the detection of these flows (**Figure 2**).

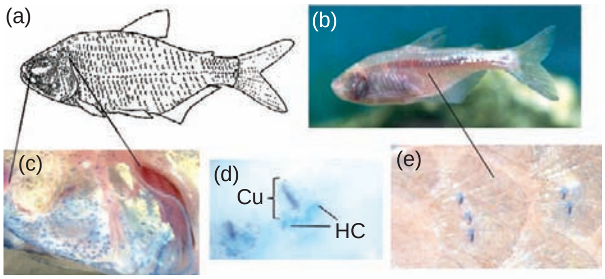

Figure 2 Distribution of SNs (small dots) and canal pores (open circles) (a) on a blind cavefish (*Astyanax fasciatus*) (b). Methylene blue-stained cupulae (Cu) and underlying hair cells (HC) in SNs on the head (c),(d) and trunk scales (e) of a blind cavefish. Line drawing in (a) from Schemmel C (1977) Zur Morphologie Und Funktion Der Sinnesorgan Von Typhilasina Pearsi (Hubbs) (Ophidioidea, Teleostei). Zoo*morphology* 87: 191–202.

From a behavioral standpoint, SNs have been shown to play a part in the orientation to slow flows. Turning and facing the current is called positive rheotaxis and is a common response in fish. It allows fish to hold station in a stream, to intercept food and olfactory information flowing downstream, and perhaps get free gill ventilation (**see also Ventilation and Animal Respiration:** Efficiency of Gas Exchange Organs). For a fish to know that it is moving in a current, it needs a stationary reference frame against which to sense the movement. This can be accomplished with either visual or tactile contact with the bottom or sides of the stream. The need for an established stationary reference frame, and the strength of visually mediated rheotaxis led to the early conclusion that in rheotaxis, the lateral line plays little part. However, later behavioral studies using selective ablation of the SNs showed that this specific submodality of the lateral line does play a useful role in rheotaxis. For a fish sitting in a slow flow, the threshold current speed at which it turns and faces upstream is much lower with an intact SN system than after ablation of this submodality. Interestingly, adding a food odor to the water even further lowers the rheotactic threshold, indicating that fish are sensing flow velocities well below that at which they turn to face upstream (**Figure 3**).

Several studies have examined the electrophysiological response of SNs to flow. In these experiments, the fish is stationary in a flume that is used to manipulate the flow around the fish. **Figure 4** shows the afferent neural response from a presumed SN of water flowing in a head-to-tail direction. The activity of the nerve increases for the duration of the increased flow providing an apparent direct measure of the flow over that part of the fish's body. The simple interpretation would be that the flow past the cupula of the neuromast (**see also Hearing and Lateral Line:** Lateral Line Structure) activates the sense (hair cells and the afferent fiber) in a nonadapting mode, giving a straightforward encoding of flow rate and direction by the firing rate of the afferent nerve. However, this interpretation is complicated by the observation that in

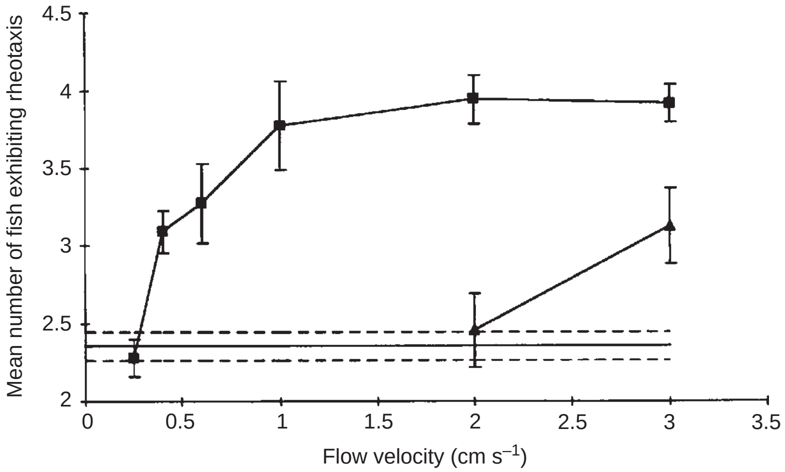

Figure 3 Mean number of cavefish exhibiting rheotaxis in the absence of an odor stimulus (triangles) and in the presence of a dilute odor stimulus (squares). The presence of the diffuse odor lowers the threshold from 2–3 to less than 0.4 cm s^{-1}. Physical ablation of the SNs raises the threshold to >8 cm s^{-1}.

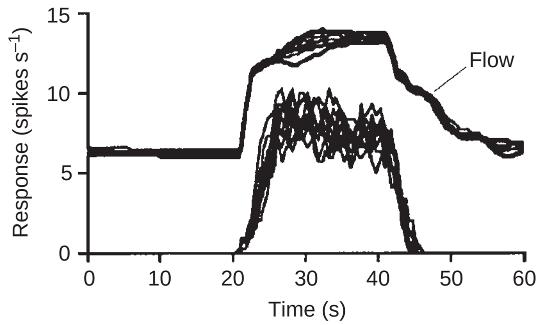

Figure 4 Response of a single anterior lateral line afferent fiber to repeated stimulation. Ten flow profiles (upper traces) are superimposed. The corresponding spike activity (lower traces) was binned (500 ms bins) and smoothed (three-point running average). The flow was increased (from 0.15 to 4 cm s^{-1}) between t = 20 s and t = 40 s. From, Voigt R, Carton AG, and Montgomery JC (2000) Responses of lateral line afferent neurones to water flow. *Journal of Experimental Biology* 203: 2495–2502.

some experiments afferent fibers can increase their firing rate during either head-to-tail, or tail-to-head flows – a finding that is inconsistent with the directional properties of hair cells. In theory, hair cells within each lateral line neuromast should respond best to one direction of flow and be inhibited to the opposite flow direction. One interpretation of this observation is that afferents are not encoding flow direction but only flow amplitude, and that the increased firing rate is not due to the direct flow *per se*, but due to the microturbulance induced over the surface of the fish. These two encoding mechanisms are not mutually exclusive and may operate at different flow rates, or differently in fish with different surface characteristics. The complexities of surface boundary layer flow in nature and in experimental situations, the precise response characteristics of cupula and hair cells, and the connectivity of afferents to hair cell populations are beyond the scope of this article. However, the important point is that the precise nature of sensory encoding by the lateral line can be problematic – even for very simple stimuli – in this case, a stationary fish in a controlled, unidirectional flow.

Obviously, the situation increases in complexity for a fish holding station in a turbulent flow, or a fish gliding or swimming actively. There is behavioral evidence that both SNs and canal neuromasts (CNs) provide information in turbulent flows that allow fish to modify their swimming to maintain station behind objects in a flow, and to enhance swimming efficiency in the presence of turbulence. There is also good evidence that gliding blind cavefish (*Astyanax fasciatus*) use their own self-generated flow to detect stationary features in their environment – an ability called active hydrodynamic imaging. However, electrophysiology in free moving animals becomes a difficult endeavor and there is little direct physiological evidence for how information from SNs and CNs is combined and used in these behavioral contexts. Functional understanding of the role of SNs and CNs is still largely based on the structural and physiological differences described below.

As shown in **Figure 2**, SNs are located on the surface of the skin of the fish, whereas CNs are located within subdermal canals (**see also Hearing and Lateral Line:** Lateral Line Structure). The effect of this is to remove the CNs from the direct influence of surface currents. Instead, they respond to the pressure gradient between the canal pores, responding to accelerating flows rather than constant-velocity flows. This protects the CNs from mechanical damage and also from being over-stimulated by ambient water currents, or by the fishes own motion. This effect is shown in **Figure 5**, where the electrophysiological responses of SNs and CNs are shown as a

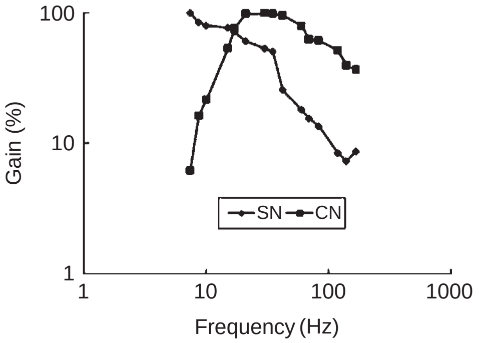

Figure 5 Frequency response characteristics of the superficial neuromasts (SNs) and canal neuromasts (CNs) in the eel (*Anguilla dieffenbachii*). Gain (%) is a relative measure of the response strength. These responses are for a vibrating bead stimulus where the amplitude of the vibration is adjusted at different frequencies to maintain a constant maximal stimulus velocity.

function of frequency. These stimulus-response curves are one of the most important ways of representing sensory function. The representation is borrowed from the field of engineering and is based on the notion that for a linear system, knowledge of how it responds to a range of frequencies allows effective characterization. In other words, you can then predict how it will respond to any arbitrary stimulus wave form. These curves are also called filter functions, showing which frequencies are being passed by the filter and which are being rejected. Using this later description, we can say that with respect to stimulus velocity, the SNs act as low-pass filters, letting low but not high frequencies through, by not responding to higher frequencies. By comparison, canals' neuromasts are band-pass filters, only responding to specific band of frequencies within the 10–80-Hz range.

The above allows further general points to be made about lateral line function, division of labor between submodalities, issues of signal and noise, and comparisons with other sensory systems. First, the filter curves effectively show the frequencies of interest where the gain is highest and sensitivity is best. SNs are interested in low frequencies associated with slow movements, whereas CNs are interested in rapidly changing movements associated with higher frequencies in the tens of hertz range. Filters are typically used to remove unwanted noise that differs in frequency from the signals of interest. Hence, CNs filter out low-frequency noise which leaves them sensitive to higher frequencies of interest; as described in the next section these higher-frequency sources are typically other animals. The ability to filter out steady flow and lower frequencies allows the CNs to operate even when the fish is exposed to ambient currents or is itself moving. The best direct physiological demonstration of this effect is the work showing lateral line afferent fibers responding to a vibrating bead. In stationary water, all fibers show a similar response. But when a background flow is added, one can quickly recognize two classes of fibers: those that become saturated, or over stimulated by the flow and cease to respond to the vibrating stimulus, and those that are unaffected by the flow and continue to encode the vibration. It is reasonable to equate these two classes of response to SNs and CNs, respectively.

Another general point is that frequency-response curves have been obtained for lateral line afferents from a wide variety of fish. It would be reasonable to hypothesize that the details of the curves for CNs would vary, according to the nature of the noise fish typically encountered, and according to the biologically relevant signals of interest. Although detailed characteristics of filter curves do vary across species, data on environmental flow noise and relevant signal characteristics are unavailable for comparison with filter functions to adequately test this hypothesis. What is clear is that within a species, the canal afferents are relatively similar in their response characteristics and not sharply tuned to particular frequencies. In this respect, the lateral line is quite different from the auditory systems that have a range of sharply tuned afferents whose best frequencies vary systematically across the range of frequencies encoded.

There is another important way in which signal and noise can be distinguished in lateral line systems. The swimming and breathing movements that fish make, and associated water flows, provide a strong source of stimulation to the lateral line, which, in most contexts, will be unwanted noise. Given that this is a self-generated noise, there are a number of behavioral and physiological strategies that can be used in mitigation.

The simplest is to cease active movement (as we do when we are listening intently). Some fish hunt using a pause/move behavior known as a salutatory search where prey is detected during the pause phase of the search. As a slightly different example, blind cavefish swim using a kick/glide motion. They sense obstacles using hydrodynamic imaging during the passive glide phase, when the flow field is more uniformly stable and less disturbed by the fish's own irregular, kicking (tail beat) motions.

A second strategy is to turn the lateral line off during active movement. The lateral line end organs have efferent innervation from the brain which can reduce the sensitivity of the lateral line during swimming. Efferent inhibition of lateral line sensitivity may also, in part, explain why blind cavefish typically collide with walls during the active kick (tail beat), but not during the passive glide phase of their swimming motion. Finally, the hindbrain processing center that receives the lateral line input and passes it on up to higher brain centers acts as a sophisticated adaptive filter which can cancel lateral line input that is generated by the animal's own movement.

Feeding

Having considered the physiological characteristics of the lateral line in the functional context of movement, it is now appropriate to add the insights into lateral line neuroethology that arise within the context of feeding. There is evidence that the lateral line contributes to the ability of fish to find the source of an olfactory stimulus being dispersed in a current, but the main consideration here is detection and localization of small moving prey. Lateral-line-mediated prey detection and capture has been studied in a wide range of species. The relevant stimulus and the way in which lateral line information guides behavior depends on whether prey is submerged or on the water surface and whether or not fish detect the current-generating movements of the prey as they occur or whether they detect the history of their movements in a trailing wake. In the case of fish feeding on relatively small, submerged prey, such as crustaceans, the stimulus is the fluctuating current driven by ventilation or swimming movements of appendages. Following prey detection, the approach is typically made in a number of steps until the fish is in the position to take a well-aimed strike at the target. The most likely contribution of the lateral line to this behavior is information about the precise location of nearby targets, both with respect to direction and distance to inform the approach and strike. In some fish the lateral line is essential for the initial detection and final strike behavior, both of which occur at fairly close range (less than 1 body length of the predator). In other, more diurnally active species vision plays a primary role in the initial detection and approach, whereas the lateral line plays a more important role in the final strike at close range.

Information about target location (azimuth, elevation, and distance) is contained in the instantaneous spatial pattern of activity across arrayed lateral line sensors. This spatial pattern is, in turn, converted into a population code or pattern of neural activity across the afferent fibers that innervate the sensors (**Figure 6**). Exactly how this population code is processed by the brain to guide behavior is not well understood, but it is likely integrated with information from other senses in a highly conserved brain region that controls orienting movements in vertebrates. For prey that move very slowly and/or remain relatively fixed in position for sufficient periods of time, snap shots of spatial patterns of activation along the lateral line may be sufficient for target localization by the lateral line. However, for prey that rapidly changes its location, the combined spatio-temporal patterns of activity across the arrayed sensors will be important. For example, some fish are able to intercept the fast-moving crustacean prey provided they are moving along, rather than across, the lateral line receptor array. Benthic stargazers (*Leptoscopus macropygus* and *Genyagnus monopterygius*) effectively catch their fish prey in darkness, but only after the prey crosses the lateral line receptor array around the mouth to trigger a strike. In both of these cases, prey-generated currents propagate at the speed of sound; thus, determinations about prey location from spatial patterns of activation can, in theory, be made instantaneously from spatio-temporal patterns as the prey rapidly changes location.

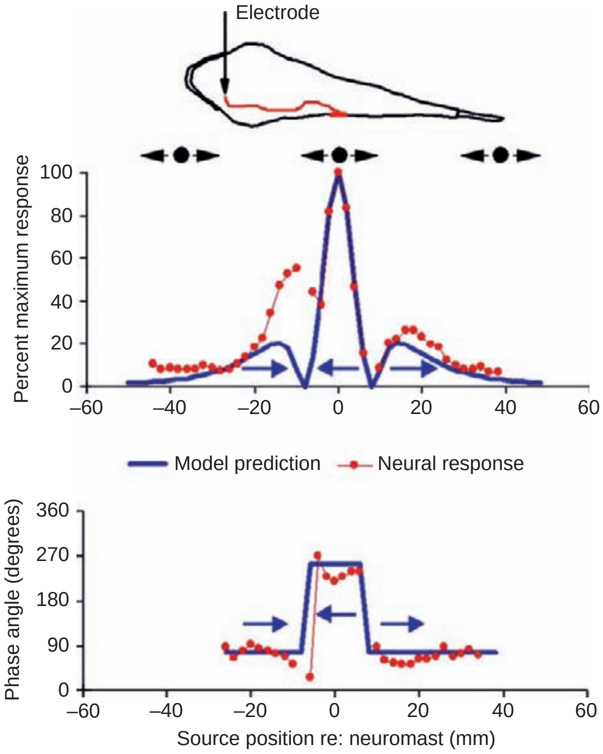

Figure 6 Neural responses to a dipole source compared with modeled predictions. The spike activity of a lateral line nerve fiber innervating a single CN on the trunk canal of a mottled sculpin (*Cottus bairdi*), was measured in response to the slowly changing locations of a 50-Hz vibrating sphere. As the source changed location, the spike activity (thin line with symbols) follows the predicted changes in pressure gradient (thick line). The phase angle, or firing time of the fiber, also follows the modeled predictions, as it shifts by a 180° for every change in pressure-gradient (flow) direction (see arrows). While this figure depicts the response of a single fiber from a single sensor midway along the trunk canal, it can also be used to illustrate the instantaneous spatial pattern of activity that would exist across multiple fibers for a single source position centered on the array.

Nocturnal catfish (*Silurus glanis*), on the other hand, track down their submerged prey in a substantially different way – by intercepting, and then following, the hydrodynamic trail of a swimming prey some time after (up to several minutes) the swimming movements have occurred. In this case, the water disturbances in the trailing wake travel at the speed of bulk water flow, which varies with the swimming speed of the prey. Recent physiological and modeling experiments have shown that the lateral line is capable of encoding information about both the spinning direction and rate at which vortices are shed in the trailing wake of a moving prey or around a submerged obstacle in a stream (**Figure 7**). In principle, fish could use this information to tell them something about the general direction, distance, and perhaps even the identity of the wake source.

Finally, a number of fish and amphibians specialize in the detection of prey that have fallen onto, or are struggling on, the water surface. In this case, the relevant stimulus is a surface wave. The spatial array of receptors that these specialists deploy adjacent to the water surface allows them to estimate direction to the target based on the orientation of the wave front passing over the receptors. Target distance is estimated by the lateral line afferents being able to encode the features of the surface wave that change as the wave propagates from the source. These include the frequencies that are present and how they disburse in time. This is because with surface waves, high frequencies travel faster, but attenuate more quickly with distance. Similar cues (e.g., changes in the spectrum) in slowly propagating hydrodynamic wakes may also inform nocturnal catfish about the distance to submerged wake sources.

Conclusion

It is not possible here to do justice to the wide literature on function and physiology of the lateral line. The neuroethological approach has been emphasized where physiological studies can be rather directly related to biologically relevant behavior in the contexts of movement and feeding. From what was a relatively unknown sensory system in the middle of last century, there is now a good sense of what the lateral line does and how. Dijkgraaf's original characterization of the lateral line as touch at distance remains remarkably apt. The lateral line is a distributed sensory system like touch and through intervening water movement it can locate objects in space, whether they are stationary and inanimate, or moving and alive. Biomechanical filter properties of lateral line structures, central control through the efferent system, and adaptive gain control in the brain enable fish to respond to the biologically important hydrodynamic signals and to distinguish them from self-generated and environmental noise. In addition, disturbances caused by underwater landscapes in self-generated and ambient flow noise may provide fish with lateral line information on the hydrodynamic scene, similar to what has been proposed for acoustic scene analysis. Significant issues remain, both within sensory encoding and within central processing of lateral line information. The practical

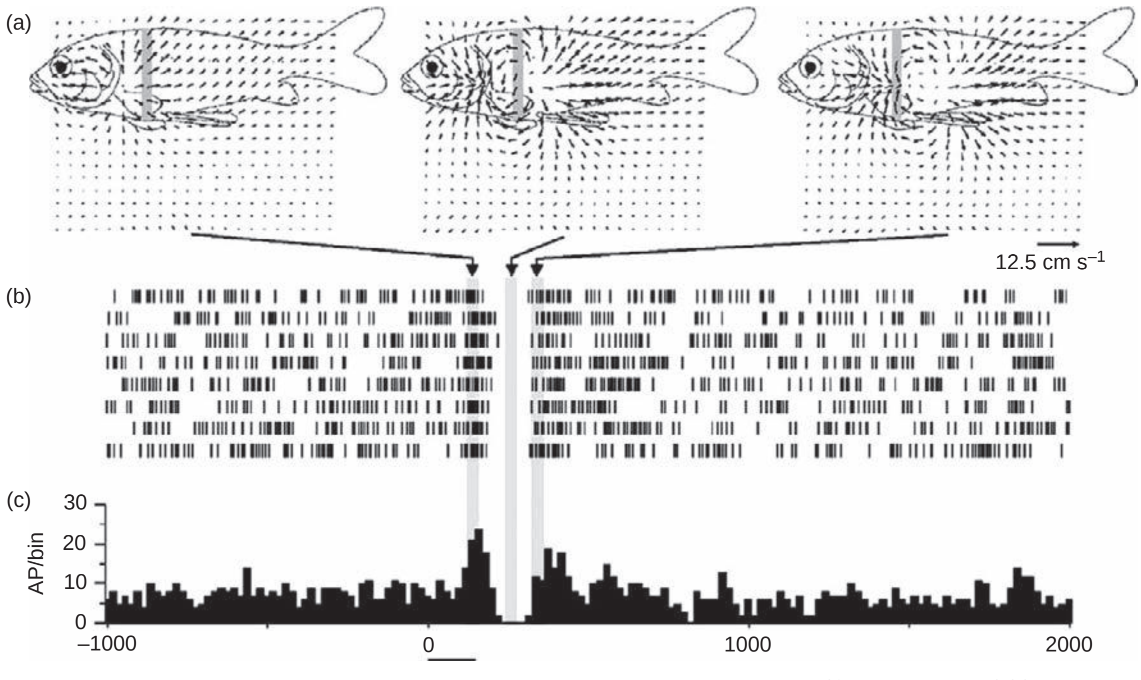

Figure 7 Particle motions associated with a vortex traveling along the surface of a goldfish (*Carassius auratus*) (a) and the corresponding responses of a lateral line nerve fiber (b, c) innervating a CN just behind the operculum of the fish. In (b), each mark represents a single action potential and each row of marks, the time series of responses to a single sweep of the vortex ring down the flank of the fish. In (c), the responses to repeated stimulus sweeps are combined into a peri-stimulus time histogram that shows the accumulated number of action potentials (AP) per each 20 ms bin during the repeated sweeps. Reproduced from Chagnaud BP, Bleckmann H, and Engelmann J (2006) Neural responses of goldfish lateral line afferents to vortex motion. *Journal of Experimental Biology* 209: 327–342, with permission from The Company of Biologists.

difficulties of keeping electrophysiology tightly aligned with an appropriate ethological context are not peculiar to lateral line studies. There is also still much to learn from a comparative perspective. Some 30 000 different species of fish, living in different freshwater and marine habitats, encounter abiotic and biotic flows that range from very orderly and predictable to highly turbulent and chaotic. Thus, the basic superficial/canal dichotomy described here is an incomplete picture of the myriad of other lateral line adaptations that have evolved in different environments – for example, the elaborate membranous canal systems and papillate SNs seen in deep-sea fishes.

Studies of lateral line function and physiology have enjoyed a resurgence in recent years – in part, because new technologies in flow visualization and computational fluid dynamics have found their way into biological studies. In addition, engineers involved in flow and flow sensing have started to recognize the quite remarkable abilities of the fish lateral line, and the potential that these have for advancing our own technologies in this area.

Larva The developing fish from hatch through transformation to the juvenile stage.

Mechanosensory The ability of cells and organisms to recognize and measure mechanical forces.

Neuromast The functional unit of the lateral line consisting of a patch of hair cells, supporting cells and the overlying cupula. Motion of the cupula relative to the sensory cells results in stimulation of the lateral line.

Placode A plate-like thickened area of embryonic ectoderm which gives rise to sensory organs.

Sensory ganglion A collection of the cell bodies of the bipolar sensory neurons that compose the cranial nerves; they sit outside the brain.

Standard length (SL) From the tip of the snout to the base of the fin rays of the caudal fin.

Stereocilia (stereovilli) Microscopic, finger-like extensions of the cell membrane composed of actin and found in sensory hair cells.

What Is the Mechanosensory Lateral Line System?

The mechanosensory lateral line system of fishes detects unidirectional and oscillatory water flows. It is found in all 30 000 + species of living fishes: the ‘Agnatha’ (the jawless fishes, the hagfishes and lampreys), the Chondrichthyes (sharks, skates, rays, and chimaeras), and the Osteichthyes (the bony fishes). It is composed of a spatial array of water flow detectors (neuromasts receptor organs) located on the head, trunk, and tail, and plays critical roles in a variety of behavioral contexts, including prey detection, predator avoidance, communication, and navigation. The lateral line systems of the Chondrichthyes and Osteichthyes are particularly well developed, with superficial neuromasts on the skin and canal neuromasts in a series of lateral line canals on the head and trunk. The lateral line system of the lampreys is composed exclusively of superficial neuromasts located in grooves on the skin of the head and trunk. The lateral line system is only present in some hagfishes, where it is represented by the presence of ciliated sensory cells located in a small number of grooves on the head.

Structure and Function of Neuromast Receptor Organs in Bony Fishes

Neuromasts are small epithelial receptor organs (~10–500 μm in length) that are composed of hundreds or, in some case, thousands of sensory hair cells, in addition to nonsensory support cells (the stem cells from which hair cells differentiate), and mantle cells (**Figure 1**). Each sensory hair cell has a ciliary bundle extending from the cell surface that is composed of a single long kinocilium and many shorter stereocilia that sit to one side of the kinocilium. The length of the kinocilium and stereocilia varies among neuromasts and may have functional implications. The location of the stereocilia relative to the kinocilium establishes the physiological polarity of a hair cell (**Figures 1–3**). All of the hair cells within a neuromast are oriented 180° to one another, thus defining the neuromast’s axis of best physiological sensitivity to water flows (**Figure 3**).

The ciliary bundles of all hair cells in a neuromast are covered by a gelatinous cupula that serves as the biomechanical interface between the hair cells and water in the

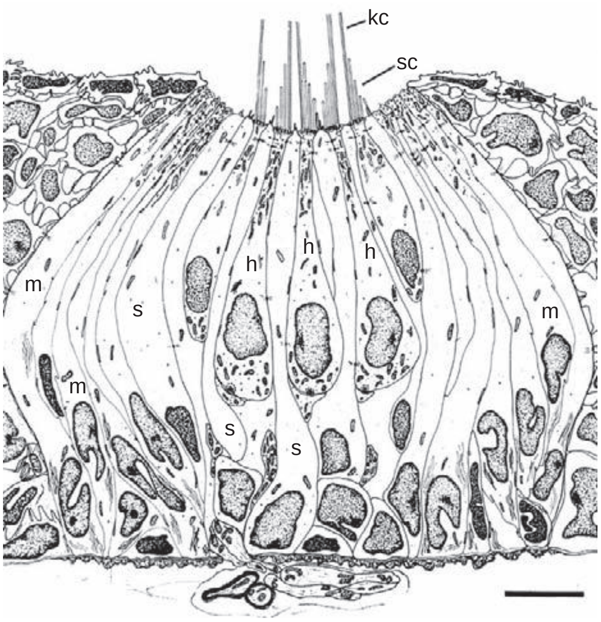

Figure 1 Schematic drawing of a superficial neuromast in Nile tilapia, *Sarotherodon niloticus* (m = mantle cells; s = supporting cells, h = hair cells). Scale = 10 μm. Reproduced from Munz H (1979) Morphology and innervation of the lateral line system in *Sarotherodon niloticus* (L.) (Cichlidae, Teleostei). *Zoomorphology* 93: 73–86, with kind permission of Springer Science+Business Media.

surrounding environment (**Figure 3**) . When water flows past a neuromast, it bends the cupula, and the ciliary bundles contained within it (**Figure 4**). This generates a stimulus (**see also Hearing and Lateral Line**: Lateral Line Neuroethology) that is transmitted to the brain via a lateral line nerve composed of the sensory neurons that innervate the hair cells.

There are two classes of neuromasts in bony fishes (**Figures 4** and **5**) – canal neuromasts in pored, fluid-filled canals, and superficial neuromasts on the skin (sometimes referred to as pit organs). Canal and superficial neuromasts demonstrate a considerable amount of interspecific variation in size and shape (**Figure 6**). Hair cells may be distributed over the entire surface of the neuromast (e.g., canal neuromasts of the zebrafish, *Danio rerio*, **Figure 6**(**b**)), but are more commonly found in a circular or oval area in the center of the neuromast, called the 'sensory strip' (**Figures 3** and **6**). Neuromast morphology is correlated with the morphology of the lateral line canals in which they are found (see below). The hair cell orientation in canal neuromasts is parallel with the long axis of the canal so that water flows in the canal have the potential to stimulate the neuromasts. Superficial neuromasts, which sit on the skin, are generally smaller than canal neuromasts and are often oriented with their axis of best physiological sensitivity parallel or perpendicular to the body axis. Some superficial neuromasts are located in lines or groups in the vicinity of canals (accessory neuromasts, **Figure 5**) and are generally oriented parallel or perpendicular to that of the neuromasts within the canals.

The hair cells that compose the neuromasts are innervated by both sensory afferent neurons (which compose the sensory lateral line nerves) and efferent neurons that form a synapse with each of the hair cells. In the Chondrichthyes and Osteichthyes, several lateral line

Wiley and Sons.

nerves, each defined by a discrete sensory ganglion, innervate neuromasts on the head and trunk. These are distinct from the ganglia of the cranial nerves of vertebrates that are traditionally denoted by roman numerals (e.g., V – trigeminal, VII – facial, IX – glossopharygeal, and X – vagus (**see also Brain and Nervous System**: Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern and **Hearing and Lateral Line**: Auditory/Lateral Line CNS: Anatomy). The anterior lateral line nerve innervates canal and superficial neuromasts above and below the eye. The middle lateral line nerve is composed of a small number of fibers and innervates a small number of neuromasts at the posterior margin of the head. The posterior lateral line nerve innervates lines of canal and/or superficial neuromasts, including the trunk canal, which may extend the length of the trunk. The lateral line nerves project to one or more lateral line centers in the medulla oblongata, which are distinct from the auditory and electroreceptive centers of the hindbrain (**see also Brain and Nervous System**: Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern and **Hearing and Lateral Line**: Auditory/Lateral Line CNS: Anatomy).

Structural Variation in the Lateral Line System among Bony Fishes

In bony fishes, the lateral line canals are contained in a remarkably consistent subset of dermal cranial bones (the lateral line bones, **Figure 7**; **see also The Skeleton**: Bony Fish Skeleton), regardless of the shape of the head, or the size or shape of the individual bones. Neuromasts are found on the floor of the canals, in which one neuromast is found between the adjacent canal pores (with the exception of one group of lungfishes).

Variation in the morphology of the cranial lateral line canals among bony fishes is defined by four canal patterns (**Figure 8**). The narrow canal pattern (**Figure 8(a)**) is the most common and is characterized by well-ossified canals with small pores, which may be extended through soft tissues to the skin surface as tubules. The narrow-branched pattern (**Figure 8(d)**) is similar to the narrow pattern, with the exception that the canal pores extend into the soft tissue overlying the bones as highly branched tubules and end in a large number of terminal pores. The reduced canal pattern (**Figure 8(b)**) occurs when some or all canals do not develop and enclose neuromasts leaving superficial neuromasts on the skin. These replacement neuromasts are often proliferated, occurring in clusters or dense lines. The widened canal pattern (**Figure 8(c)**) evolved convergently in only a dozen or so families of teleost fishes, including those that live on or near the benthos and those that live in the water column at great depths (e.g., mesopelagic and bathypelagic fishes). Widened canals are greater in diameter than narrow canals, and, as a result, may cover much of the head, but they have incompletely ossified canals that leave large openings in the canal roof. Their very large canal neuromasts (often an order of magnitude larger than those in narrow canals in fish of the same size) are often diamond shaped (**Figure 6**) and may sit in constrictions in the canals under a bony bridge, which is the remnant of the ossified canal roof. The epithelium that covers the canals is generally pierced by small pores and is thought to be deformed by water flows that cause fluid to move in the canal, thus stimulating the canal neuromasts.

The lateral line canals on the trunk demonstrate considerable diversity among species (**Figure 9**). One lateral line canal is generally found on the trunk of bony

fishes, but multiple canals do occur (e.g., in greenlings, pricklebacks, and some cichlids). The trunk canal is composed of a series of overlapping lateral line scales, each of which contains a canal segment in which one canal neuromast is found (**Figure 10**). The single lateral line canal may run straight down the body to the base of or onto the caudal fin, or in more evolutionarily derived fishes, it may arch above the pectoral fin before returning to the mid-flank (over the horizontal septum) and proceeding to the caudal fin. In some benthic fishes, the canal is placed high on the body (e.g., stargazers), and in fishes that live just under the water surface, it is placed low on the body (e.g., flying fishes). In other fishes, the canal may be incomplete (e.g., damselfishes), or divided into two portions (a disjunct pattern, e.g., cichlids), or a trunk canal may be absent (e.g., herrings and relatives), but superficial neuromasts are widely distributed on the body.

The spectrum of variation in lateral line morphology among bony fishes is fairly well understood, but the functional significance of the variation in lateral line morphology has been well established in only a few cases (e.g., functional differences between canal and superficial neuromasts, and between narrow and widened canals on the head; **see also Hearing and Lateral Line**: Lateral Line Neuroethology). The lateral line system is linked to the swimbladder and/or the inner ear in a limited number of fish groups (e.g., herrings and relatives, some catfishes, and some butterfly fishes), which is likely to broaden the functional roles of the lateral line system.

Development of the Lateral Line System in Bony Fishes

Both the neuromasts and the sensory neurons that innervate the hair cells are derived from a series of specialized patches of ectoderm on the head (the lateral line placodes). The development of the lateral line system commences during the embryonic period (prior to hatch), and extends through the larval (posthatch) and juvenile periods of a fish's life history. Lateral line development on the head occurs in three stages: (1) migration of placode-derived primordia and differentiation of hair cells in embryonic neuromasts, (2) growth of neuromasts (increases in size, changes in shape), and (3) formation of the pored lateral line canals (via intramembranous ossification of dermal bone – without a cartilage model) around a subset of neuromasts (the presumptive canal

neuromasts), as the canals become integrated into a conserved subset of dermal bones.

The genetic mechanisms underlying the first stage of lateral line development, the patterning and differentiation, have become the subject of recent detailed experimental studies using the zebrafish. Following neuromast patterning and differentiation, their size and shape change and two subsets of superficial neuromasts become apparent: presumptive canal neuromasts (those that will become enclosed in bony canals) and superficial neuromasts (that remain on the skin throughout life).

The development of the lateral line canals (the third stage of development) generally begins toward the end of the larval period, which may occur many weeks after fertilization (e.g., 28 days postfertilization in zebrafish). The timing of development generally varies among species, canals, and canal segments within a canal. Formation of individual canal segments is initiated in the vicinity of individual presumptive canal neuromasts, and the pattern of canal development, which has been described in detail in zebrafish and a cichlid, appears to be conserved among bony fishes.

The development of a lateral line canal segment around a single neuromast occurs in several stages (**Figure 11**). After canal segments form around individual canal neuromasts, adjacent canal segments may grow toward one another, and fuse leaving a common pore between them, thus forming a pored canal. The occurrence of one canal neuromast between the adjacent canal pores in most bony fishes is a result of this developmental pattern. Some variation in the morphology of the lateral line system among

fishes can be attributed to the degree to which this developmental process is completed (e.g., the reduced canal pattern). Throughout the juvenile and adult phases of a fish's life history, the ossified lateral line canals continue to increase in diameter in concert with the increase in the size of the bones in which they are contained.

The development of the lateral line canal on the trunk starts with the establishment of a series of superficial neuromasts along the body axis as a result of the rostro-caudal migration of one or more lateral line placode-derived primordia on the head. At the end of the larval stage, scales begin to develop in a caudal-to-rostral direction, and then the lateral line canal segments develop in the lateral line scales in rostro-caudal sequence (**Figure 10**), resulting in one neuromast within the canal segment of each scale. The distribution of superficial neuromasts on the trunk is not particularly well known in many fishes, but it is common to observe an increase in the number of superficial neuromasts, including the formation of linear stitches on the scales, as in the goldfish (**Figure 5**) and zebrafish.

The Lateral Line System of Chondrichthyan Fishes

The mechanosensory lateral line system in the Chondrichthyes (sharks, skates, rays, and chimaeras) consists of lateral line canals containing neuromasts, superficial neuromasts located on the skin, and the vesicles of Savi, which are found only in some rays (**Figures 12** and **13**).

The lateral line canals of sharks, skates, and rays are narrow and cylindrical. They are composed of soft tissue (unlike those of bony fishes), are found in the dermis, and have tubules that extend to the skin surface ending in terminal pores. The number and course of the lateral line canals, which may be quite complex, are related to head shape and body form. On the head of most sharks, pored lateral line canals are distributed between the eyes, below the eyes, and on the upper and lower jaws, and a single

canal moves onto the trunk along the mid-flank to the end of the vertebral column in the upper lobe of the heterocercal tail (**Figure 12**). In the hammerhead sharks (genus *Sphyrna*), some of the canals extend onto the cephalofoil, the lateral extensions of the head that give these fishes their name (**Figure 12**). The dorso-ventrally flattened skates and rays have well-developed canals on both the dorsal and ventral surfaces of the head, including canals that extend onto the dorsal and ventral surfaces of the greatly expanded pectoral fins, which are fused to the head (**Figure 12**).

In addition to pored canals, some species (e.g., Atlantic stingray, *Dasyatis sabina*) may have nonpored canals on the ventral surface of the head or body that likely function differently than pored canals. It is thought that deformation of the skin overlying these canals stimulates the canal neuromasts. Torpedo rays, electric rays, and stingrays also have small structures, the vesicles of Savi, pouches that occur in linear series or clusters on the ventral side of the snout, which contain either one neuromast (e.g., stingrays) or one large and two smaller neuromasts (e.g., torpedo rays, **Figure 12**). Like the nonpored canals, the vesicles of Savi are not open to the external environment and are thought to provide a tactile sense.

The canal neuromasts are distinct in morphology and distribution from those in bony fishes. The neuromasts of bony fishes are well-defined, focal populations of hair cells that are clearly separated by the nonsensory epithelial cells in the canal lining, but the neuromasts of sharks, skates, and rays have been described as being composed of either a continuous or a nearly continuous sensory epithelium. Unlike bony fishes (with the exception of some lungfishes), several neuromasts are located between adjacent canal tubules. As in bony fishes, the hair cells in the sensory epithelia within the canals have well-defined ciliary bundles, and the hair cells are oriented 180° to one another – parallel with the canal axis. Superficial neuromasts sit on the skin, between modified placoid scales in sharks, or on the smooth skin of skates and rays, and are generally found on the dorsal surface of the body (above the trunk canal in sharks, or on the dorsal surface of the body in skates and rays).

The chimaeras (or ratfishes), an enigmatic group of chondrichthyans, have either narrow tubular canals (family Callorhynchidae) or open grooves (families Rhinochimaeridae and Chimaeridae) on the head, and the overall distribution is similar to that in the other chondrichthyan fishes. However, unlike the canals of other Chondrichthyes, the canals and grooves of chimaeras are supported by C-shaped rings (variously described as cartilaginous or calcified). As in sharks, skates, and rays, the canal neuromasts are described as being elongate and almost continuous. However, in some members of the Chimaeridae (e.g., *Hydrolagus*), the open grooves on the underside of the snout have periodic dilations, and discrete neuromasts (not elongated sensory epithelia) are found in the canals between dilations (**Figure 13**). Superficial neuromasts have not been reported in these fishes.

The neuromasts and sensory neurons that innervate the hair cells in chondrichthyan fishes are thought to be derived from cranial placodes as they are in bony fishes, but the way in which the neuromasts differentiate and grow, and the way in which the lateral line canals develop, are not well understood.

The Lateral Line System of Jawless Fishes

Paleontological investigations have revealed that the lateral line system evolved with the first vertebrates and is present as canals in the bony head shields of the extinct ostracoderms from more than 400 million years ago. In contrast, the lateral line system of the living jawless fishes, the hagfishes, and lampreys, which only have an internal cartilaginous skeleton, consists solely of superficial neuromasts, if at all it is present (**Figure 14**).

The lateral line system of lampreys (order Petromyzontiformes) is similar to that of jawed fishes with respect to the general morphology and distribution of neuromasts on the head, and their innervation by a series of lateral line nerves that project to the hindbrain. However, the neuromasts are reported to lack cupulae. The ammocoetes larvae of lampreys have already developed a functional lateral line system, with neuromasts that are similar to those of adults.

Among hagfishes, only members of the family Eptatretidae (e.g., *Eptatretus*) are known to have a lateral line system; the system is apparently absent in hagfishes of the family Myxinidae. In *Eptatretus stoutii*, the lateral line system consists of a series of about 11 short depressions or

grooves rostral and caudal to the eye spot, which appear unpigmented and vary in size, number, and position among individuals. This general morphology is similar to that represented by the early developmental stages of the lateral line system in jawed vertebrates. The depressions contain flask-shaped sensory receptor cells that may have a single cilium and a corolla of shorter microvilli, are reported to lack cupulae, and are unlike the directionally polarized hair cell bundles of the hair cells in the well-developed neuromasts of chondrichthyan and osteichthyan fishes. Sensory cells in the grooves are innervated by bundles of cranial nerve fibers that form two nerves that project to the hindbrain. The function of the sensory cells is not clear, but they are thought to transduce hydrodynamic disturbances. The system is thought to be derived from a small number of cranial placodes, but the development of hagfishes is currently known only from a small number of embryos.

Glossary

Active electrolocation The ability of weakly electric fish to orient and detect objects based on their electric sense.

Electric field A spatial gradient in electrical potential. In animals, these can be actively generated by an electric organ or passively generated due to the uneven distribution of ions between the inside of the animal and the surrounding water. Direct current (DC) fields are steady, whereas alternating current (AC) fields are changing.

Electric organ An organ specialized for generating external electric fields. Myogenic electric organs are derived from skeletal muscle and are composed of individual cells called 'electrocytes'. Neurogenic electric organs are derived from neuronal axons.

Electric organ discharge (EOD) Electrical discharges resulting from the summed excitation of the cells (electrocytes) of the electric organ of electric fishes that function both in communication and in locating nearby objects. Short (100 ms to several tens of milliseconds) electrical pulses of various voltages (a few millivolts to several hundred volts) are generated at various rates (a few to over 1000 times per second.

Electrocommunication Communication based on electric signals.

Electroreceptor A sensory cell specialized for the detection of external electric fields. Ampullary electroreceptors are sensitive to low-frequency fields up to ~50 Hz, whereas tuberous electroreceptors are sensitive to high-frequency fields up to tens of kilohertz such as those produced by an EOD.

Electrosense The ability to detect electric fields. A passive electrosense is one in which external electric fields are detected, whereas an active electrosense is one in which self-generated electric fields are detected.

Humans have been familiar with the special abilities of strongly electric fish since antiquity. Egyptian tombstones depict images of the electric catfish *Malapterurus electricus*. Ancient Arabic texts refer to both *Malapterurus electricus* and the torpedo rays *Torpedo* spp. as 'thunderer' or 'trembler'. The ancient Romans used the shocks of these fish as therapeutic treatments for a wide range of medical ailments. However, it was not until the eighteenth century that the painful, numbing sensations caused by these fish were convincingly demonstrated to be caused by electricity. This discovery of animal electricity set the stage for the famous experiments of Luigi Galvani, in which he demonstrated that frog leg muscles could be made to contract by connecting nerves of the muscle in series with two different metals and the spinal cord. Galvani incorrectly attributed this effect to a unique form of electricity – an innate vital force housed within animal tissue that was released by the metal. His contemporary, Alessandro Volta, disagreed. Volta maintained that the contractions were not due to intrinsic electricity, but extrinsically generated current provided by contact between the two different metals. Volta ultimately proved correct, but the experiments of Galvani provided the first direct evidence of the electrical basis for nervous and muscular activity in all animals. The controversy engendered by these experiments led to the invention of the first battery to produce a reliable, steady electrical current – the Voltaic pile – which Volta created as an artificial model of an electric organ by stacking alternating disks of two different metals separated by cardboard soaked in brine.

When Darwin published *On the Origin of Species* in 1859, he devoted an entire chapter to problems with his theory of natural selection, which he entitled 'Difficulties on theory'. One area of concern was the evolution of electric organs, of which Darwin remarked "The electric organs of fishes offer another case of special difficulty; it is impossible to conceive by what steps these wondrous organs have been produced…" By that time, anatomists had discovered several groups of fish with relatively small organs similar in structure to the electric organs of *Malapterurus electricus*, *Torpedo* spp. and the electric eel *Electrophorus electricus*. Some of these were shown to generate electric fields, but they were far too weak to serve as any kind of a weapon, leading Du Bois-Reymond to dub them pseudo-electric. Because of morphological similarities between skeletal muscle and electric organ, Darwin correctly concluded that electric organs likely evolved from muscle, with strong electric organs evolving from weaker versions. Due to the absence of any apparent common ancestor, he further concluded (again, correctly) that the electric organs found in different groups of extant fish must have evolved independently. The problem, as Darwin saw it, was explaining how a weak electric organ could serve any adaptive function. Not for another century did Lissman and Möhres provide convincing experimental evidence that weak electric organs are used for communication (electrocommunication) as well as for navigation and orientation (active electrolocation). Such behaviors require a specialized sensory structure – an electroreceptor – for detecting electric fields.

In the late seventeenth century, Stefano Lorenzini described in detail a series of pores and associated canals distributed throughout the body of *Torpedo* spp. that were later found in many species of aquatic vertebrates, the so-called ampullae of Lorenzini. In 1773, John Walsh, the first person to detect actual sparks from an electric fish (an electric eel), provided the first direct evidence for an electric sense. Walsh found that an electric eel would approach a pair of recording electrodes and discharge its organ whenever the electrodes were short-circuited, leading him to conclude that eels could detect electrical conductors. Du Bois-Reymond, consistent with his opinions on weak electric organs, believed that the ampullae of Lorenzini served no useful function. Physiological experiments from the 1930s through the 1960s led various researchers to conclude that the ampullae were used for thermoreception, mechanoreception, chemoreception, and eventually electroreception. The latter was ultimately confirmed through clever behavioral experiments by Kalmijn, which conclusively demonstrated the existence of a passive electrosense in sharks and rays that was used to locate prey. Concomitant to these developments, the discovery of electrocommunication and active electrolocation by Lissman and Möhres had inspired an intensive effort to identify and characterize the necessary receptor cells. This culminated in the discovery of electroreceptive units in the lateral line nerve by Bullock and colleagues that were sensitive to much higher frequencies than the low-frequency ampullary receptors, making them well suited to detecting the specialized discharges of weak electric organs.

Today, research in the field is as varied as the diversity of organisms possessing an electrosense. Molecular biologists, electrophysiologists, neuroanatomists, mathematical modelers, and evolutionary biologists continue to study this distinctly foreign sensory system to ask broadly relevant questions ranging from information processing by sensory systems and the neural organization of motor output to the evolution of animal communication and the process of speciation. The section begins with an overview of electroreceptors (**see also Detection and Generation of Electric Signals:** Morphology of Electroreceptive Sensory Organs) by Jørgen Mørup Jørgensen, who describes the morphology of ampullary electroreceptors used for passive electrolocation and tuberous electroreceptors used for detecting actively generated electric fields for the purposes of active electrolocation and social communication. Jørgensen also summarizes the basic patterns of electroreceptor evolution across vertebrates, highlighting their multiple, independent origins. Michael Hofmann goes on to describe the physiology of ampullary electrosensory systems (**see also Detection and Generation of Electric Signals:** Physiology of Ampullary Electrosensory Systems), while Maurice J Chacron and Eric Fortune describe the physiology of tuberous electrosensory systems (**see also Detection and Generation of Electric Signals:**

Physiology of Tuberous Electrosensory Systems; in both cases, the authors focus on the peripheral encoding of sensory information and mechanisms for the detection of behaviorally relevant stimuli within the central nervous system. Gerhard von der Emde and Jacob Engelmann describe how tuberous electrosensory systems are used in active electrolocation (**see also Detection and Generation of Electric Signals:** Active Electrolocation) for the detection and analysis of objects in the environment. This behavior relies on the active generation of electric fields, and Angel Caputi describes in detail the morphology of the electric organs (**see also Detection and Generation of Electric Signals:** Electric Organs) that generate these fields, paying special attention to the relationship between structure and function. Masashi Kawasaki, discussing the generation of electric signals (**see also Detection and Generation of Electric Signals:** Generation of Electric Signals), describes how the central nervous system controls the timing of electric organ output. Kawasaki considers both the general principles of electromotor circuits as well as the evolutionary variation in these pathways as it relates to differences in electric signaling behavior. The section ends with a description of the development of electroreceptors and electric organs (**see also Detection and Generation of Electric Signals:** Development of Electroreceptors and Electric Organs) by Frank Kirschbaum and Jean-Pierre Denizot. Despite the diversity of approaches and interests, readers will recognize throughout this section an appreciation for comparative approaches to biological problems, as well as a common bind that holds the field together: a deep interest in the amazing capabilities of these animals and the fundamental insights they provide into the origins and operations of our own biology.

Ampullae of Lorenzini Ampullary organ in cartilaginous and some bony fishes.

Ampullary organs Mucous-filled tubular structures in many fishes with open pores in the skin connecting to the outside and electroreceptors at the blind end.

End buds Cone-shaped sensory organs in the skin of lampreys.

Gymnarchomast Tuberous electrosensory organ in the skin of the bony fish *Gymnarchus* with a single sensory cell that has an apical invagination with numerous microvilli.

Gymnomast Tuberous electrosensory organ in fishes belonging to the family Gymnotidae. Typically, there are a few sensory cells with many microvilli in a closed chamber.

Knollenorgan Tuberous electrosensory organ used for electrocommunication among mormyrid fishes. The sensory cells are equipped with numerous microvilli and are specialized for detecting the electric organ discharge of another conspecific fish.

Mormyromast Tuberous sensory organ used for active electrolocation in the skin of mormyrids. Two types of electrosensory cells are exposed to different parts of a closed chamber.

Siluromast Tuberous organ with a single electroreceptor in the skin of the silurid *Pseudocetopsis*.

Tuberous organ Electrosensory organs in the skin of some teleosts that lack an external opening to a pore.

Introduction

The history of electroreception is a fascinating story involving mysterious, tubular, jelly-filled structures, for a long time believed to be slime-secreting organs (**see also Detection and Generation of Electric Signals**: Detection and Generation of Electric Signals in Fishes: An Introduction). These organs were first found in elasmobranchs, and, after their discoverer, termed 'ampullae of Lorenzini'. They remained a puzzle for several hundred years after their first description. As anatomical techniques improved, it became clear that these organs were, in fact, sense organs.

It is now clear that these special sensory organs, which are sensitive to many different types of stimuli, including weak electric fields, arose very early in the evolution of vertebrates. With the exception of hagfishes, all other anamniotic craniate classes, including lampreys, cartilaginous fishes, and a number of bony fishes, as well as urodele and caecilian amphibians, have electroreceptors. Organs that are sensitive to weak electric fields have also been identified in monotreme mammals.

It is known that weak electric fields, important for many aquatic vertebrates, are used for prey detection, identification of objects in the environment, and social communication. It is therefore a real mystery why many fishes apparently have lost this valuable sense during evolution.

The structure, or morphology, of electroreceptive sense organs provides a platform for the understanding of their function. This article briefly describes the different types of electroreceptive organs found in various vertebrates.

Lampreys: Electroreceptive End Buds

Adult lampreys have widespread superficial epidermal sensory organs called end buds on the head and trunk. The sensory cells are directly exposed to the surrounding water and thus have no duct. Each end bud consists of 3–30 slender sensory cells that are separated from one another by supporting cells. The apical surface of each sensory cell is equipped with a hair bundle consisting of 80–90 microvilli. Presynaptic synaptic bodies lie opposite to afferent nerve boutons.

The ammocoete larvae of lampreys and newly metamorphosized lampreys do not possess end buds, although they appear to have a sense for weak electric fields.

Instead of end buds, they have a number of scattered multivillous sensory cells. This cell type shares many characteristics with the sensory cells belonging to the octavolateralis system. Such multivillous cells are found in small groups in the gill vent papillae and on the tail.

Solid indication of an electroreceptive sensory system in adult lampreys is the presence of a dorsal octavolateral nucleus in the medulla oblongata and responses to electrosensory stimuli recorded from single afferent nerve fibers. The sensory cells are excited by cathodal stimuli and both end buds and multivillous cells may be categorized as nonteleost ampullary organs lacking a duct.

Ampullary Organs

General Structure

Electroreceptive ampullary organs are characterized by a tube-like duct, with a pore in the skin, and a sensory epithelium at the end of the tube (**see also Detection and Generation of Electric Signals**: Physiology of Ampullary Electrosensory Systems). The canal leading from the sensory epithelium to the environment varies considerably in length. It is filled with a mucous jelly that has a very low electrical resistance. The wall of the ampullary duct is composed of flattened cells that are connected to each other by tight junctions and desmosomes, creating a boundary with high electrical resistance.

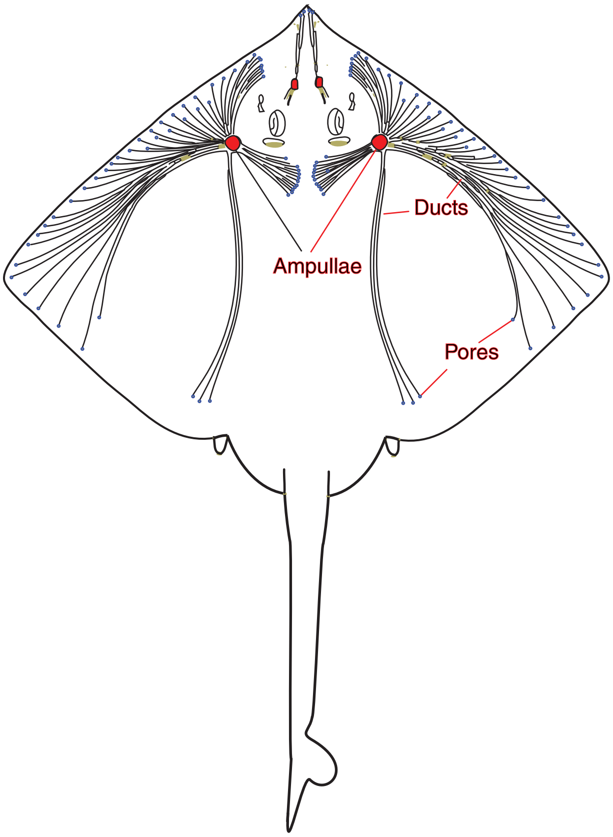

Figure 1 Dorsal view of a ray *Raja* with the position of ampullae of Lorenzini. The tubes spread out from clusters of ampullary ends to cover a large part of the wings and body.

Nonteleost Fishes: The Ampullae of Lorenzini

The ampullae of Lorenzini are defined here as ampullary sense organs that project to a dorsal octavolateral nucleus in the medulla oblongata and are excited by cathodal stimuli. With this definition, the organs of Lorenzini include the electroreceptive organs in nonteleost fishes and the ampullary organs in amphibians.

The morphology of the sensory cells in the ampullae of Lorenzini is characterized by a narrow apical area exposed to the ampullary lumen. Typically, a short cilium extends from a basal body. The cilium may be surrounded by a few microvilli. Basally, synaptic sheets or round bodies form contact with a single or a few afferent nerve endings.

Ampullary Organs in Cartilaginous Fishes (Chondrichthyes)

Cartilaginous fishes include sharks, skates, and rays, as well as chimaeras.

The ampullae in the marine species generally have long canals that lead to sensory cells situated deep in the dermis. However, the canal length as well as shape may vary considerably within the same individual (**Figure 1**). The pores are found in the head region of all species and in the pectoral fins of rays and skates. The sensory epithelium covers the interior of the ampullary end, which often forms several blind ending sacs called diverticulae (**Figure 2**).

The sensory ampullae are located in clusters and the total number of ampullary organs in an individual varies considerably among species. Some species have only 148 ampullae, as found in *Heterodontus francisci*, or 162 ampullae, as found in *Torpedo marmorata*, while other taxa have more than 2000. The maximum number of 2824 has been found in the hammerhead shark, *Sphyrna lewini.*

The ampullae vary in shape, as shown in **Figure 2**. The ampulla may be simple with one enlarged chamber and, in some cases, a few diverticulae. This type is found in electric rays belonging to the genus *Torpedo.* A number of simple ampullae may together form assembled ampullae, as in the shark *Hexanchus.* More common is a lobular type, with 2–80 diverticulae arranged side by side, all of which open into a central ampulla. This type is found in most sharks, rays, and skates. A section of such an ampulla shows the chambers (**Figure 3**). In some chimaeras, the chambers appear as slender pockets forming a finger-shaped ampulla.

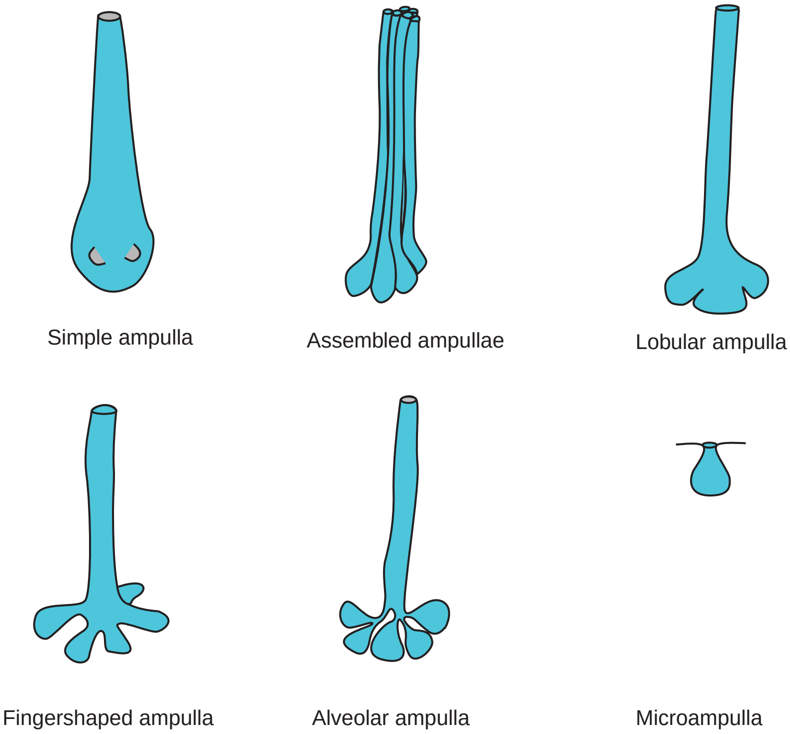

Figure 2 Different types of ampullae of Lorenzini known from various cartilaginous fishes. Not drawn to scale.

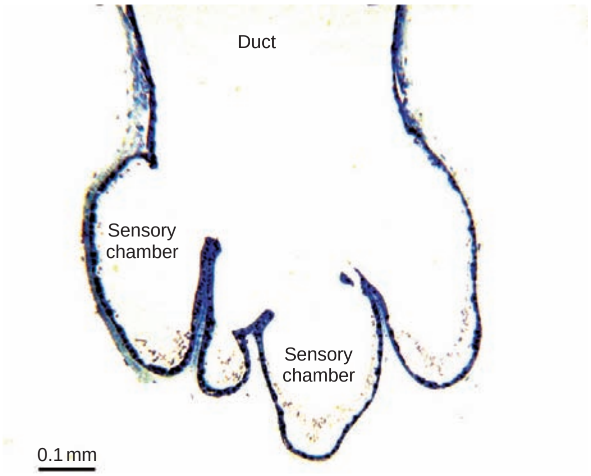

Figure 3 Light micrograph of a section from an ampulla with several sensory chambers from the spotted dogfish (*Scylliorhinus canicula*).

Some sharks, such as the piked dogfish (*Squalus acanthias*), have chambers that are connected to the central canal by slender ducts; this type may be termed alveolar. In permanently freshwater elasmobranchs, such as *Potamotrygon*, short ducts end in simple microampullae.

In a detailed study of 40 species of rays belonging to the genus *Raja*, it was found that the majority of ampullary organs are located on the ventral side of the animal. It also appears that fish-eating rays have their ampullary pores distributed over a larger part of the body than those species that feed primarily on invertebrates. In addition, deep-dwelling species have larger ampullae with more chambers than shallow-water species.

Ampullary Organs in Bichirs and Reedfish (Polypteriniformes)

Extant fishes belonging to this superorder are a small group of African fishes of the genera *Polypterus* and *Erpetoichthys* (synonym *Calamoichthys*). The ampullary organs in these species are distributed on the head, with the highest density on the snout region in front of the eyes. The ampullary organs occur as simple tubes in the skin, except where an ampullary organ seems to divide, forming two organs. The sensory epithelium consists of electroreceptor cells separated by supporting cells. The apical part of the sensory cell is characterized by having a single cilium surrounded by 8–10 microvilli. Basally in the receptor cell, synaptic sheets or rounded synaptic bodies are seen opposite to the afferent nerve endings.

Ampullary Organs in Sturgeons and Paddlefishes (Acipenseriformes)

The ampullary organs of sturgeons have been examined in the genera *Scaphirhynchus*, *Acipenser*, and the paddlefish

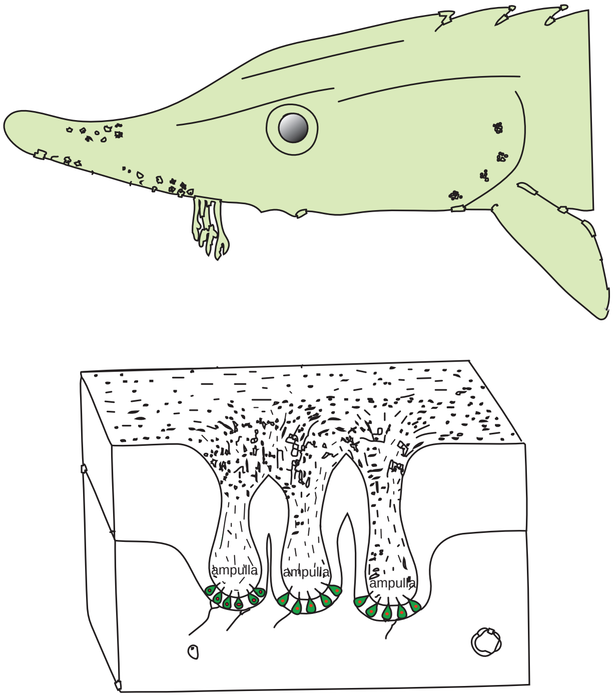

Figure 4 The head of a sturgeon (*Acipenser ruthenus*) with ampullary organs on the snout and gill cover.

Polyodon spathula. In all species examined, the ampullary organs occur on the head, including the rostrum, and, in some species, the opercula. The ampullary organs occur in clusters of 5–30 single organs (**Figure 4**). Occasionally, two to five ampullae may share a common pore. The pear-shaped sensory cells are apically equipped with a cilium, and a single nerve fiber ramifies below the sensory epithelium of each ampulla to form several afferent boutons in contact with the sensory cells. These boutons have synaptic sheets opposite to the afferent boutons.

Recent studies of electroreception in the paddlefish have shown convincingly that this species uses its sensory ampullae for passive detection and feeding on plankton.

Ampullary Organs in Lungfishes (Dipnoi)

The extant lungfishes have ampullary organs embedded in a thick epidermis. Their distribution is unusual among other nonteleost bony fishes, because they are found not only on the head, but also on the trunk and tail fin. The large, pear-shaped sensory cells are equipped with an apical cilium, which may be surrounded by a microvilli (**Figure 5**). Basally in the cells, synaptic sheets surrounded by synaptic vesicles are found opposite to the afferent nerve endings.

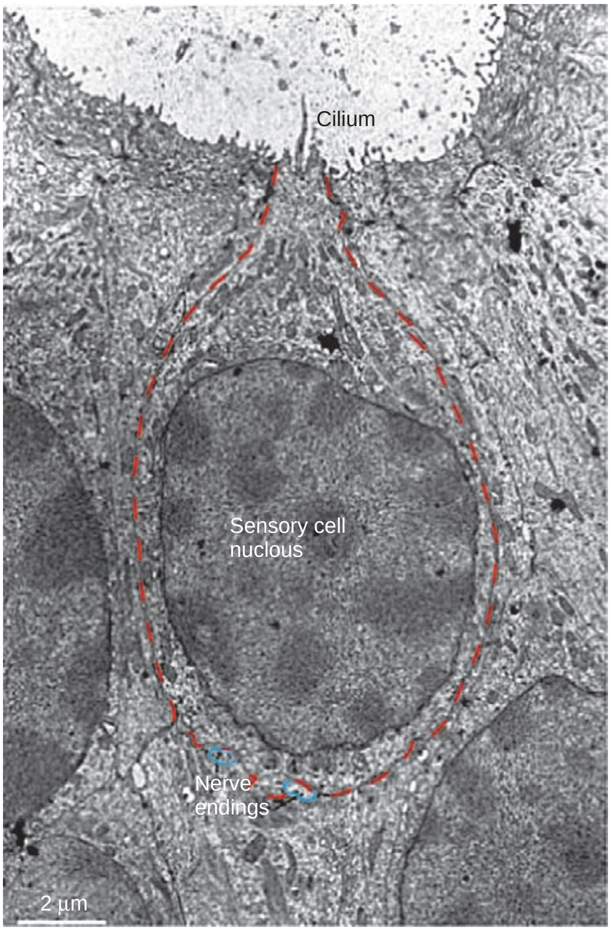

Figure 5 An ampullary sensory cell from an African lungfish (*Protopterus annectens*) as seen using a transmission electron microscope. The sensory cell membrane is marked with a dashed red line. Apically is seen a cilium surrounded by few microvilli. Small nerve endings are seen at the basal end of the sensory cell.

Ampullary Organ in Coelacanths (Coelacanthiformes)

We have information only from *Latimeria chalumnae*, one of the two species in this group. The sensory cells are situated in a rostral organ consisting of an irregular chamber in the ethmoid region. It has three pairs of openings to the surrounding water. As in all other ampullary organs, the tubes leading to the pores are filled with a jelly-like substance. Deep crypts that are lined by a sensory epithelium consisting of sensory and supporting cells are found in a part of the chamber. Although no well-fixed tissue has been examined, it seems that the sensory cells are very much like the ampullary sensory cells found in other nonteleost fishes.

Additional evidence for electroreception is that the rostral organs are innervated by branches of the superficial ophthalmic ramus of the anterodorsal lateral line nerve that projects to a distinct dorsal nucleus in the medulla oblongata.

Ampullary Organs in Caecilian and Urodele Amphibians

A number of species belonging to caecilian and urodele amphibians have ampullary organs that are located on the head. Each ampulla contains 10–30 pear-shaped sensory cells, all of which are innervated by a single afferent nerve fiber.

In larval *Ichthyophis* (Caecilian), each sensory cell has a single apical cilium surrounded by a few microvilli, while the urodeles show a more varied pattern. In the axolotl (*Ambystoma mexicanum*), the sensory cells have approximately 200 microvilli around an eccentric cilium. In the European cave salamander (*Proteus anguinus*), some sensory cells have an apical cilium, while others only possess a basal body. Electroreceptive sensory cells of other urodeles belonging to the genera *Triturus* and *Salamandra* have apparently no cilia or basal bodies, but possess numerous long microvilli.

Basally in the electroreceptive cells, very large synaptic spheres up to 3 μm in diameter are found opposite to the afferent nerve endings. Electrophysiological evidence of electroreception and the role of electroreception during feeding have been demonstrated in the axolotl (*Ambystoma mexicanum*). The nerve fibers from the amphibian ampullary organs project to a dorsal nucleus in the medulla.

Ampullary Organs in Teleosts

Ampullary organs are not found widely in teleosts. However, they have been demonstrated in species belonging to the orders Osteoglossiformes (family Mormyridae with many electroreceptive species, family Gymnarchidae with one species, family Notopteridae with two species with electroreceptive organs: *Xenomystus* and *Papyrocranus*), Siluriformes (many species in all studied families), and Gymnotiformes (many species belonging to all families).

With few exceptions, these electroreceptive teleosts are freshwater teleosts, and a characteristic is a rather short ampullary duct (**Figure 6**). By contrast, in the few electroreceptive saltwater teleosts, for example, *Plotosus* which belongs to the order Siluriformes, the ampullary ducts are long, as found in cartilaginous fishes.

Nerve fibers from the teleost electroreceptors project to a lateral lobe in the medullary octavolateralis area, which is distinct from the dorsal nucleus of nontelostean fishes. Another difference between teleosts and nonteleosts is that the teleost electroreceptors are primarily excited by anodal fields, while nonteleost electroreceptors are excited by cathodal fields. This naturally leads to the hypothesis that the electroreceptive organs of these two main groups have an independent evolutionary history.

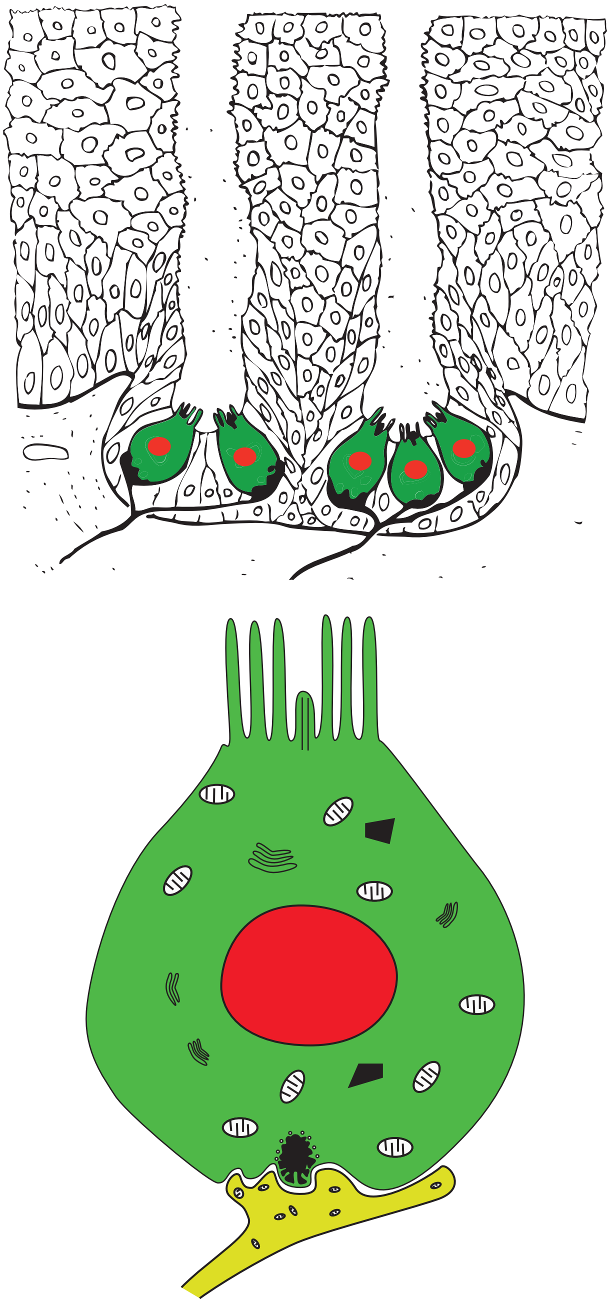

Figure 6 Above are two ampullae from the African knifefish *Xenomystus nigri* (Nothopteridae, Teleostei) and below is an isolated sensory cell with an apical cilium and microvillae.

The evolutionary line leading to osteoglossiform fishes is so far removed from the gymnotiform and siluriform line that it has been suggested that these teleost lines evolved ampullary organs independently. Furthermore, it is commonly believed that the origins of the different electroreceptive cells are the hair cells of the mechanosensory lateral line and inner ear. **Figure 7** shows two

different electroreceptive sensory cells and a lateral line hair cell.

Ampullary Organs in Notopterid Fishes

Fish belonging to the order Osteosteglossiformes contain the family Notopteridae, with many species in Asia and a few in Africa. Only the African species are known to possess electroreceptive organs. The ampullary organs in the African knife fish *Xenomystys nigri* (**Figure 6**) are not only distributed all over the head and along the body, but are particularly numerous slightly dorsal to the horizontal septum. Each organ has four to eight pear-shaped sensory cells, which apically have 40–60 microvilli and a short cilium, up to 1 μm. So far, this species is the only known teleost with an apical cilium on its electroreceptive cells. The cilium arises from a basal body and is found between the microvilli. These microvilli are about 2.5 μm long and have a diameter of 0.2–0.3 μm. Mitochondria are primarily seen in the apical part of the cell and below the centrally located nucleus. One or a few round synaptic bodies surrounded by clear vesicles are found opposite to a single nerve bouton.

Amullary Organs in Mormyrid Fish

Mormyrid ampullary organs are distributed all over the head as well as dorsally and ventrally along the body. The ampullary ducts in two species of *Gnathonemus* have a length of about 150 μm or less and a diameter of 20 μm. Each organ contains three to eight egg- or pear-shaped sensory cells (**Figure 8**), separated by supporting cells. Each sensory cell has a number of apical microvilli, which extend for a short distance into the ampullary canal. The nucleus is found in the center of the sensory cell. In addition to mitochondria and vesicles in all parts of the cytoplasm, the sensory cell has about 20–30 synaptic sheets opposite to the afferent nerve boutons, which contact the basal or lateral parts of the cell. A single nerve fiber divides to contact all of the sensory cells in a single ampullary organ.

Ampullary Organs in the Teleost *Gymnarchus*

Gymnarchid ampullary organs are distributed all over the head and body of the fish. The ampullary lumen is 10–20 μm in diameter and only one sensory cell is generally found in the ampulla (**Figure 8**). The shape of the sensory cell is unique in that the ampullary lumen extends almost half way down into the apical part of the cell. The surface of the cell has a sparse number of short microvilli that are about 1 μm in length and 0.1 μm in diameter. Synaptic sheets surrounded by numerous vesicles are found opposite to several synaptic boutons, all of which are connected to a single nerve fiber.

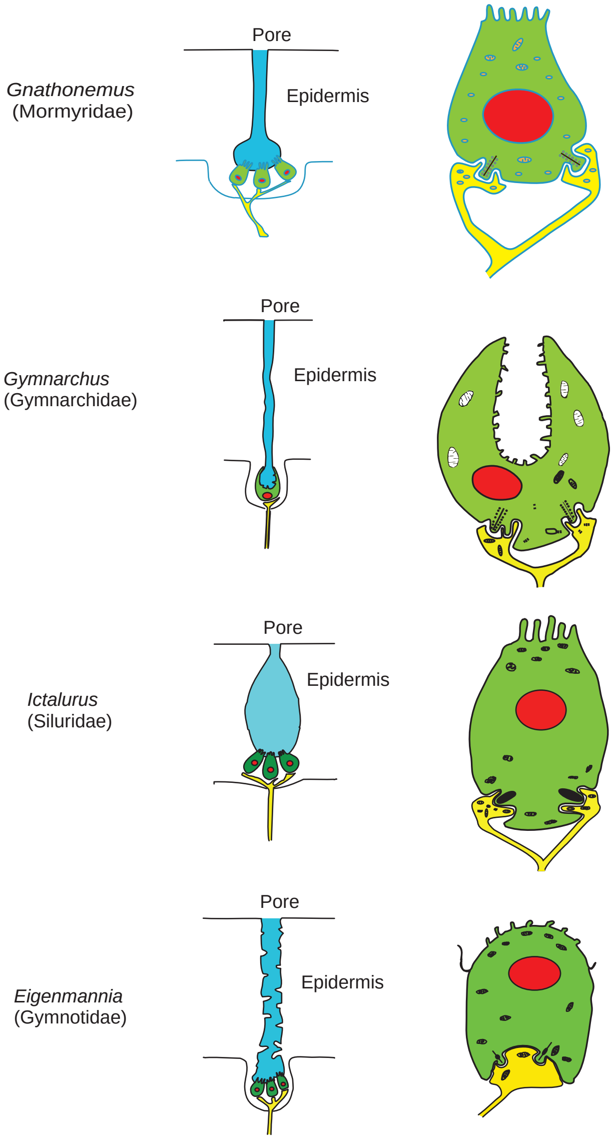

Figure 8 Teleost ampullary organs and individual sensory cells from representatives of four different families. Not drawn to scale.

Ampullary Organs in Silurid Fishes

Silurid ampullary organs are most numerous in the head, but are also found along the side of the body. In *Plotosus,* they are primarily found at the base of the fin rays. The ampullae of the transparent catfish (*Kryptopterus bicirrhus*) are distributed all over the body of the fish.

In the freshwater silurids, the ampullae are situated in the epidermis (**Figure 9**); only a few reach deep into the dermis. In *Pseudocetopsis,* usually only one or two sensory cells are found in the bottom of the ampullae, while the electroreceptive ampullae of *Ictalurus* (*Amiurus*) contain 5–15 sensory cells and *Kryptopterus* has 10–30 sensory cells. In all of the species mentioned, these cells are equipped with a sparse distribution of short microvilli (**Figure 10**). The marine species (e.g., *Plotosus*) have long ducts, reaching about 3 cm deep into the dermis, and the sensory cells have numerous long microvilli.

Ampullary Organs in Gymnotid Fishes

Generally, the Gymnotid ampullary organs are found scattered on the head and in bands along the side of the body. Between two and eight pear-shaped sensory cells protrude slightly into the ampullary lumen (**Figure 8**), exposing about 15–20% of the sensory cell surface to the lumen. Irregularly distributed microvilli that are less than 1 μm in length and with a core of microfilaments are seen on the surface. Numerous mitochondria are found around the central or luminally placed nucleus. Basally, 10–15 synaptic bodies are found opposite to a single large nerve bouton, which measure about 5 μm in diameter. These dark staining presynaptic bodies or rods have a peculiar structure consisting of a roundish body with a rod-like structure pointing centrally into the cell and a foot process that reaches into the synaptic lobe of the sensory cell that projects into the bouton. These synaptic bodies are surrounded by numerous clear vesicles with a diameter of 20–30 nm.

Tuberous Electroreceptive Organs

Tuberous organs have so far only been demonstrated in teleost fishes (**see also Detection and Generation of Electric Signals**: Physiology of Tuberous Electrosensory Systems). They differ from ampullary organs in that they do not have a duct from the surface of the skin to the

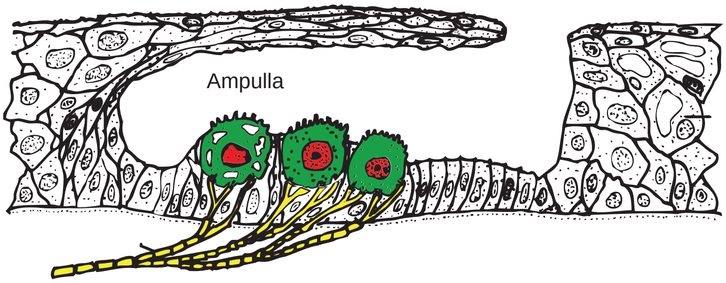

Figure 9 A section of an ampullary organ from the transparent catfish (*Kryptopterus bicirrhus*).

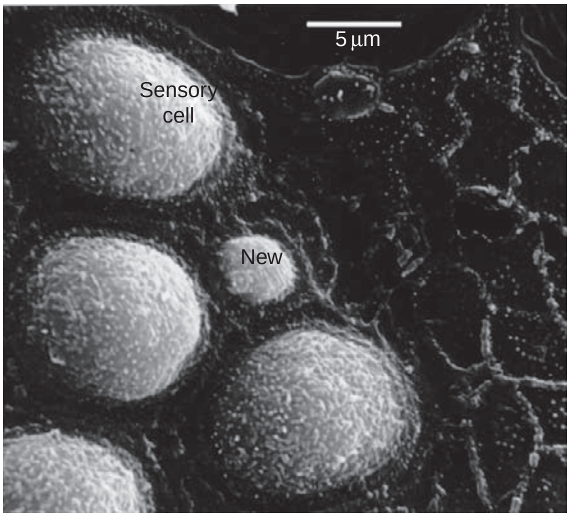

Figure 10 Scanning electron micrograph of an opened ampulla of the transparent catfish (*Kryptopterus bicirrhus*) showing the surface of a few sensory cells with a few small microvilli. The size of the surface of the cells differs considerably, probably due to the cells in different phases of sensory cell turnover.

sensory organ. Instead, the sense organ is covered by a plug of loosely packed epidermal cells. The sensory cells open into an intraepidermal cavity. The sensory cells are different from the ampullary sensory cells, both in structure (see **Figure 11**) and function. It is believed that tuberous organs also have evolved from the mechanosensory hair cell. The primary function of the tuberous sensory cells is believed to be communication by detecting signals from the weak electric organs in other fishes.

Tuberous Organs in Mormyrids

Two distinct types of tuberous organs are found in mormyrids, the so-called knollenorgan and mormyromast (**Figure 11**). Each knollenorgan is composed of three to four sensory cells and a number of supporting cells. These sensory cells lie in a narrow cavity, or sensory chamber, which is limited externally by flattened epidermal cells. Below the sensory cells, a number of supporting cells are found. Some pear-shaped supporting cells, situated below the sensory cells, are filled with rough endoplasmic reticulum, indicating that they are involved in production of the jelly that fills the sensory chamber. The sensory cells are large, up to 40 µm in diameter with an apical or central nucleus. Most of the surface is covered by a large number of microvilli up to 3 µm in length and 0.1–0.15 µm in diameter. A large number of mitochondria are found below the microvilli. Basally, the sensory cell sits on a platform in which the synapses are found. All sensory cells in an organ are innervated by a single nerve fiber that divides to form several boutons on the individual sensory cells.

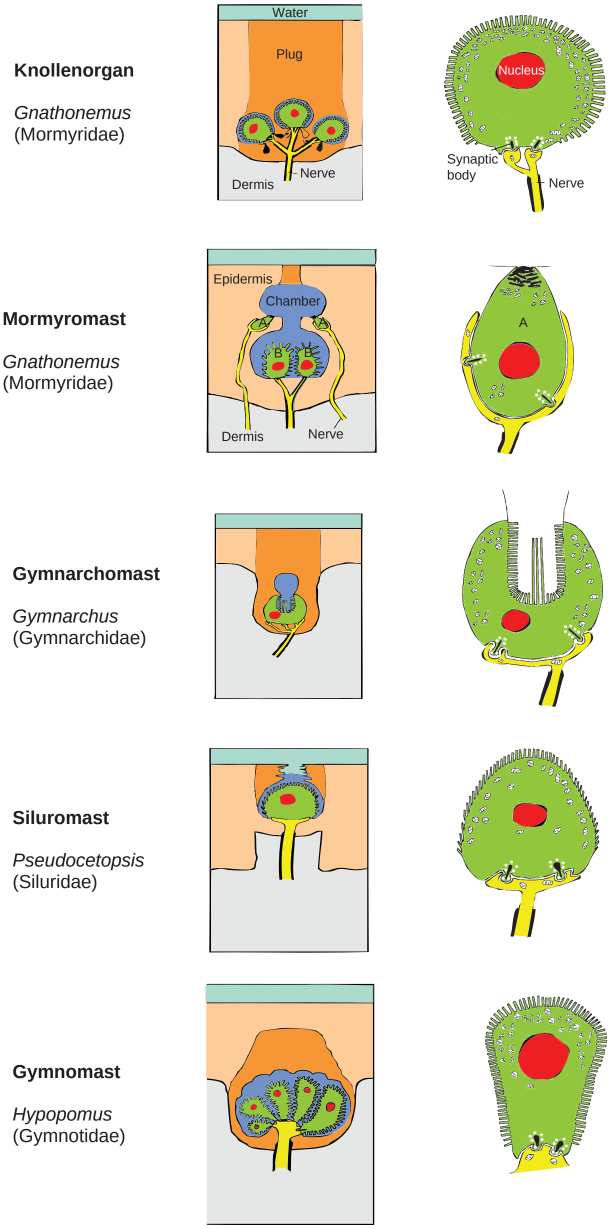

Figure 11 Five different tuberous organs and their sensory cells found in teleost fishes.

The mormyromast is a complicated structure involving at least two different sensory cells with separate innervation. The mormyromast has two chambers that are connected by a narrow canal. The shallower chamber contains type-A sensory cells, while the deeper chamber has type-B sensory cells, which look like the sensory cells of the knollenorgan. Six to thirteen type-A cells lie in a circle in the outer (superficial) chamber and these are separated by supporting cells. The apical part of this pear-shaped type-A cell is characterized by numerous membrane foldings. The type-A cell is embraced by finger-like projections of the afferent nerve that stretches up along the lateral part of the cell. The synaptic sheets indicate the position of synapses. The type-B sensory cell sits on a platform, with the majority of the cell surface exposed to the deep chamber. Numerous long and slender microvilli stretch out into the chamber jelly. The type-B cells form basal contacts with nerve endings, which originate from a single fiber.

Tuberous Organ in *Gymnarchus*

Gymnarchus has a peculiar sensory cell in the tuberous organ, which has been called a gymnarchomast. A single sensory cell opens into a jelly-filled chamber. The cell has an apical depression filled with numerous microvilli. The microvilli originating from the bottom of the depression form a long projection into the apical cavity. The cell nucleus is located basally. A single nerve fiber splits to form several nerve endings at the basolateral part of the sensory cell. In some gymnarchomasts more sensory cells are seen located together, and organs with more than one sensory cell have been termed gymnarchomast type II. However, it is uncertain whether this type of organ is a further developmental stage of the gymnarchomast type I.

Silurid Tuberous Organ

In silurids, tuberous organs have only been described from one species, *Pseudocetopsis*. This organ, the siluromast, is located rather superficially in the epidermis (**Figure 11**). It contains a jelly-filled cavity with a single spherical sensory cell having a diameter of about 25 μm and numerous apical microvilli that increase in height toward the cell apex. The nucleus has a central position. A single afferent nerve flattens out at the base of the sensory cell.

Gymnotid Tuberous Organs

In gymnotids the tuberous organ, the gymnomast, is described in a number of species (**Figure 11**). A cavity contains 25–35 elongate sensory cells. The exposed lateral and apical surfaces of these cells are enlarged by microvilli that stretch out into the gymnomast chamber. In some species, a single nerve fiber splits to innervate all sensory cells with several nerve boutons. In other species, such as *Hypopomus*, the nerve ending is a single large knob that forms synapses with all the sensory cells in a single gymnomast.

Monotreme Electroreceptive Organs

The monotreme mammals include the platypus (*Ornithorhynchus anatinus*) and two species of spiny anteaters (*Tachyglossus aculeata* and *Zaglossus bruijnii*). In all species, the bill or snout contains specialized mucous glands with electroreceptive nerve endings. The platypus has about 40 000 electroreceptive mucous glands, while *Zaglossus* has about 3000 and *Tachyglossus* about 100.

In platypus the electroreceptive organs are distributed in narrow stripes on the entire bill, while the spiny anteaters have their organs on the outermost part of the snout. The sense organs always consist of a large coiled mucous gland, where naked nerve endings open into a capsule of epidermal cells, which forms around the middle portion of the mucous gland.

Glossary

Alternating current (AC) fields Electrical fields that alternate constantly, e.g., electrical power lines typically carry sinusoidally changing voltages with a frequency of 50–60 Hz.

Direct current (DC) fields Steady electric fields, e.g., batteries supply a more or less constant voltage over their lifetime.

Dorsal octavolateral nucleus (DON) The target of primary afferent electrosensory fibers in the hindbrain of all nonteleost species.

Introduction

The ampullae of Lorenzini were described in 1678 by the Italian physician Stefano Lorenzini in elasmobranchs (**see also Detection and Generation of Electric Signals**: Electric Organs). Their function remained elusive for a long time, until behavioral and physiological studies showed that the receptor cells at the base of the ampullae respond to mechanical stimulation, temperature changes, salinity changes, and electric fields. About 50 years ago studies established that the detection of weak electric fields is the natural function of the ampullae.

Initially thought to be a specialization in elasmobranchs, electrosensory ampullae have been found in all basal fish groups (**Figure 1**). Electroreception was lost, however, in neopterygian fish (teleosts, including gars and bowfin), but re-evolved in some groups of teleosts (catfish, gymnotids, and mormyrids). Electroreception was also lost with the transition to a terrestrial life. Larval salamanders and gymnophians still have electroreceptors, but anurans and all other land vertebrates are not known to have an electric sense. Notable exceptions are *Echidna* and the platypus. These primitive mammals have modified trigeminal nerve fibers sensitive enough to pick up weak electric fields from prey items.

The widespread occurrence of electroreception in basal fish groups suggests that this sensory system played an important role in early vertebrate evolution. Besides some behavioral evidence of electroreception in lobster, there are no invertebrates known to have an electric sense.

Some fish have electric organs and can produce much larger electric fields (**see also Detection and Generation of Electric Signals**: Electric Organs). They probe the environment with this field and can detect any object that distorts this field (**see also Detection and Generation of Electric Signals**: Active Electrolocation). These fields are created actively by fish, which are called active electrosensory fish in contrast to the passive electrosensory fish that only sense external fields. The other difference is that the electric organ discharges consist of higher frequencies that are above the upper frequency limit for detection by the ampullae of Lorenzini. For this reason, the active and passive electrosense are sometimes also called high- and low-frequency electroreception, respectively. Natural stimuli of the ampullae of Lorenzini, therefore, are weak electric fields from animate and inanimate sources that have a low frequency.

Sources of Electric Fields

There are many sources of electric fields in the aquatic environment. Most important are probably those produced by other animals. Every animal has an electric field around its body, which is strongest in the head and gill region. Measured directly at the skin, it can be as high as a few millivolts in freshwater teleosts, but is usually 10 times weaker in seawater elasmobranchs. Invertebrates, a major prey of many fish, also show electric fields comparable to those of fish.

These ever-present, steady, direct current (DC) fields are modulated by the animal's own movement. Respiration is an important source of these modulations, but any movement will change the field to some degree.

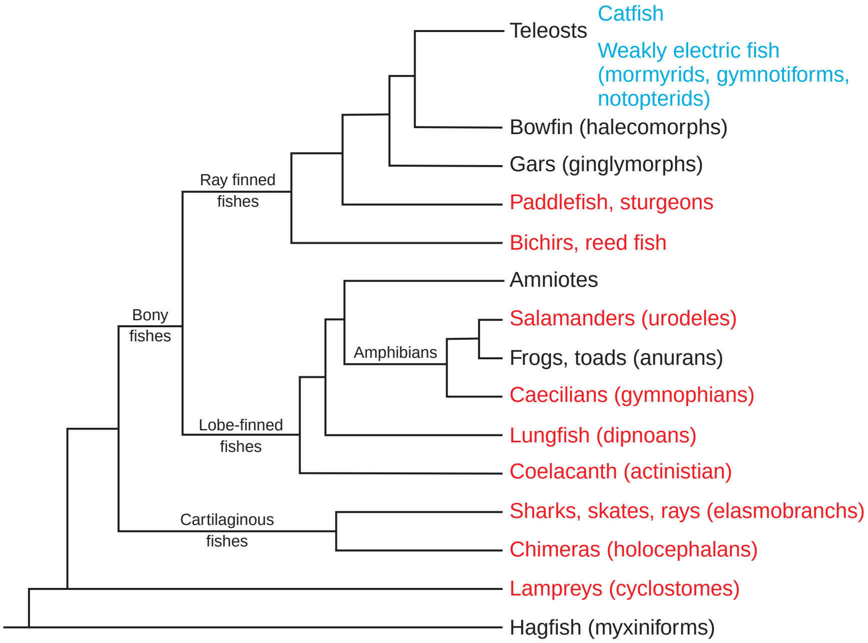

Figure 1 Cladogram of the major fish and amphibian groups, with the presence of electroreception indicated in color. All group names in color represent groups with ampullary organs. The red color represents fish groups with primitive, homologous ampullary organs and the blue-coded groups represent teleosts with derived (re-evolved) ampullary electroreceptors. Note that most teleosts do not have electroreception. Only the few groups shown in the figure re-evolved electroreception.

In addition, the electrical activity of muscles can directly add higher-frequency components. **Figure 2** shows an example of an electric field from a small water flea (*Daphnia*). Both steady DC and higher-frequency, alternating current (AC) fields are present. Because ampullary electroreceptors adapt to steady fields, they do not respond to pure DC electric fields. However, there is always a relative movement between the source and the receiver, so the electric potential at a given receptor changes over time when a source passes by. Consequently, the DC field is transformed into an AC event when the source passes by a receptor, as shown in **Figure 2(a)**.

There are also larger-scale electric fields produced by geophysical processes. Any physical or chemical boundary will produce electric fields that could be used by electrosensory animals for orientation and navigation. Examples are filtration potentials when water is flowing through the substrate or potentials arising between waters with different temperature or salinity. There are also streaming potentials that are proportional to water currents in a river. There is some evidence that catfish and sharks use this information, but little is known about how widespread the detection of large-scale electric fields is.

Some fish can produce larger electric fields with specialized organs (**see also Detection and Generation of Electric Signals**: Electric Organs). Well known are the strong discharges of electric eels and some rays (*Torpedo*) used as a defense or to stun prey. Other groups of fish

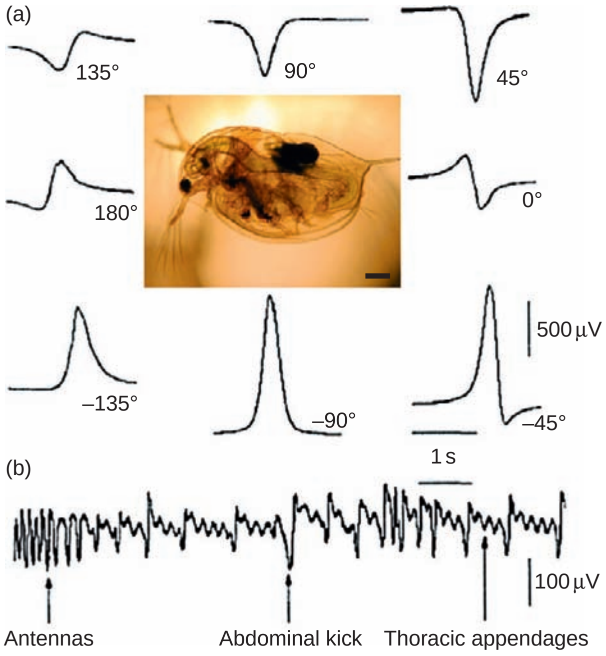

Figure 2 Electrical potential of a water flea (*Daphnia,* scale = 200 μm). (a) Electrical signal of a live *Daphnia* that was fixed on the tip of a stick and swept close to a recording electrode with different body orientations. have evolved weakly electric organs and use them for electrolocation and navigation (**see also Detection and Generation of Electric Signals**: Active Electrolocation). Although these organs produce higher-frequency electric fields well above the frequency range of the ampullary electroreceptors, they can be detected by very sensitive ampullary receptors. Examples include some catfish that specialize in locating and preying on weakly electric fish. Some rays also produce weak discharges in the low-frequency range and use them to communicate with conspecifics during courtship.

Morphology of the Ampullary Organs

The ampullae of Lorenzini are located in the head and sometimes also on the trunk. They consist of either short (freshwater fish) or long (seawater fish) canals that are connected to the outside with a pore. **Figure 3** gives an example of a fish with a very high number of pores, the paddlefish. Individual ampullae are constantly multiplying by division (**Figure 3**(**b**)). For more details on ampullary morphology, the reader is referred to **Detection and Generation of Electric Signals**: Morphology of Electroreceptive Sensory Organs. Here, we focus on aspects that are important for the encoding of electric fields.

To measure an electric field, a two-point measurement is necessary. For ampullary organs, one point is the pore in the skin. Because the canal wall has high resistance and the gel inside the canal has low resistance, the canal acts as a cable, carrying the electric potential to the apical surface of the electroreceptor. The receptor cell then measures the voltage between this apical potential and the potential below its basal membrane.

Figure 4(**a**) shows a schematic drawing representing a fish with long canals in an electric field. Electrosensory fish that live in seawater have long canals and the skin has relatively low resistance, that is, the fish is transparent to electric fields. The electrodes to the left and right of the fish produce a quasi-homogenous field. If the voltage between the electrodes is 10 μV and the distance between the electrodes is 10 cm, the field strength in between can be expressed as 1 $\mu V\ cm^{-1}$. Because the length of the canal 1 in **Figure 1**(**a**) is 2 cm, the voltage drop across the receptor is 2 μV. The voltage drop at canal 2 is zero because the canal is perpendicular to the field lines and parallel to the isopotential lines. In summary, the length

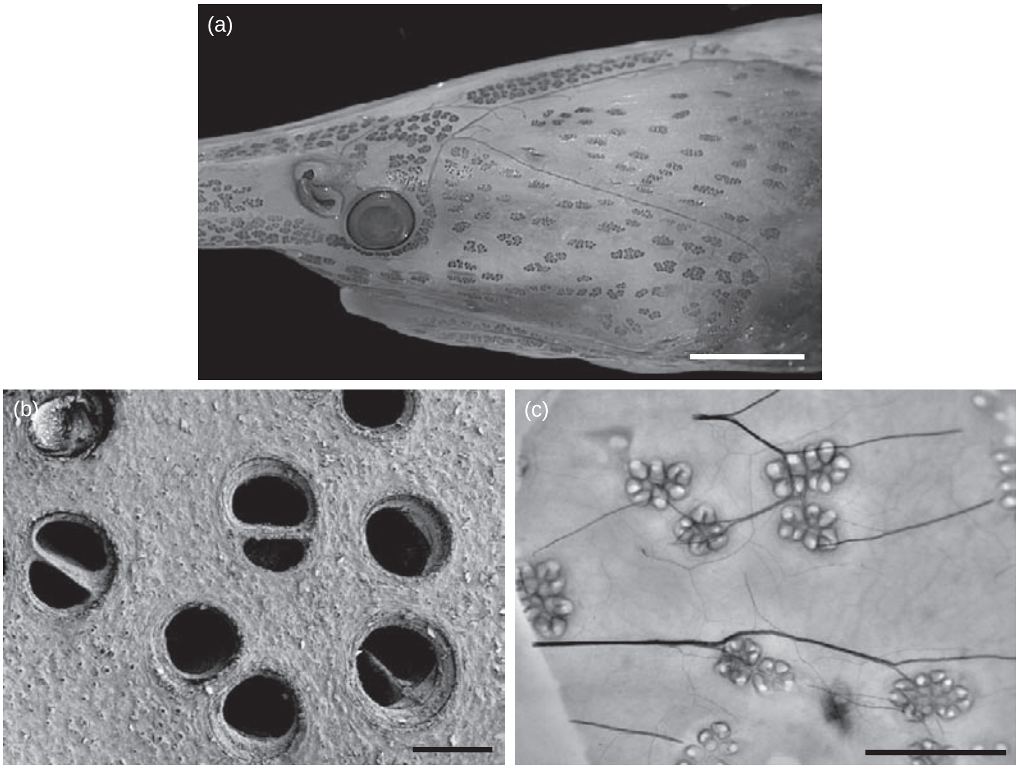

Figure 3 (a) Head of a paddlefish with ampullae of Lorenzini and lateral line canals stained. The ampullae are organized in clusters. Up to 75 000 individual pores have been counted in a larger specimen (scale = 2 cm). (b) Scanning electron microscope of individual pores in the paddlefish. Ampullae are constantly added during growth by division. Several stages of divisions are clearly visible (scale = 0.5 mm). (c) Sudan stain of a skin sample after bleaching with peroxide. The pore clusters are heavily innervated by large, myelinated fibers (scale = 1 cm).

of the canal determines sensitivity and the orientation of the canal provides information about the orientation of the electric field.

There is one more important aspect to reiterate. Electroreceptors are insensitive to DC fields because they rapidly adapt. Only changes in field strength can be detected, by varying either the source potential or its orientation. If the fish depicted in **Figure 4**(**a**) rests on the bottom, neither receptor would be able to measure anything. Only if the fish starts moving and changing direction would the receptors detect changes in electric field strength.

In freshwater, fish have a skin with relatively high resistance and electric fields cannot penetrate well. However, since the resistance of the body fluids inside the fish is low, the entire fish would assume a potential that is the average of the potentials on the skin (**Figure 4**(**b**)). As a consequence, the canals can be short and their length does not change the sensitivity. Otherwise, the situation is similar to the seawater fish described above.

Although there are always large-scale electric fields in the natural environment, it is currently not well investigated to what extent fish use this information for orientation. It is well established that small electric fields from other fish or invertebrates are detected. **Figure 5** shows a scenario where a small source dipole representing a prey fish is close to a larger electrosensory fish.

If we consider a freshwater fish with a short canal and high skin resistance, the receptor would measure the difference between the potential at the pore and the mean body potential inside. A small dipole source would not have any measurable effect on the potential inside the fish. However, if the dipole is close to one pore, the corresponding receptors at the base of the ampulla would certainly respond to that. The situation is similar in seawater fish with long canals. Because of the remote position of the end of the long canal, the potential there would not be affected by a small dipole close to the pore. As a consequence, the length of the canal is not important, in contrast to the situation in a large field.

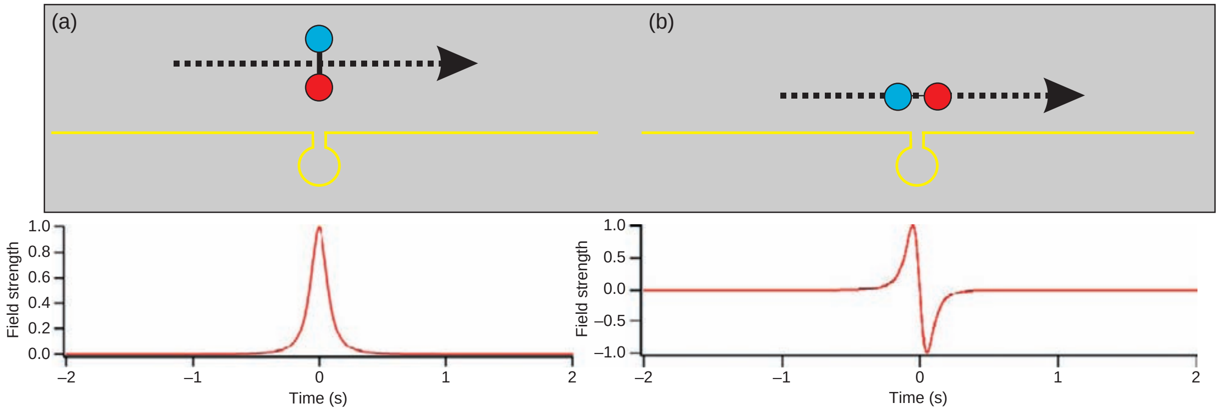

Figure 5 An electrical dipole with a DC field is moved over a receptor with the dipole oriented either perpendicular to the movement direction (a) or parallel to it (b). In the perpendicular mode, the positive pole (red) is always closer to the fish and the signal never becomes negative (graph of (a)). In the parallel mode, the receptor is first closer to the positive (red) pole, but after passing the center of the dipole, the receptor is closer to the negative (blue) pole and the signal at the receptor becomes negative. The field strength is normalized.

The voltage at the pore also depends on the orientation of the dipole. If the dipole is oriented perpendicular to the skin, the closer pole always dominates. If the dipole is oriented parallel to the skin and centered over the pore, both poles cancel each other out and the voltage at the pore is zero. In both cases, however, a static source would not be detected due to the rapid habituation of the receptors. If the source is moving parallel to the skin surface, however, the signal at the pore changes in time in a characteristic way as shown in **Figure 5**. The frequency range of this signal can be determined by calculating the Fourier transformation and it depends on the distance to the dipole and the relative velocity. Frequencies up to 10–30 Hz can be present in realistic situations. This correlates with the upper frequency limit for detection as measured by applying sinusoidal fields with different frequencies.

Physiology of the Receptors

The receptor cells at the base of the ampullae are innervated by afferent nerve fibers that carry information to the hindbrain. The voltage across the receptor cell is greatly amplified and regulates neurotransmitter release at the synapse to the afferent nerve fiber. The nerve fiber produces spontaneous action potentials and the rate of these action potentials is modulated by the neurotransmitter. Apart from the high amplification, the response to electric fields is also filtered. The system is insensitive to DC fields and responds best in the range between 1 and 10 Hz. There is hardly any response above 50 Hz. Filter properties are well investigated in the paddlefish, in which the receptors resemble a derivative filter in combination with a low-pass filter. A derivative filter is a filter where the gain is proportional to the frequency of the signal. This filter is not designed to cut off frequencies, but gradually attenuates lower frequencies.

In all nonteleost species, afferent fibers respond with increased spike rate if the pore becomes more negative and with a decreased spike rate if the pore becomes positive. In teleosts, the response is reversed; spike rate increases if the pore becomes more positive.

Without stimulation, the electroreceptors produce a constant spontaneous rate of action potentials. Detailed analysis of the spike train, however, reveals the presence of oscillations. Apparently, the membrane potential of the receptor cell itself is subject to oscillations that modulate the spike rate of the afferent fiber. Such oscillations are also known to be present in the high-frequency electroreceptors of active electrosensory fish and in mechanosensory vestibular and auditory hair cells, where they contribute to frequency tuning. In the passive electrosensory system, they are thought to increase sensitivity.

Information Processing in the Hindbrain

Electrosensory afferent fibers enter the hindbrain and terminate in the dorsal octavolateral nucleus (DON). Here, they make synaptic contact with large, multipolar secondary neurons that in turn project to the midbrain. These multipolar DON cells also receive extensive input from the cerebellum through the crista cerebellaris. Response properties of these secondary neurons are well investigated in a number of species. In catfish, two populations of neurons are present, which increase their spike rate in response to either positive or negative stimuli. In skates, secondary neurons have focal receptive fields with an inhibitory surround or sometimes two focal points, one inhibitory and the other excitatory. In the paddlefish, response properties of secondary cells are very similar to primary afferents.

One major function of the DON seems to be to filter out unwanted noise. The fish's own movement modulates its own electric field and these movements are detected by their electroreceptors. There are two known mechanisms for canceling out such unwanted noise. Modulations of the fish's own electric field affect all electroreceptors and such noise common to all of them can be filtered out by subtracting the average signal of all receptors from the signals at individual receptors. Only signals different from this common mode would then be transmitted to higher brain areas.

The other mechanism is more complex because it involves an adaptive filter. The modulation of the electric field due to respiration cannot easily be predicted. What is predictable is its timing. Any signals that are reliably correlated with the timing of inspiration and expiration are probably not due to external sources, and through plasticity, the circuit filters out these signals. If an electrical stimulus is given in phase with the fish's own respiration, hindbrain neurons initially respond to it, but slowly adapt with repeated presentation. Parallel fibers from the cerebellum are a major source of input to the secondary hindbrain neurons, and they provide the signal that marks the timing of respiration. The signal coming from the cerebellum is thought to provide a mirror image of the actual electrosensory input caused by respiration and this is used to cancel the sensory input. Indeed, if the artificial stimulus that was paired with the respiration is suddenly stopped, a mirror image of the initial response becomes visible and this also eventually disappears with time.

Higher Electrosensory Areas

Secondary neurons in the hindbrain DON send information to the midbrain. In teleosts, the major target is the torus semicircularis. In elasmobranchs, most fibers terminate more laterally, in an area called the lateral mesencephalic nucleus, but some fibers also project directly to the mesencephalic tectum. In the paddlefish, all three targets receive direct projections from the DON (**Figure 6**). It is not well known how electrosensory information is processed and integrated with information from other modalities. Electrophysiological recordings in the fore- and midbrain have mostly been made to localize electrosensory areas, but responses to different stimuli have rarely been investigated.

In the catfish, there are different populations of neurons with different best frequencies and different latencies in the torus semicircularis. In the rostro-caudal axis, there is evidence for a somatotopic arrangement, that is, neurons with receptive fields on the head are found more rostrally in the torus semicircularis and neurons with receptive field on the trunk more caudally. A similar somatotopic organization is found in the lateral mesencephalic nucleus of an elasmobranch.

One of the biggest problems for the electrosensory system, as opposed to the visual system, is the lack of directional sensitivity of the receptors. In the eye, the lens focuses the image onto the retina and individual photoreceptors only respond to a tiny fraction of the image. In the electrosensory system, the most important effect on response magnitude is the distance from the source to the receptor, but not its location in space. For a large fish capturing tiny water fleas, such as the paddlefish, the location of the prey is important and therefore we expect central mechanisms to enhance spatial resolution. In paddlefish, an edge detection filter in the tectum may be doing just that. Similar to algorithms used widely in digital image processing, tectal neurons seem to calculate the third derivative of electrosensory signals and thus are similar to an algorithm developed for computer vision, the Laplacian of Gaussian filter, that is used to detect edges in images.

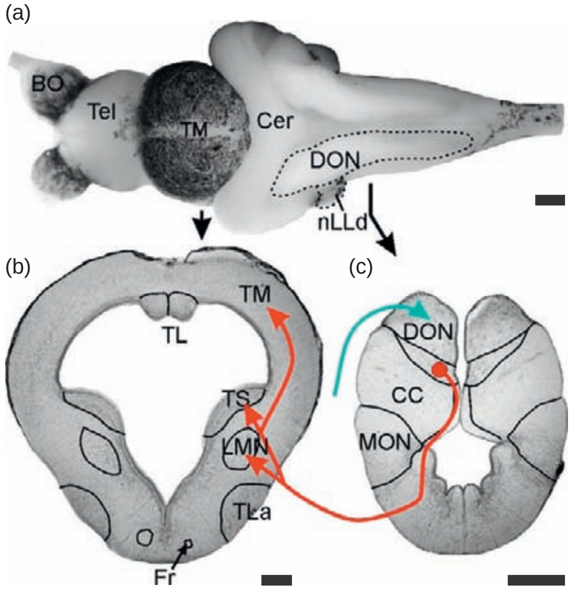

Figure 6 Central projections of the electrosensory system in a paddlefish. (a) Dorsal view of the brain with the large DON in the hindbrain. Arrows indicate the level of the frontal cross sections shown in (b) and (c). Primary afferent fibers first enter the DON in the hindbrain (blue arrow in (c)). Secondary neurons in the DON project to several areas of the midbrain (red arrows from (c) to (b)). Electrosensory-Guided Behavior

The first evidence that some fish can detect electric fields came from behavioral observations. Catfish avoid larger metal objects and sharks can be attracted to small dipole fields resembling prey. Avoidance and prey capture are probably the most important and best-investigated behaviors. In many situations, the electrosense is the best for sensing prey hidden in the substrate. Like a metal detector, skates and rays scan the substrate for hidden prey, and the visual system is certainly not capable of locating objects underneath the fish's disk. Olfaction and the mechanosensory lateral line are certainly used as well, but for precise localization, the electrosense is preferred. Sharks will strike at an electrical dipole hidden in the sand even if an odor source is located a small distance from the dipole.

Paddlefish are related to sturgeons, but in contrast to sturgeon, which scan the substrate for hidden invertebrates, the paddlefish feeds on tiny water fleas, the major component of freshwater zooplankton. These water fleas can be located in three-dimensional (3D) space using electroreceptors distributed throughout the dorsal and ventral surface of the head. More importantly, the electric field of the water flea is extremely small, and the paddlefish therefore has the highest sensitivity and highest number of receptors of any freshwater electrosensory fish. Their peculiar rostrum carries a large number of receptors to detect the prey well in front of the mouth. Smaller paddlefish feed on individual *Daphnia* and it is critical not to spend too much energy catching each one.

Paddlefish can catch *Daphnia* with their electrosense alone. Even in complete darkness, the number of *Daphnia* caught does not decline. There is one advantage of using the electrosense over the visual system. Murky water contains many particles, but only live prey produce an electric field. This means that small dipole sources always mean prey, but the visual system would suffer from false alarms. Paddlefish therefore can feed in murky waters where other fish cannot.

Another important function of the electrosense is to detect predators. A large approaching dipole field almost always means danger. There are few studies on avoidance responses in electrosensory fish, but large metal objects create corrosion potentials and can scare fish away. For fish conservation it is important to assess the impact of man-made submerged structures on electrosensory fish. Catfish and sturgeons are an important part of the freshwater ecosystem and sturgeons make extensive migrations to their spawning grounds. Man-made structures, especially metallic ones, may have great impact on spawning migrations, but there are virtually no studies on this topic.

There is little information on whether the electrosense is used for orientation and navigation. Large-scale electric fields are present in every aquatic environment and could be used as landmarks. Catfish align to these fields and artificial fields could be used to locate hiding places. However, it is not known to what extent catfish use large-scale fields in a natural environment.

An interesting hypothesis is that fish sense the weak electric field that is induced by swimming through the Earth's magnetic field. Elasmobranchs have the capacity to detect these induced fields. In fact, there are observations that sharks follow magnetic field lines and magnetic anomalies in the seafloor. There are also more controlled experiments on rays that show orientation to magnetic fields. Whether they detect these fields by sensing the electric field induced during swimming or whether they have other magnetosensors is unknown.

In some elasmobranchs electroreceptors are also used for communication. Skates (Rajidae) possess electric organs along the sides of their tail. In contrast to the strong electric discharges of the torpedo ray, skates produce only weak electric fields used mainly during courtship. There is also evidence that electroreception is used for communication in the absence of electric organs. Stingrays (*Urolophus halleri*) do not have electric organs, but strong modulations of their normal DC electric field caused by respiratory movements are detected by conspecifics buried in the sand.

Glossary

Amplitude modulation Refers to a signal in which changes in amplitude carry sensory information.

Corollary discharge Refers to a copy of a motor command that is sent from motor areas to sensory areas in the brain. It is often used to predict and eliminate sensory responses to self-generated stimuli.

Electrosense Ability to detect electric fields. A passive electrosense is one in which external electric fields are detected, whereas an active electrosense is one in which self-generated electric fields are detected.

Feedback Refers to projections from central brain areas back to more peripheral sensory areas.

Frequency modulation Refers to a signal in which changes in instantaneous frequency carry sensory information.

Information theory Refers to the mathematical theory of communication developed by Claude Shannon that is used in a variety of applications today.

Neural code Refers to the patterns of neural activity and transformations by which sensory input to motor outputs to give rise to behavioral responses by the organism.

Phase locking Refers to the tendency of certain neurons to fire at a preferred phase of a periodic signal.

Rate code Refers to a neural code in which information is carried solely by the firing rate (i.e., the number of action potentials per unit time) of a neuron.

Temporal code Refers to a neural code in which information is carried by the specific timings of action potentials.

Introduction

Weakly electric fish produce weak electric fields using specialized electrogenic organs. The electrical output of the organ is known as the electric organ discharge, or EOD (**see also Detection and Generation of Electric Signals:** Electric Organs and Generation of Electric Signals). There are two phylogenetically independent orders of weakly electric fishes: the Gymnotiformes of South America and the Mormyriformes of Africa. These clades evolved within two distantly related groups, the ostariophysans and osteoglossomorphs, respectively.

Gymnotiform and mormyriform fishes can both be classified as either pulse type or wave type, depending on the temporal structure of their EOD. Wave-type weakly electric fish generate continuous, highly periodic EOD waveforms (**Figure 1(a)**), whereas pulse-type weakly electric fish emit short, typically less than 2 ms, stereotyped pulses with longer periods of silence, typically greater than 10 ms, between pulses (**Figure 1(b)**). In some species the inter-pulse intervals are nearly constant, whereas in other species the inter-pulse intervals can vary over orders of magnitude.

Both wave- and pulse-type weakly electric fish can detect perturbations of the autogenous EOD using tuberous electroreceptors that are distributed on their skin surface: this is referred to as active electrolocation since the animal actively generates the sensory signal (**see also Detection and Generation of Electric Signals**: Active Electrolocation). Tuberous electroreceptors also detect the EODs of other individuals in the context of communication (**see also Sensory Systems, Perception, and Learning**: Shocking Comments: Electrocommunication in Teleost Fish). There are several classes of tuberous electroreceptors that encode different features of the animal's electric field. All species have at least two classes of tuberous electroreceptors, one type (amplitude coding) that encodes EOD amplitude modulations (AMs), and another type (time

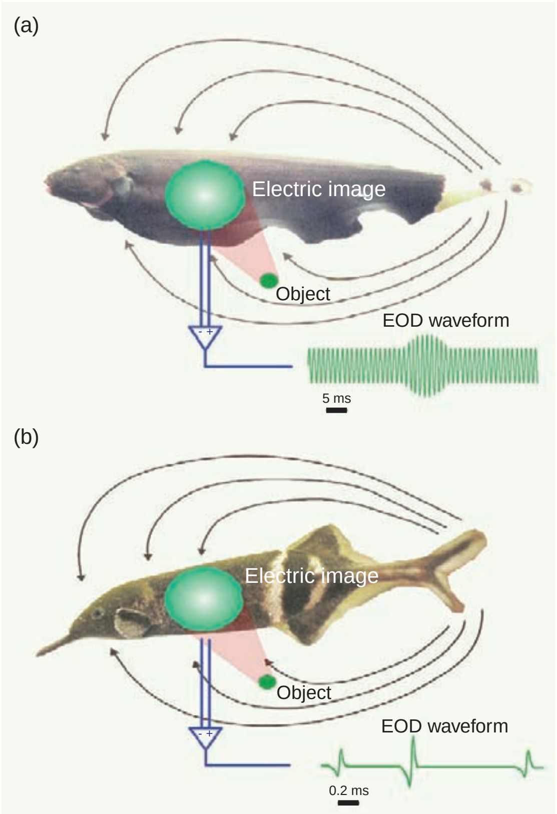

Figure 1 The principle of active electrolocation in weakly electric fish. (a) The wave-type gymnotiform species *Apteronotus albifrons* emits a highly periodic quasi-sinusoidal EOD. (b) The pulse-type mormyriform species *Gnathonemus petersii* emits pulses of electricity with strong variability in the interpulse interval. In both cases, one can easily record the EOD by placing a pair of metal wires close to the animal and connecting them to an amplifier. Objects with a conductivity different than that of the surrounding water (e.g., rocks, plants, other fish, and plankton) will distort the EOD; for example, a conductive object will locally increase the EOD amplitude. The projection of this distortion on the animal's skin surface is referred to as the electric image.

coding) that encodes EOD timing and frequency modulations (FMs). Information from these electroreceptors is transmitted to the electrosensory lateral line lobe (ELL) in the hindbrain. ELL neurons in turn project to the electrosensory midbrain and higher-order areas.

We first review the characteristics of amplitude- and timing-sensitive peripheral electroreceptive neurons in wave- and pulse-type gymnotiform and mormyriform weakly electric fishes. We then review the characteristics of ELL neurons with a particular emphasis on the role of feedback pathways in wave-type gymnotiforms. We conclude by highlighting some of the characteristics of higher-order neurons and their roles in behaviorally relevant computations.

Amplitude Coding

Both mormyriform and gymnotiform weakly electric fish have tuberous electroreceptors embedded in the skin that can encode AMs of the EOD. In gymnotiform fish, these receptors are known as P-units since it was originally found that the probability of firing increased linearly with EOD amplitude. In mormyriform pulse-type fish, these receptors are known as mormyromasts. **Figure 2** illustrates the coding strategy used by wave-type as well as pulse-type gymnotiform and mormyriform weakly electric fishes.

Amplitude Coding in Pulse-Type Fish

Mormyromasts in pulse-type mormyriform fishes usually respond with one or more action potentials to each EOD pulse (**Figure 2(a)**). In mormyromasts, the latency between the EOD pulse in the water and the first action potential decreases for increasing EOD amplitudes. There is very low trial-to-trial variability in the relationship between latency and EOD amplitude – these afferents use a timing code to transmit information about EOD amplitude (**see also Detection and Generation of Electric Signals:** Active Electrolocation).

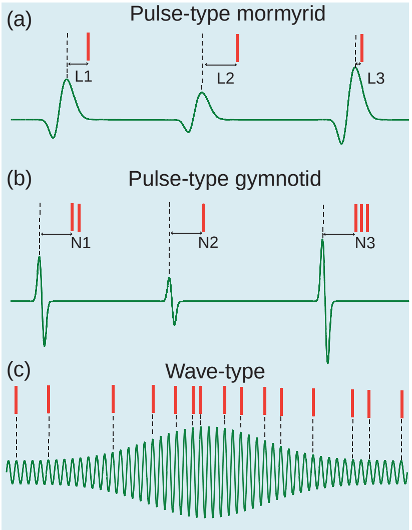

Figure 2 Amplitude coding in wave-type, pulse-type mormyriform, and pulse-type gymnotiform weakly electric fishes. (a) Mormyromasts in mormyriform pulse-type fish typically fire a single action potential (red bars) in response to each EOD pulse. However, the latency L between the EOD pulse and the action potential decreases monotonically with increasing EOD amplitude. (b) By contrast, burst duration coders in gymnotiform pulse-type fish fire a burst of action potentials in response to each EOD pulse. While the latency to first spike does not vary much with increasing EOD amplitude, the number of spikes in the burst (N) increases monotonically with increasing EOD amplitude. (c) P-units in gymnotiform wave-type fish and O-units in mormyriform wave-type fish fire action potentials that are phase-locked to the EOD but skip a random number of EOD cycles between firings. Their probability of firing an action potential increases with EOD amplitude.

Tuberous encoding in pulse-type gymnotiform fishes involves a different strategy. Tuberous neurons in gymnotiform fish exhibit little variation in the latency to the first spike, but instead modulate the number of spikes per burst as a function of EOD amplitude (**Figure 2**(**b**)). These are known as burst duration coders.

Amplitude Coding in Wave-Type Fish

In wave-type gymnotiform fishes, P-units exhibit some phase locking to the EOD with preferred phase near a local maximum. As the firing rates of P-units are usually lower than the EOD frequency, these neurons skip a more-or-less random number of EOD cycles between action potentials (**Figure 2**(**c**)). Increases and decreases in EOD amplitude will increase or decrease the firing rates of these units: the firing rate varies roughly linearly with EOD amplitude. These neurons encode AM information in a rate code. As one might expect, these units exhibit rectification for very low EOD amplitudes, because the firing rate cannot by definition be negative, and these units also saturate for very high EOD amplitudes. Recent studies have shown that these afferents have broad, flat tuning curves over the range of salient frequencies, from near 0 Hz to around 100 Hz.

In wave-type mormyriform fish, O-units have properties similar to those of P-units in wave-type gymnotiform weakly electric fish. Because both gymnotiform and mormyriform clades evolved independently, it is interesting to note that they evolved similar coding strategies for AM information carried by wave-type EODs.

Time Coding

As mentioned previously, weakly electric fish can also detect the timing of their EODs and therefore FMs (i.e., transient changes in the EOD frequency). Contrary to amplitude-coding strategies, time-coding strategies follow the same general principles in both pulse- and wave-type gymnotiform and mormyriform fishes.

Time Coding in Pulse-Type Fish

Pulse-marker units in gymnotiform and knollenorgans in mormyriform pulse-type weakly electric fish fire one phase-locked action potential per EOD pulse. These units therefore track changes in the EOD frequency (**Figure 3**(**a**)). In mormyrids, individual knollenorgans respond at various phases of an EOD pulse, so that relative differences in the timing of action potentials among knollenorgans additionally encode the EOD waveform (**see also Sensory Systems, Perception, and Learning:** Shocking Comments: Electrocommunication in Teleost Fish).

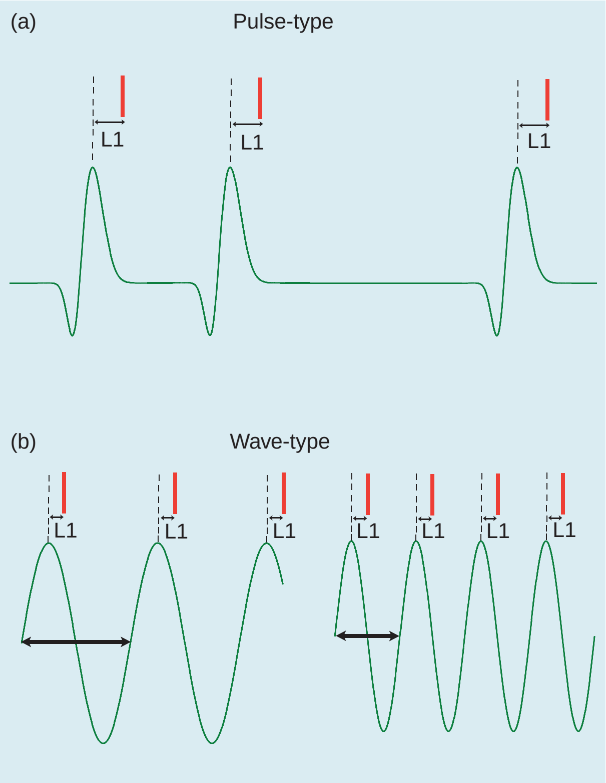

Figure 3 Time coding in wave-type and pulse-type weakly electric fishes. (a) Pulse-marker units in pulse-type gymnotiforms and knollenorgans in mormyriforms fire one action potential per EOD pulse and this tracks changes in EOD timing and frequency. (b) T-units in wave-type gymnotiforms and S-units in wave-type mormyriforms fire one action potential per EOD cycle (i.e., 1:1 phase locking). Their instantaneous firing rates thus provide a measure of the instantaneous EOD frequency.

Time Coding in Wave-Type Fish

T-units in gymnotiform wave-type weakly electric fish and S-units in wave-type mormyriform fish encode the timing of each EOD cycle and therefore the instantaneous EOD frequency by firing one action potential per EOD cycle at a precise phase (**Figure 3**(**b**)).

Projections to Higher-Order Neurons

The various types of electroreceptor units all project into a hindbrain structure known as the ELL. Anatomical and physiological studies have shown that the time-coding pathways preserve fine temporal information carried by time-coding afferents. In all classes of weakly electric fish, neurons receiving input from time-coding afferents have similar physiology: they fire one action potential per EOD cycle or EOD pulse. These neurons receive no descending feedback from central nervous system (CNS) circuits and thus appear to be a feedforward-only system. By contrast, information from amplitude-coding afferents is subject to complex processing that includes

Table 1 Summary of coding strategies used by tuberous electroreceptors

	Amplitude coding	*Frequency coding*
Wave type	*P-unit or O-unit.* Skips a random number of EOD cycles between firings. Probability of firing on any given EOD cycle increases with EOD amplitude.	*T-unit or S-unit*. Fires one action potential per EOD cycle. The phase of firing advances with increasing EOD frequency or amplitude.
Pulse-type gymnotiform	*Burst duration coder.* Fires a burst of spikes for each EOD pulse. The number of spikes in the burst increases with increasing EOD amplitude.	*Pulse marker unit.* Fires one action potential per EOD pulse at a precise phase.
Pulse-type mormyriform	*Mormyromast.* Fires one or more action potentials in response to each EOD pulse. The latency to the first action potential decreases with increasing EOD amplitude.	*Knollenorgan.* Fires a single phase-locked action potential in response to each EOD pulse.

descending feedback in ELL circuits. Tuberous electroreceptors fire not only in response to the animal's own EOD pulse, but also in response to EOD pulses emitted by conspecifics. As described below and reviewed in detail (**see also Detection and Generation of Electric Signals:** Active Electrolocation), pulse-type mormyrid fish generate a corollary discharge of each EOD pulse, allowing them to distinguish between self-generated and externally generated EODs within the ELL. Mormyromasts thereby give rise to a sensory pathway specialized for encoding self-generated EODs, whereas knollenorgans give rise to a sensory pathway specialized for encoding externally generated EODs. The basic properties of the electroreceptor types reviewed here are summarized in **Table 1**.

Physiology of ELL Neurons Receiving Input from Amplitude-Sensitive Electroreceptors

Amplitude Coding in Wave-Type Gymnotiform Fish

The ELL contains multiple segments devoted to processing tuberous input with the number of segments varying from species to species. The anatomy of an ELL segment in the gymnotiform weakly electric fish *Apteronotus leptorhynchus* is shown in **Figure 4(a)**. P-type electroreceptors project to pyramidal cells within the ELL. There are two types of pyramidal cells: basilar pyramidal cells receive direct electroreceptor input on their basilar dendrites, whereas nonbasilar pyramidal cells receive indirect electroreceptor input through local inhibitory interneurons. More recent studies have shown large morphological and molecular heterogeneities within the pyramidal cell population. Pyramidal cells are organized in both basilar and nonbasilar columns each consisting of superficial, intermediate, and deep cells. Pyramidal cells are the sole output neurons of the ELL. While all pyramidal cells project to the midbrain, only deep pyramidal cells give rise to the feedback input that is received mostly by superficial and intermediate pyramidal cells. These feedback projections can account for up to 95% of synaptic input to ELL pyramidal cells.

Pyramidal cell physiology is well characterized in general *in vivo* and there are important differences between superficial, intermediate, and deep pyramidal cells. Deep pyramidal cells have broad tuning curves and the highest spontaneous firing rates (>35 Hz) while superficial pyramidal cells have narrower tuning curves and the lowest firing rates (<15 Hz) with intermediate pyramidal cells having characteristics between these limits. Studies have shown that pyramidal cell tuning is both segment and context specific: pyramidal cells can change their tuning to match the temporal frequency content of both prey-related and communication-related stimuli.

Feedback pathways play important roles in regulating pyramidal cell responses to electroreceptor afferent input and many studies have elucidated their functions, which include gain control, cancellation of reafferent input, and regulation of burst firing, as described below.

Cancellation of Self-Generated stimuli

Sensory processing of electrosensory information is context dependent. For example, a given fish might be more interested in detecting a suitable mate or a prey item at different times of day and periods of its life. Indeed, tuberous electrosensory systems are modulated to vary the relative salience of information from conspecifics or prey items. Another example of context-dependent processing of electrosensory stimuli is the perception of movement. The fish's locomotion through the environment generates broad stimulation of the electrosensory system. This reafferent sensory stimulation must in turn be distinguished from external sensory stimuli such as a nearby predator or prey item. For weakly electric fish, tail movements that bring the tail closer/farther from a given point on the skin will increase/decrease the local EOD amplitude. Such signals can interfere with the detection of signals caused by external sources. In many species, the movement-related information is cancelled in the ELL. Different

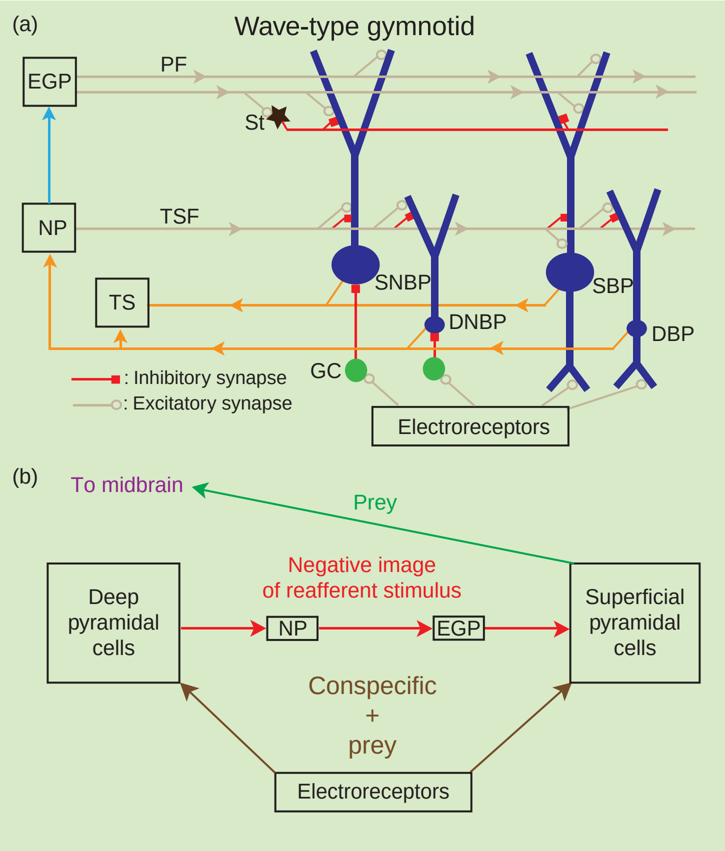

Figure 4 (a) Simplified anatomy of the ELL in *A. leptorhynchus*. Electroreceptors project to pyramidal cells: basilar pyramidal cells receive direct excitatory input while superficial nonbasilar pyramidal cells receive indirect inhibitory input via interneurons called granule cells (GC) There are large heterogeneities within the pyramidal cell population. Superficial basilar and nonbasilar pyramidal cells (SBP, SNBP) have large apical dendrites while deep basilar and nonbasilar pyramidal cells (DBP, DNBP) have small apical dendrites. Only deep pyramidal cells project to the nucleus praeminentialis (NP) while all pyramidal cell types project to the midbrain TS. Most interestingly, it is superficial pyramidal cells that receive the most feedback directly from NP via the tractus stratum fibrosum (TSF) and indirectly from granule cells in the eminentia granularis posterior (EGP) via parallel fibers (PFs). The direct projection from NP to ELL is called the direct feedback pathway while the indirect projection via EGP is called the indirect feedback pathway. (b) Functional circuit for cancellation of spatially diffuse electrosensory stimuli. Both superficial and deep pyramidal cells receive input from electroreceptors that respond to both conspecific and prey-related stimuli. Conspecific-related stimuli are spatially diffuse while stimuli caused by prey are spatially localized and only the former activate the negative image that is received mostly by superficial pyramidal cells, thereby allowing these cells to respond exclusively to prey stimuli.

species use different neural architectures to achieve this cancellation. Pulse-type mormyrid fish use a corollary discharge of the EOD command and an efference copy in order to achieve this function (**see also Detection and Generation of Electric Signals:** Active Electrolocation). Wave-type fish, however, have no such efference copy and must rely on other sensory signals and feedback pathways.

While electroreceptors in wave-type fish are sensitive to EOD AMs caused by tail movement, superficial ELL pyramidal cells are mostly insensitive to these same AMs. A series of elegant experiments performed by Bastian revealed that these neurons receive a negative image of the expected reafferent stimulus: the two inputs will cancel if the negative image has the right amplitude. Tail movements activate proprioceptors that project to the EGP and participate in generating the negative image. However, later studies revealed that tail bending is not required for cancellation; it can occur with tuberous electrosensory input only.

The necessary circuitry to achieve this was recently uncovered: deep pyramidal cells are strongly modulated by self-generated stimuli. In fact, these cells provide the necessary cancellation input to superficial pyramidal cells through feedback pathways. This mechanism relies on the fact that the electric images caused by different behaviorally relevant signals have different spatial extents: electric images caused by a fish's own EOD will cover the entire body surface, electric images caused by conspecifics will tend to cover most, if not all, of the animal's skin surface (these are often referred to as global stimuli), and the electric images caused by prey will only cover a small fraction of the animal's skin (local stimuli). Studies have shown that prey stimuli will not activate the negative image but that spatially diffuse stimuli will. As such, the cancellation circuit segregates spatially localized prey stimuli from spatially diffuse stimuli (**Figure 4**(**b**)).

Regulation of Burst Firing

Another major role for feedback pathways is to regulate the strength of pyramidal cell responses to sensory inputs. ELL pyramidal cells in *A. leptorhynchus* have a burst mechanism that is heavily regulated by feedback pathways. Pyramidal cells have much lower firing rates than receptor afferents (5–50 Hz) and they instead respond to changes in EOD amplitude with bursts of spikes (**Figure 5**(**a**)). Most interestingly, while receptor afferents use rate codes to transmit information about sensory stimuli, pyramidal cells use a timing code: spike bursts carry different information from isolated spikes. Bursts tend to code for low temporal frequencies of AM, while isolated spikes code for higher frequencies (**Figure 5**(**b**)).

Recent studies have focused on understanding the contributions of both ion channels and regulation of ion channel conductances by neuromodulators toward altering the responses of ELL pyramidal cells to sensory input.

Comparison between Wave-Type Gymnotiform and Mormyriform Weakly Electric Fish

Electrophysiological studies of ELL neurons in *Gymnarchus niloticus*, the only known species of mormyriform wave-type fish, show remarkable parallels with gymnotiform weakly electric fish. Separate neuron classes in the ELL respond to either AM or FM. Most surprisingly, these fish also lack a corollary discharge in stark contrast with their pulse-type cousins. Thus, tuberous electrosensory systems that have evolved independently apparently use similar strategies to code for behaviorally relevant stimuli, providing a nice example of convergent evolution. Further studies are needed, however, to understand the cancellation of self-generated stimuli in *G. niloticus*.

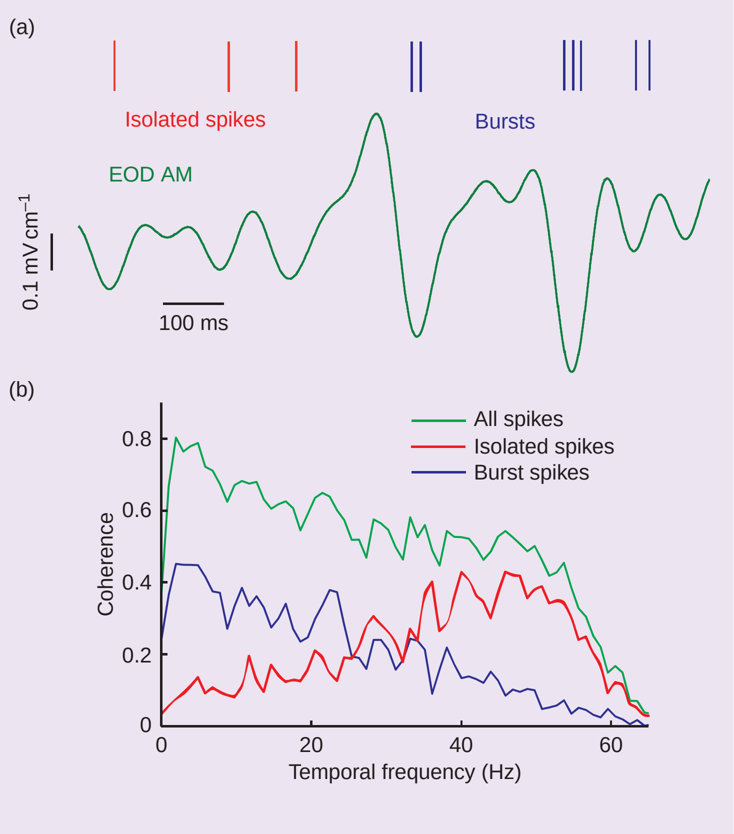

Figure 5 Physiology of ELL pyramidal cells in *A. leptorhynchus*. (a) Time-varying EOD amplitude (green) and spiking response of an example ELL pyramidal cell. This cell fired action potentials that were either isolated (red bars) or part of bursts (blue bars).
(b) Coherence between the spike train of an example pyramidal cell and time-varying EOD amplitude. The coherence computed from the spike train (green) shows that this cell responds to all frequency components contained within the stimulus. However, the coherence computed from burst spikes alone (blue) was greater for low frequencies while the coherence computed from isolated spikes alone (red) was greater for higher frequencies. Hence, action potentials can code for different aspects of the stimulus (here temporal frequency), depending on whether they are isolated or belong to a burst.

Physiology of Midbrain Neurons: Integration of Sensory Information

The torus semicircularis (TS) is a midbrain structure that is used to process electrosensory as well as auditory and mechanosensory information. In gymnotiform weakly electric fish, the TS is somatotopically organized and receives information from all of the maps in the ELL. It is hypertrophied and has distinct layers. Some of the layers in the dorsal torus receive direct tuberous inputs from ELL pyramidal cells, while others receive ampullary inputs (**see also Detection and Generation of Electric Signals**: Physiology of Ampullary Electrosensory Systems). These neurons send information to the ventral layers of TS. Information from P-type and T-type tuberous electrosensory systems is first sent to the ventral layers of the TS. Thus, the TS is a site of convergence, first from the various maps of the ELL in the dorsal TS, and second from P-type and T-type neurons in the deep layers of the TS. The TS is also where selectivity for specific behaviorally relevant stimulus features emerges in the ascending electrosensory pathway.

By contrast, the TS of mormyrid pulse-type fish is divided into separate nuclei that receive input from different groups of afferent neurons: neurons within the nucleus lateralis (NL) receive ampullary/mormyromast input while neurons in the nucleus exterolateralis (EL) and nucleus medialis ventralis (NMV) receive input from knollenorgans. We review some of the properties of midbrain neurons in both gymnotiform and mormyriform fishes below.

Emergence of Selectivity for Salient Stimuli

TS neurons exhibit more selective responses to electrosensory stimuli than do receptor afferents or ELL neurons. Specifically, these neurons often respond to a much narrower range of temporal frequencies or spatiotemporal features than ELL pyramidal cells. The mechanisms underlying the increase in selectivity in the TS have been intensively studied in relation to two behaviorally relevant stimuli – social stimuli related to the ‘jamming avoidance response’ (JAR) and moving electrosensory images.

Tuberous Mechanisms Underlying the JAR

The JAR behavior occurs in some wave-type species when two or more conspecifics are near each other, within ~1 m, and the fish have similar EOD frequencies, within about 10 Hz of each other. This tends to occur more in gregarious species such as *Eigenmannia virescens* (**Figure 6(a)**). When fish are close to each other, the electric fields mix and produce interference patterns. Interference patterns of 3–8 Hz are detrimental and impair each fish’s ability to electrolocate nearby objects. To avoid these detrimental interference patterns, each fish may change its EOD frequency. The JAR behavior differs between species and is best studied in the gymnotiform wave-type weakly electric fish *E. virescens* (**Figure 6(b)**). In this species, the animal with the lower EOD frequency decreases its EOD frequency while the animal with the higher EOD frequency increases its EOD frequency. This behavior thereby increases the frequency of the interference patterns produced by the interactions of the EODs to 20 Hz or more. Interference patterns greater than 20 Hz do not have detrimental effects on electrosensory perception. The JAR behavior is most strongly elicited by interference patterns at rates of 3–8 Hz, but only weakly by electrosensory stimuli at rates above 20 Hz.

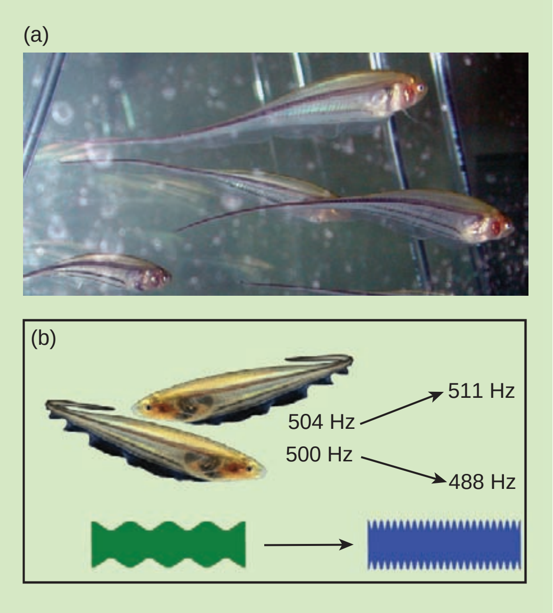

Figure 6 (a) *Eigenmannia viriscens* are gregarious (i.e., they tend to stay in groups). (b) The JAR of *Eigenmannia*. When two conspecifics are in close proximity and the EOD frequencies are within about 10 Hz (504 and 500 Hz shown here), the electric fields combine to produce spatially widespread AMs at the difference in frequencies in the EOD, which here is 4 Hz. The trace below shows a 1-s sample with a 4-Hz AM. This combined electric signal elicits the JAR, in which the higher EOD frequency fish raises its frequency, and vice versa for the lower EOD frequency fish. The result is a higher AM rate; 23 Hz is shown here.

Most surprisingly, the JAR behavior is similar in both wave-type gymnotiforms and *G. niloticus*. Overall, both groups compute the sign of the frequency difference similarly although some computations occur in different brain areas. These computations require simultaneous knowledge of the AMs as well as the phase modulations occurring on different parts of the body.

In wave-type gymnotiform fish, these AMs are encoded by P-units and subsequently encoded by ELL pyramidal cells. Many neurons within the layers 1–5 of TS respond strongly to low-frequency stimuli below

10 Hz and weakly to higher-frequency stimuli above 20 Hz. These low-pass responses are generated by a suite of mechanisms in TS, including passive membrane properties, short-term synaptic depression, and subthreshold membrane conductances. Similar mechanisms are found in the TS of *G. niloticus*.

Phase differences across the body give rise to timing differences between inputs from T-type (in wave-type gymnotiform fishes) or S-type (in *G. niloticus*) afferents across the animal's body. In *Gymnarchus*, these timing differences are detected by ELL neurons, whose sensitivity matches that of the animal's behavior. In wave-type gymnotiform fish, these differences are detected by neurons in lamina 6 of the TS. Specifically, giant adendritic cells within this layer receive input from multiple ELL spherical cells and are thought to average this input. Giant cells then project broadly across lamina 6 onto the somata of small cells that also receive local input from spherical cells on their dendrites. These small cells possibly perform a comparison of the local EOD phase with respect to an EOD phase that is averaged across the animal's body by responding specifically when input from the dendrites is coincident with input from the soma. The sensitivities of small cells to timing differences are still significantly less than that of the animal's and, in contrast to *Gymnarchus*, further integration appears to take place: one must look in the diencephalon to find neurons whose sensitivity matches the behavior.

As mentioned above, some neurons in the deep layers of the TS receive input from both the amplitude-coding and time-coding pathways. These neurons likely play a critical role in the JAR as they compute the sign of the frequency difference between fish, which is required to determine the proper direction of the change in EOD frequency. Some neurons are active when the frequency difference is positive, while others respond when the frequency difference is negative. Similar neurons are found within the TS of *G. niloticus* where nonlinear voltage-dependent conductances enhance their selectivity to particular combinations of AM and PM information.

Processing of EOD Waveform

Some neurons within the TS of pulse-type mormyrids are sensitive to small differences in EOD waveform. This circuit potentially functions in an analogous manner to the circuit found within lamina 6 in gymnotiform wave-type fish. Specifically, small cells within the EL pars anterior receive delayed excitatory input from nELL neurons and inhibitory input from giant cells within the same nucleus. This circuit would allow the small cells to respond selectively to EOD pulses of certain duration in a 'delay line blanking' mechanism. A major difference between the duration coding circuit in pulse-type mormyrids and similar circuits found in wave-type gymnotiform fishes is that the former uses both excitation and inhibition while the latter uses only excitation.

Tuberous Mechanisms for Processing Moving Objects

The electrosensory perception of moving objects is an important function in weakly electric fish. Prey capture can be achieved in complete darkness: under these conditions, it is likely that the tuberous electrosensory system is the primary source of salient sensory information for the control of the behavior. A critical feature for the behavior is the determination of the direction of movement of the prey stimulus. Selectivity for the direction of object motion first emerges at the level of the TS. P-type tuberous neurons in the dorsal layers can have strongly directionally selective responses to moving objects, whereas neurons in the ELL do not. Such neurons respond vigorously when an object moves in a particular direction (head-to-tail or tail-to-head) but weakly or not at all when the object moves in the opposite direction. Direction selectivity in these neurons is thought to derive from short-term synaptic plasticity and further studies are needed to understand the mechanisms giving rise to this computation.

Conclusion

Tuberous electrosensory systems use a variety of strategies to code for natural sensory input. On the one hand, the combination of neural mechanisms and strategies used to achieve the same computation in some distantly related species shows a remarkable level of convergence; on the other, a remarkable level of diversity exists in brain mechanisms and computations among more closely related species. Indeed, biological systems can often implement multiple solutions for the same functions, and the comparative approach is required in order to identify and understand the fundamental principles underlying neuron computations and behavioral control.

Glossary

Active electrolocation The ability of weakly electric fish to orient and detect objects based on their electric sense.

Electric image A two-dimensional modulation of the self-produced electric field at the sensory surface (electroreceptive skin) that is caused by the presence of an object in the environment.

Electric organ corollary discharge (EOCD) Neuronal copy of the electromotor command that is sent from motor areas involved in electric organ discharge (EOD) generation to sensory areas involved in processing electrosensory information. Among other functions, it is used to predict and eliminate responses to self-generated stimuli.

Electric organ discharge (EOD) Electrical discharges resulting from the summed excitation of the cells (electrocytes) of the electric organ of electric fishes that function both in communication and in locating nearby objects. Short (100 ms to several tens of milliseconds) electrical pulses of various voltages (a few millivolts to several hundred volts) are generated at various rates (a few to over 1000 times per second).

Fovea Classically, it is the location of the highest density of cone photoreceptors and thus the highest spatial acuity in the eye. More recently, the term is also attributed to regions of high receptor densities within the sensory surface in several other senses.

Reafference The sensory consequence of motor activity.

Somatotopy A topographic map-like representation of a sensory surface in the animal's brain.

Introduction

For acquiring information about their surroundings, weakly electric fish actively emit electric signals with a specialized electric organ (**see also Detection and Generation of Electric Signals**: Electric Organs). Electric organ discharges (EODs) are species specific, either continuous sinusoidal signals or short pulses of 100 μs to a few milliseconds in duration. In African mormyridae, pulse-EODs are constant all-or-nothing events, which are emitted in an irregular train of pulses depending on behavioral context (**Figure 1(b)**; **see also Detection and Generation of Electric Signals**: Generation of Electric Signals). Nearby objects distort the field generated by the EOD (**Figure 1(c)**), and the animal senses these modulations of the EOD to analyze its surroundings.

We focus on the African mormyrid *Gnathonemus petersii* (**Figure 1(a)**), or elephantnose fish. This fish is probably the best-studied mormyrid with respect to its active electrolocation system. It can link and assemble local features of sensory patterns to construct representations of objects in complex scenes and thus solve complex object-recognition tasks.

EOD Carrier Modulation as a Source of Environmental Information

Modulations of the EOD are caused by objects close to the animals' skin that differ in impedance from the surrounding water. Depending on the impedance difference between object and water, the current flowing locally through electroreceptors next to the object is either decreased or increased, resulting in a decrease or increase in voltage at the receptor (**Figure 1(d)**, top). Capacitive properties of nearby objects can additionally alter the waveform of the local EOD (**Figure 1(d)**, bottom).

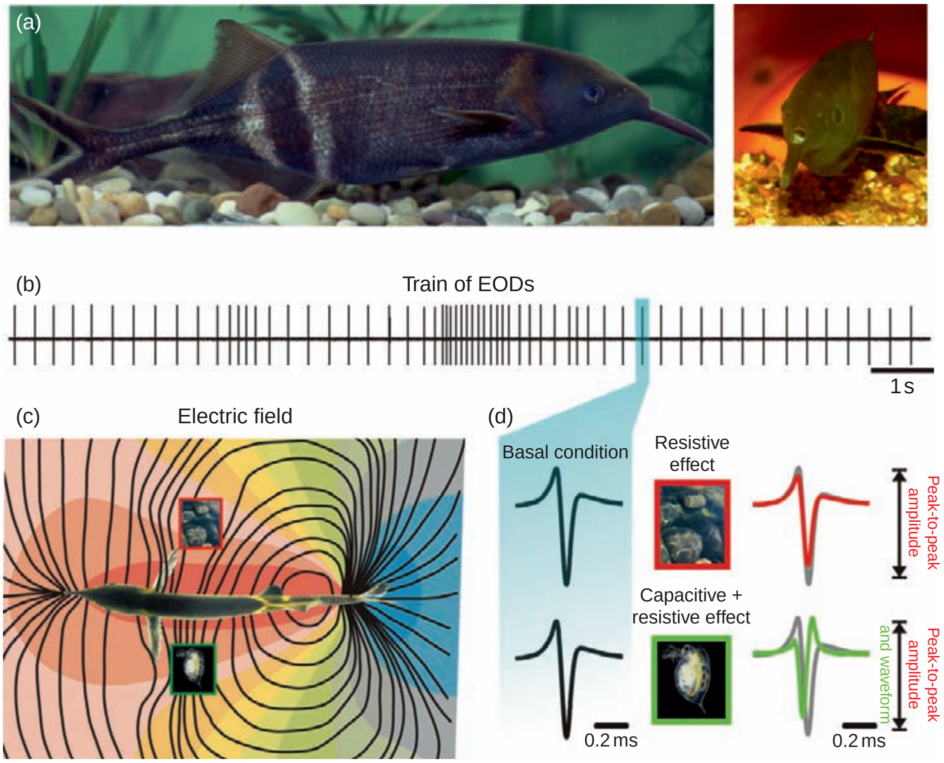

Figure 1 (a) Photograph of a *Gnathonemus petersii*, a member of the African weakly electric Mormyridae family. (b) A sequence of pulse-type electric organ discharges (EODs) emitted by the weakly electric fish *G. petersii*. While the interval between EODs can vary, EOD amplitude is constant. (c) Schematic of the electric field that surrounds the animal when an EOD is emitted. The solid lines indicate the current flow, while the electric field potential intensity is shown in a color code. Insulating objects (stones) locally decrease the amplitude of the field, which means that the current flow is quenched to the sides of the object (above). Conductive and or capacitive objects such as the little prey copepod shown below increases the field intensity locally; thus, they cumulate a higher current density (d) Comparison of the potential modulations of the signal carrier by inanimate, resistive objects (stones) as opposed to a living prey item (copepod) with a complex impedance consisting of resistive and capacitive components. While objects that differ in their resistance from that of water only modulate the peak-to-peak amplitude of the EOD (red signal, top row), complex impedances alter both the EOD amplitude and its waveform (green signal, bottom row). The basal EOD is shown in gray and the modulated EOD in color.

The electric image of the objects is thus projected onto the electroreceptive skin, which covers almost the entire body. In mormyrids, a typical electric image has a centre-surround (or Mexican hat) spatial profile (**Figure 2**). A conductor projects an image with a large center region where the local EOD amplitude is increased, surrounded by a small rim area where the amplitude is decreased. Images of nonconductors are of opposite arrangement: local EOD amplitude decreases centrally and slightly increases in the surrounding rim area.

Electric images are always blurred, or out of focus, because no focusing mechanisms comparable to the lens of an eye exist. Hence, when projecting three-dimensional (3D) objects on the 2D sensory surface, there is no one-to-one relationship between spatial object properties and image shape. In addition to shape, size, and geometrical properties of the object, electric images depend on object distance and location along the fish's body, the fish's body proportions, bending movements of the fish's body, the presence of additional objects, background conductance, and more. For example, electric images of two objects fuse in a nonlinear way depending on the distance between them (**Figure 2**).

Prereceptor Mechanisms

Before a sensory stimulus hits the receptor cells, it is modified by structures external to the receptors. In active electroreception, such prereceptor mechanisms were initially described in South American weakly electric fish, where they enhance the perception of electric images. In *G. petersii*, the low resistive internal electric properties and the elongated shape of the fish's body constitute part of these prereceptor mechanisms. While the EOD waveform is reasonably constant, the EOD amplitude changes from caudal to rostral along the fish's body. The overall effect of the prereceptor mechanisms detailed below is that EOD amplitudes are fairly constant in the head region where highest electroreceptor densities occur.

Figure 2 Schematic drawings explaining the concept and properties of electric images. The left-hand side shows how the two-dimensional (2D) image (the change in current flowing through the animals' skin in the presence of an object with respect to the current pattern without any object present) depends on the distance (*z* coordinate) of an object. With increasing distance, the location of the peak in the image remains constant (*x*, *y*); while the overall amplitude decreases, the image increases in width and the slope of the images becomes more shallow (blur). The right-hand side shows that electric images interact in a nonlinear fashion if two objects are in close proximity. Thus, electric images are apposition images. The bottom data show modeled transects through electric images for two small spheres that are progressively moved closer to each other. Note that for 6-mm interobject distance, the peaks of the electric image begin to fuse to one single peak. Modified from Engelmann J, Bacelo J, Metzen M, *et al.* (2008) Electric imaging through active electrolocation: Implication for the analysis of complex scenes. *Biological Cybernetics* 98(6): 519–539.

The elongated chin appendix (Schnauzenorgan) of *G. petersii* is mainly stimulated by current impinging from the front of the fish. This can be attributed to the presence of two effects: the constantly open mouth funnels current between the mouth and the nares, and the internal tissue of the Schnauzenorgan funnels current stimulating the Schnauzenorgan receptors. The thin and elongated shape of the Schnauzenorgan constitutes an additional mechanism termed 'tip effect', to locally increase EOD amplitude. Thus, several passive prereceptor mechanisms enhance the electrical field properties in a manner ideal for active electrolocation at the region of the animal's body that has the highest fovea-like densities of electroreceptors (see below).

When *G. petersii* forages, they move their Schnauzenorgan rapidly, which might cause changes of the electric-field distribution around the body and hinder active electrolocation with the Schnauzenorgan. However, relying on the tip effect, the electrical field moves together with the Schnauzenorgan. This results in constant EODs at the tip of the Schnauzenorgan, analogous to a spot light that moves along the ground and dynamically scans the environment.

Behavioral Performance during Object Detection and Analysis

During active electrolocation, weakly electric fish detect and analyze several object properties based on the electric images. Among these is the electrical resistance of objects determined by measuring the change in amplitude. Mormyrids and gymnotiforms can also perceive capacitive object properties. This requires that the animals measure either EOD waveform distortions (mormyrids) or phase shifts (gymnotiforms). The range of capacitive values that an animal can detect depends on the duration of its EOD: shorter EODs enable the detection of lower capacitances. The detectable range of capacitances corresponds to the range of capacitive values of animated objects found in the natural habitat of the fish. Therefore, capacitance detection could be used to find living objects such as food or other fish.

Mormyrids also localize objects in 3D space. When presented with two objects at different distances, *G. petersii* can learn to choose the farther of the two objects. This capability constitutes a true sense of

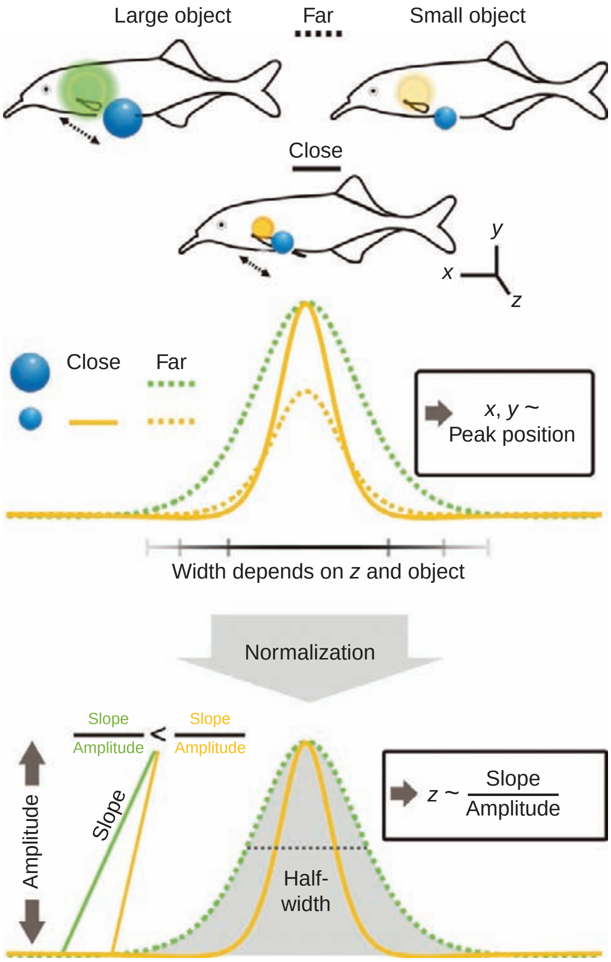

Figure 3 (a) Schematic comparison between the electric images of a small and a larger sphere when both are at the same distance (top row), and for the smaller object at a closer distance (middle). Transects below show the spatial amplitude distributions of the electric images. Note that the positions of the peaks *x* and *y* are similar in all three cases, whereas the widths and slopes of the images depend on size and distance of the objects. (b) The electric images of the closer small sphere (yellow) and the further removed large sphere (green) differ in width and slope but not in amplitude. Normalizing images by their amplitudes results in a size-invariant measure for distance – the slope/amplitude ratio.

depth perception, based on measuring the normalized maximal slope of the electric image (**Figure 3**). Fish can measure the slope of the electric image by determining the intensity change at the image's edges, or the fuzziness of the edges. For the normalized slope, they set this slope value in relation to the maximum intensity in the image's center.

Even though the electric sense lacks focusing mechanisms, weakly electric fish also perceive an object's 3D shape. In a two-alternative forced-choice procedure, *G. petersii* quickly learns to recognize objects of various shapes and discriminate them from different shapes. Shape recognition persists even when the objects are rotated in space, indicating a viewpoint-independent recognition of objects. *G. petersii* also demonstrates size constancy during object recognition, that is, they recognize an object of a certain shape even if its electric image appears larger or smaller because of variation in object distance. Fish can also identify the size of an object independently of its distance (**Figure 4**). For analyzing the shape or size of a new object, fish perform the so-called probing motor acts, that is, they swim around the object, scanning it with their sensory surface from several viewpoints. This is in contrast to distance measurements, which can be achieved instantly and do not require scanning movements.

The electric images of objects located close to each other fuse in a nonlinear way, leading to complex electric images (**Figure 2**). In spite of this effect, *G. petersii* is able to perceive the shape of an object even when it is positioned right in front of a large background (**Figure 4**). This ability persists even if the object and the background are made from the same material, for example, a metal object in front of a metal background. When trained to discriminate between two objects placed next to each other and a solid object of the same length, *G. petersii* is able to detect gaps as small as 2–3 mm between the two objects. It is currently not known how the fish perform these tasks.

These findings show that weakly electric fish have a remarkable ability to analyze complex 3D scenes and can identify object properties even in a natural setting containing many objects of various sizes, shapes, and materials.

Foveation in Electrolocation

In visual systems, foveation is an important mechanism for detailed object analysis. Behavioral, anatomical, and physiological studies reveal several similarities between certain electroreceptive skin regions and the eyes of pigeons. Two separate foveae have been found in *G. petersii*, one located at the Schnauzenorgan and the other between the mouth and the nares, the so-called nasal region. Both match the requirements of a fovea: (1) a higher density of electroreceptors compared to the rest of the sensory epithelium; (2) an overrepresentation of these areas in the brain; (3) structural/morphological and physiological specializations of the receptors and accompanying structures within the foveae; and, finally, (4) the animals show behavioral adaptations for focusing a stimulus onto the foveae for detailed analysis (**Figure 5**).

Similar to the pigeon's eye, the two foveae of *Gnathonemus* serve separate functions: the nasal region is a long-range guidance system that is used to detect obstacles or other objects in front of and to the side of the animal, for example, during foraging. The

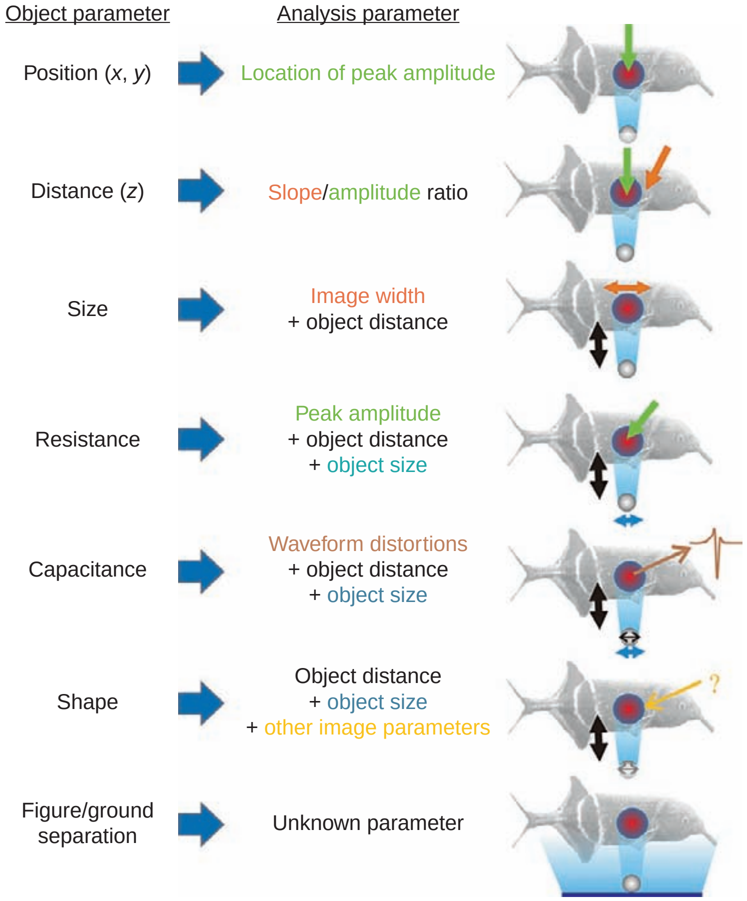

Figure 4 Object properties (object diameter >5 mm) (left) and the parameters of the electric image (right) that *G. petersii* employ for their determination during active electrolocation. In order to recognize most object parameters, combinations of several image parameters are necessary.

Schnauzenorgan, on the other hand, is a short-range movable (prey-) detection system that is used to find and identify prey on the ground or inspect object details. Both systems work simultaneously to ensure an optimal sensory inspection of the nocturnal environment of the fish.

Electroreceptors for Active Electrolocation

Weakly electric fishes have two classes of electroreceptor organs (**see also Detection and Generation of Electric Signals**: Morphology of Electroreceptive Sensory Organs). Ampullary organs respond to low-frequency electric signals of animate and inanimate origin (**see also Detection and Generation of Electric Signals**: Physiology of Ampullary Electrosensory Systems). These receptor organs are used for passive electrolocation.

The second class of these organs, tuberous electroreceptor organs, are found only in clades that also have electric organs, that is, in the South American Gymnotiformes and the African Mormyriformes. Tuberous receptors are tuned to electric signals with high carrier frequencies, and are generally most sensitive to the dominant frequencies of the fish's own EOD. In both groups, tuberous receptors encode the amplitude and the phase of the fish's own EOD (**see also Detection and Generation of Electric Signals**: Physiology of Tuberous Electrosensory Systems).

Mormyromasts and Knollenorgans are the two types of tuberous electroreceptors found in mormyrid fish. Knollenorgans are exclusively used to detect the EODs of other mormyrids for communication (**see also Sensory Systems, Perception, and Learning**: Shocking Comments: Electrocommunication in Teleost Fish), whereas mormyromasts are responsive to the animal's own EOD and modulations of the EOD caused by the external environment. Each mormyromast houses two types of receptor cells that are tuned to different aspects of the signal carrier, that is, one channel for amplitude (A-cells) and one for waveform encoding (B-cells). Afferents of both types of receptor cells terminate somatotopically in two zones of the electrosensory lateral line lobe (ELL) of the brain.

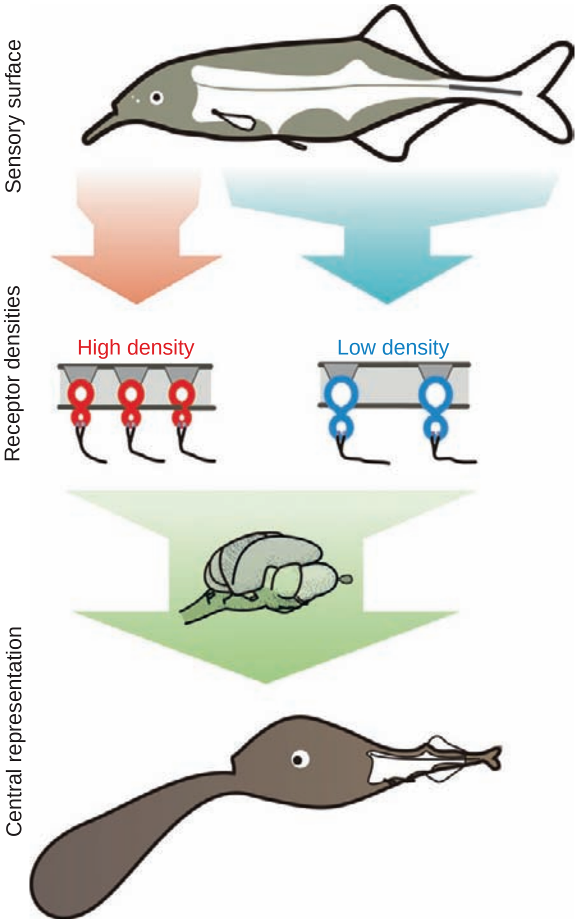

Figure 5 Schematic of the peripheral and central foveation mechanisms in *G. petersii*. The top drawing shows the sensory surface of the fish (light gray filling). The middle part indicates that the Schnauzenorgan and the head region contain the highest densities of mormyromast electroreceptors. This asymmetry of the receptor distribution is further enhanced in the ELL, where a central magnification of the Schnauzenorgan region and the head region takes place. Thus, about 2 times as much brain area is devoted to the processing of information from the Schnauzenorgan than would be expected based on receptor density. In the sketch below, the sizes of the electroreceptive skin areas are shown in proportion to their representation in the brain. Note that in this drawing, the Schnauzenorgan and the nasal region appear overproportionally large relative to the rest of the body.

Peripheral Encoding

Latency coding of EOD amplitude and electrical imaging

In response to an EOD, mormyromast receptor cells generate graded receptor potentials that give rise to action potentials in primary afferents. To an undistorted EOD, most afferents of A- and B-cells respond with a burst of 2–6 action potentials. Both types of afferents respond with an increase in the number of spikes and a decrease in spike latencies when the stimulus amplitude increases. The coding of EOD intensity by the latency of the first spike is continuous, whereas the transition in spike number is discrete. Thus, mormyrid fish are good examples of spike-latency encoding.

As modulations of the EOD amplitude by natural objects are small, animals must extract latency changes in a sub-millisecond range. This is reflected in the precision with which afferents respond to an object moving through the receptive field (see **Figures 6(a)** and **6(b)**). The resulting electric image is a typical Mexican-hat-like modulation of the basal EOD amplitude. This is linearly translated into the spike latencies of the afferents. Only very intense modulations induce additional changes in the number of spikes.

Encoding of waveform

Only the B-cells are extremely sensitive to minute waveform distortions of the local EOD as they occur in the presence of capacitive objects. For capacitance detection, *G. petersii* measures these EOD waveform distortions based on the differential input of the A- and B-type electroreceptor cells (**Figure 7**). However, central mechanisms are needed to extract impedance unambiguously, because both receptor types are affected by amplitude. It should be noted that in nature, capacitive objects will always induce both amplitude and phase modulations of the EOD.

Central Processes

Information Processing in ELL

ELL circuitry

Sensory input of mormyromast afferents is relayed to a layer of granule cells in the ELL. Here, the temporal code of the afferents is transformed into a rate code. Granule cells are either gamma-aminobuytric acid-ergic (GABAergic) or glutamatergic and make synapses on the basal dendrites of both inhibitory interneurons and two types of efferent neurons. Efferent neurons that are inhibited by sensory input are the large ganglion (LG) cells, while large fusiform (LF) cells are excited by sensory input. The most prominent interneurons, the Purkinje-like medium ganglion (MG) cells, provide inhibitory input to these efferent cells (**Figure 8**).

In addition to the peripheral sensory input, several central afferents provide projections to the ELL (**Figure 8**). These central afferents are related to specific neuronal tasks such as noise cancellation, the differentiation of re- and exafferent input, and the decoding of the latency code of the sensory afferents (**see also Detection and Generation of Electric Signals**: Physiology of Tuberous Electrosensory Systems).

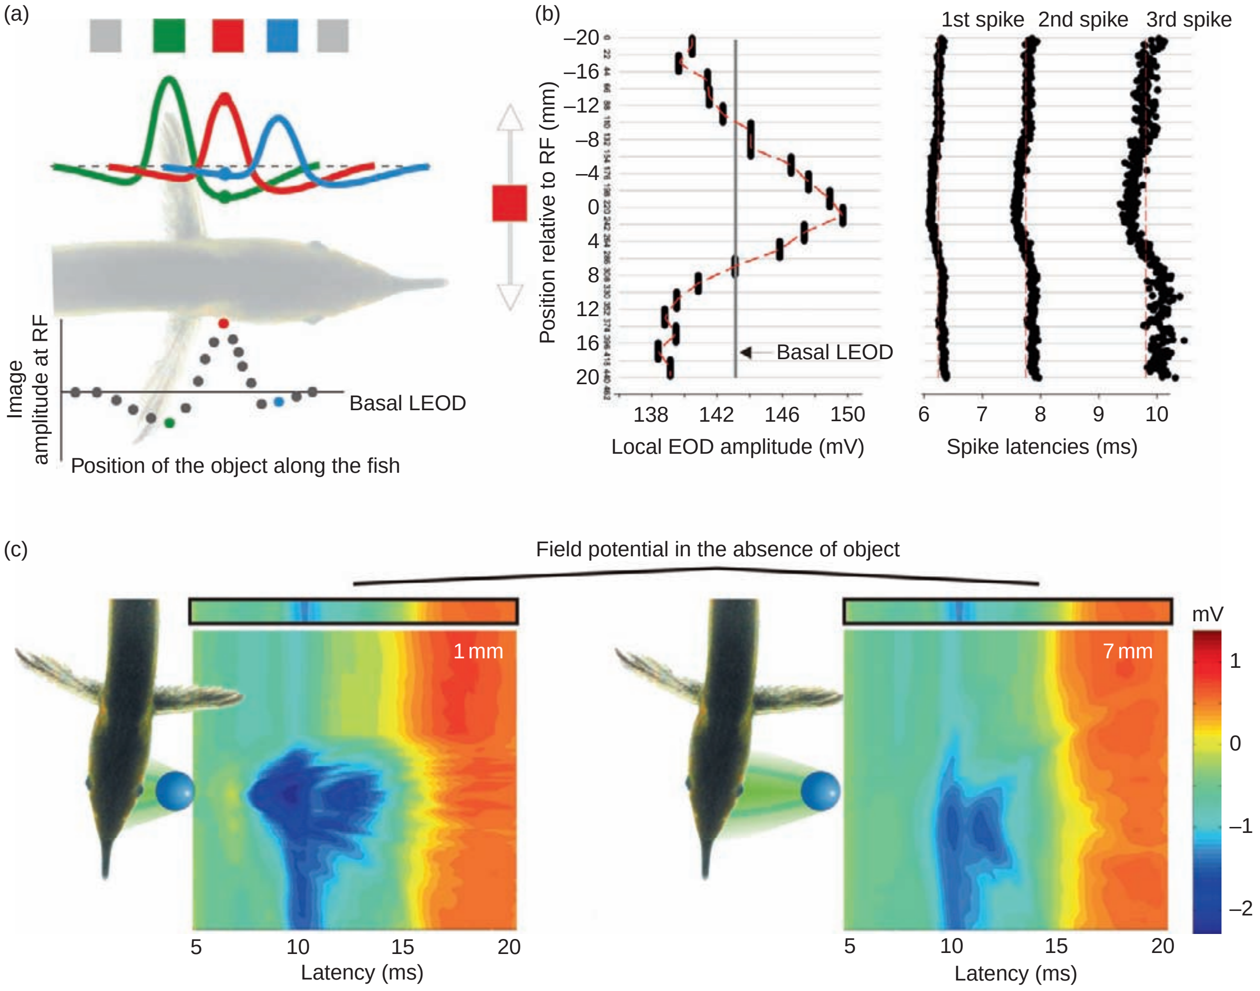

Figure 6 Response patterns of primary afferents and field potentials in ELL. (a) Schematic of the recording and stimulation procedure. An object is moved through the receptive field of a mormyromast (located at the red dot). At each position, the object casts a slightly different image on the skin. The receptor therefore responds to the local modulation of each image as it occurs at the location of the receptor pore on the skin. (b) Raster diagram of the changes in the basal EOD amplitude (left) and the spike latency of a mormyromast A-cell afferent (right) recorded simultaneously. The horizontal lines separate recordings obtained from spatially neighboring positions. Note that the electric image is faithfully encoded in the latency of the first spike. Note that high stimulus amplitudes (peak of the image) lead to short latencies of the spike response and vice versa. (c) Color maps showing the field potential recorded in the ELL as a function of time and object position. The horizontal axis of each graph shows time and the vertical axis represents the location of the object along the longitudinal axis of the fish. The two graphs show results for an object distance of 1 mm (left) and 7 mm (right). The top parts indicate the field potentials in the absence of an object, and any difference to the graph below is due to the presence of the object and the corresponding change in sensory input. As the object is moved further away from the animal (*z*-axis), the width of the neuronal representation contained in the field potential increases but the response amplitudes steeply decline. Data in (c) are modified from Gomez L, Budelli R, Grant K, and Caputi AA (2004) Pre-receptor profile of sensory images and primary afferent neuronal representation in the mormyrid electrosensory system. *Journal of Experimental Biology* 207(14): 2443–2453.

Latency Code to Rate Code Transformation in Granule Cells

The mormyromast receptors provide an example of temporal coding, because the latency of the first spike conveys all the information about amplitude and phase of the external EOD. Afferent fibers form mixed chemical and electrical synapses onto granule cells in the ELL. A second excitatory input from the juxtalobar nucleus, which conveys EOD-time-locked input (electric organ corollary discharge (EOCD)), also synapses on the granule cells. This corollary discharge input gates the reafferent input from the mormyromast electroreceptors, thus preventing granule cells from responding to the EODs of other fish. Granule cells have the potential to transform the latency-encoded stimulus amplitude conveyed by the afferents to a rate code, because they respond gradually to excitatory postsynaptic potentials (EPSPs). In addition, the efficiency of synaptic input

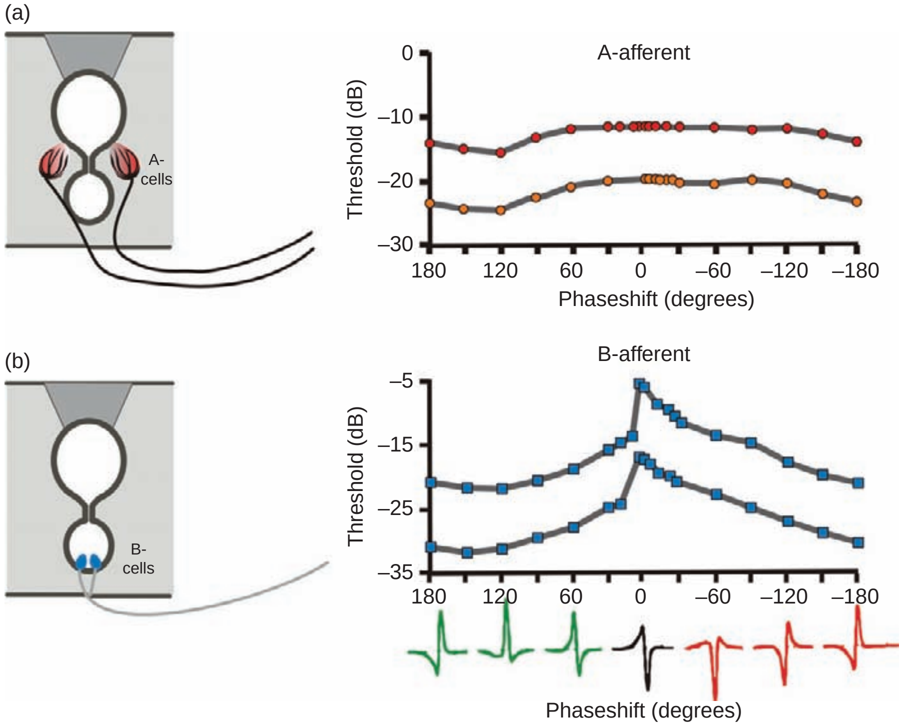

Figure 7 Response of two A- (a) and two B-cell (b) afferents to phase-distorted EODs. Afferents were stimulated with phase-shifted versions of their natural EOD (shown in black). This manipulation only affects the waveform but maintains a constant peak-to-peak amplitude and power spectrum of the EOD. While A-afferents have relatively high thresholds and respond to waveform-distorted EOD similar as they do to their natural EOD (a), B-cell afferents are least sensitive to the undistorted EOD and respond highly sensitive to weak waveform distortions characteristic for living prey items, which correspond to phase shifts in the range between 0° and –45°. Modified from von der Emde G and Bleckmann H (1997) Waveform tuning of electroreceptor cells in the weakly electric fish, *Gnathonemus petersii*. *Journal of Comparative Physiology A* 181(5): 511–524.

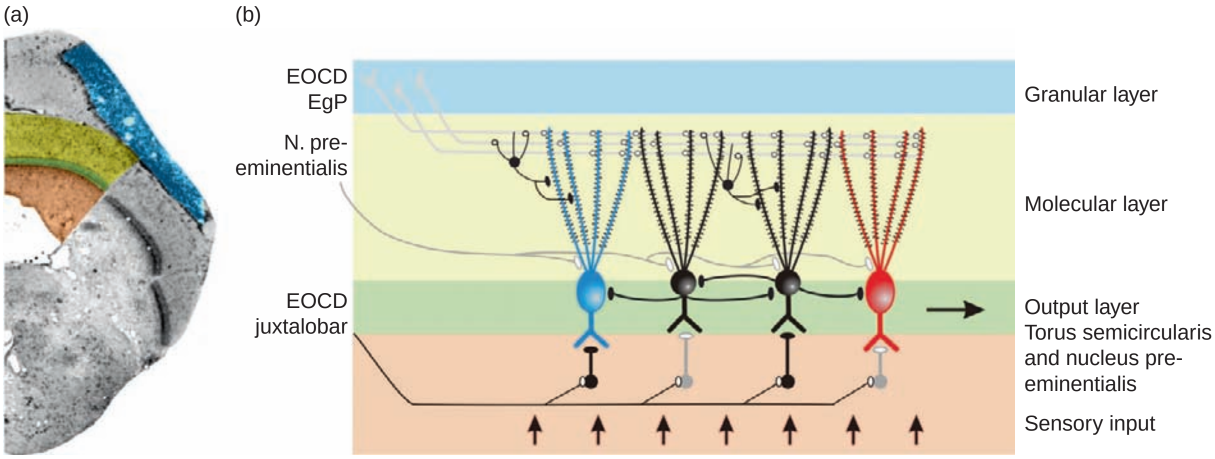

Figure 8 (a) Photomicrograph of a section through the ELL of *Gnathonemus*. Laminar regions of the medial zone of the ELL are highlighted in the same colors as used in the schematic of the ELL (b). (b) Schematic of the layered organization of the ELL. On the left and below, sources of input to the ELL are shown. Primary sensory input from electroreceptors converges on granular cells in the granular layer. These cells also receive strong corollary discharge-related input from the juxtalobar nucleus (electric organ corollary discharge (EOCD)). Local interneurons (black) and ELL efferent cells of two varieties (blue and red) are found in the ganglionic layer (output layer). While large ganglionic cells (I-cells, blue) are inhibited by sensory input, large fusiform cells (E-cells, red) are excited. The local interneurons (medium ganglionic neurons, black) are either inhibited or excited by the sensory input and provide local inhibitory feedback to the efferent cells. Afferents of nucleus preeminentialis supply direct electrosensory feedback input to the basal apical dendrites of these cells of the ganglionic layer. A third central source of afferents comes from the eminentia granularis (EgP), which sends massive bundles of parallel fibers to the molecular layer of the ELL. This input conveys corollary discharge input (EOCD), sensory input of other modalities, as well as predictive signals that drive plasticity in this system. The photo was kindly provided by K. Grant.

in driving granule cells depends on the timing between sensory and juxtalobar input. Thus, the synaptology of granule cells makes them ideal candidates for a coincidence-based transformation of latency-encoded afferent input to a rate code.

Spatial coding

The coding accuracy of finite spatial coordinates depends on the tuning width of the neurons. Narrow receptive fields are best suited to encode 1D (e.g., EOD amplitude) and 2D parameters (localization of a stimulus), while for encoding three dimensions, optimal tuning widths exist. Electric images are 2D by nature, and sensory information of these images is relayed to the topographically ordered array of neurons in ELL (**Figure 9**). This 2D representation enables fish to determine the 3D coordinates of objects (*x*, *y*, *z*). Object location (*x*, *y*) is directly accessible as the location of the maximal amplitude from the map within ELL (**Figure 3(a)**). Object distance (*z*), however, must be extracted using measures related to the amplitude and width of the electric images (**Figure 3(b)**).

With regard to orientation (*x*, *y* coordinates), the spatial resolution ultimately set by the mormyromast density is maintained at the early processing stages. Mormyromast afferents and efferent cells of ELL show characteristically small receptive fields of only a few millimeters in diameter (**Figure 9**). The fine sampling array, especially at the foveal regions, contributes to the acuity in discriminating between two objects (see below).

Specific circuits within ELL enhance the 2D representation by mechanisms of lateral inhibition based on a rapid and topographically specific inhibition of the granular cells (large multipolar intermediate layer (LMI) neurons **Figure 10**). Similar to contrast-enhancing lateral inhibition in the visual system, this might enhance contrast of the otherwise blurred sensory input.

Determining the distance to an object depends on determining the blurriness of the image. Blur itself depends on both object size and distance; thus, a normalization that effectively measures the blurriness of the image is required. Behavioral data suggest that animals detect the so-called slope/amplitude ratio for distance detection. In a simplified approach based on small objects only, this would be equivalent to determining the half-width of a Gaussian electric image.

For simple images, a neuronal algorithm has been proposed (**Figure 10**). In a first step, the peak amplitude of the image can be obtained from the mean activity of the population of all ELL neurons. Normalizing the population response by this mean rate, the number of neurons active above a certain threshold could then indicate half-width or slope as a measure of distance. Optimally, this two-step process is carried out in two parallel somatotopic maps, of which the map used to

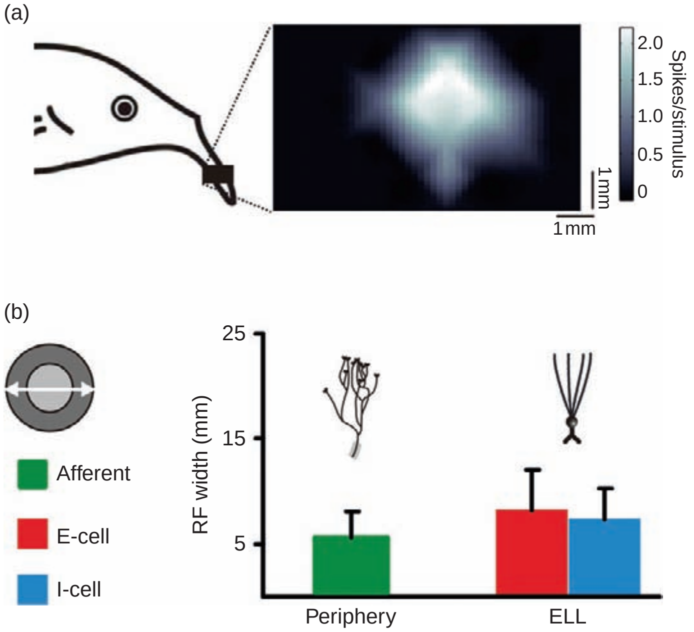

Figure 9 (a) Two-dimensional receptive field of a primary afferent fiber innervating a mormyromast on the Schnauzenorgan. The receptor organ was stimulated by an artificial local dipole, but the dimensions documented here are comparable to those that can be seen during stimulation with small objects in the presence of the EOD. (b) Mean width of receptive fields of primary afferents (green) and of efferent cells (red and blue) of the ELL (large fusiform cells, E-cells, and large ganglionic cells, I-cells). Note that the efferent neurons of the ELL have receptive fields of similar widths than the peripheral afferents, which might enhance the spatial acuity of the system (see text).

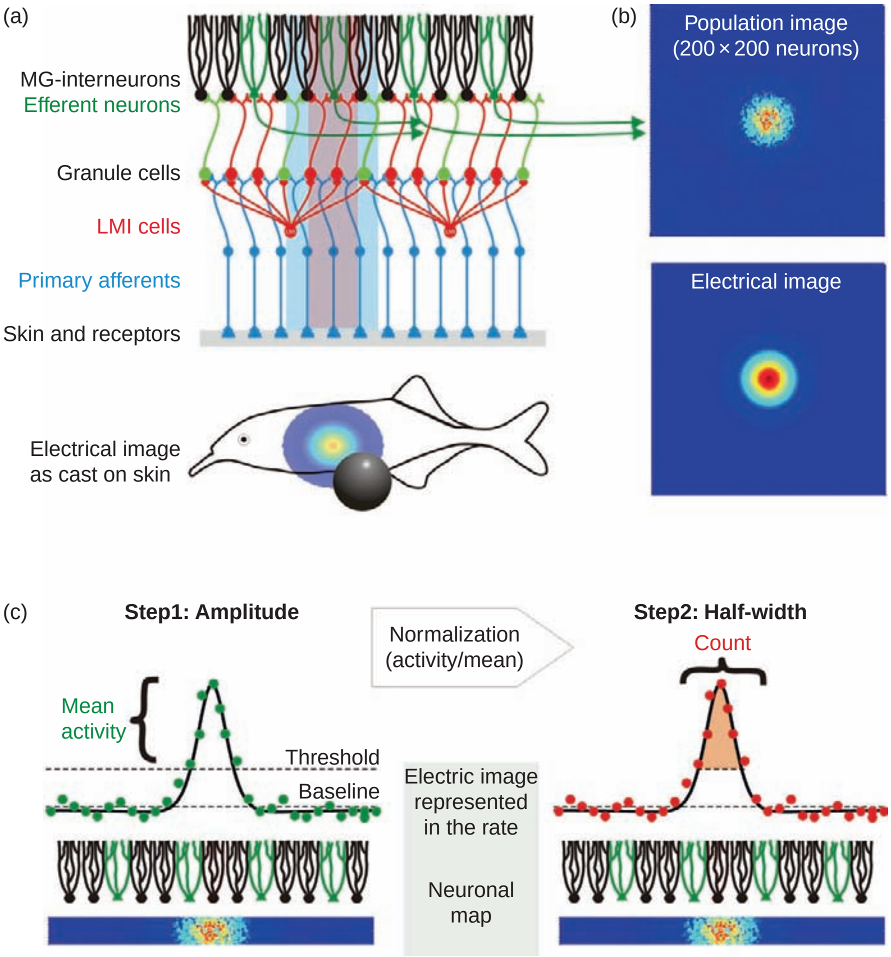

Figure 10 (a) Schematic of the conversion of an object's peripheral electric image on the skin to its neuronal excitation pattern within the ELL network. The spatial spread and blurriness of the neuronal representation is likely to be reduced by the local inhibitory LMI cells (see text). (b) Comparison of a theoretical 2D image cast onto the skin and its neuronal representation in the ELL. The topographical arrangement of the ELL maintains the peripheral image but adds noise. (c) Possible two-step procedure for the extraction of the distance of a small object. In an initial step, electric image amplitude as represented by the ongoing activity of the ELL output could be determined as the mean rate count above a threshold. Second, the response profile of the population would be normalized by this mean activity. It follows that the number of neurons (= the spatial extent of the image) active above a threshold would represent the normalized width of the electric image. In the simplified case of Gaussian-shaped electric images of smaller objects, this is equivalent to determining the slope/amplitude ratio, which was found to explain animal-detection performance in behavioral experiments.

determine the mean amplitude should have wider spatial tuning than that used to determine image width. As two parallel maps of the electrosensory environment exist (maps of the medial and dorsolateral zones of the ELL, medial zone (MZ), and dorsolateral zone (DLZ)), and these converge topographically in the midbrain nucleus lateralis, the MZ and DLZ might be a way to establish parallel processing of the amplitude and width parameters discussed above.

Plasticity

Functionally, plasticity in electrosensory fishes enhances the detection of weak signals embedded in noise by the subtraction of predictions based on the recent sensory past from the current sensory input (**Figure 11**). This is equivalent to forward models where future states of the sensory input are predicted based on associations between recent input and motor commands.

Predictive input is conveyed by the parallel fibers that target the apical dendrites of efferent cells and Purkinje-like MG-cells within the ELL, while sensory information from afferents impinges on the basal dendrites in ELL. Temporal association of sensory and predictive inputs (EOCD) can lead to associative spike-timing-dependent plasticity in MG-cells. Key to this is the occurrence of broad spikes generated in the proximal apical dendrites shortly after (within ~50 ms) the parallel-fiber input (**Figure 12**).

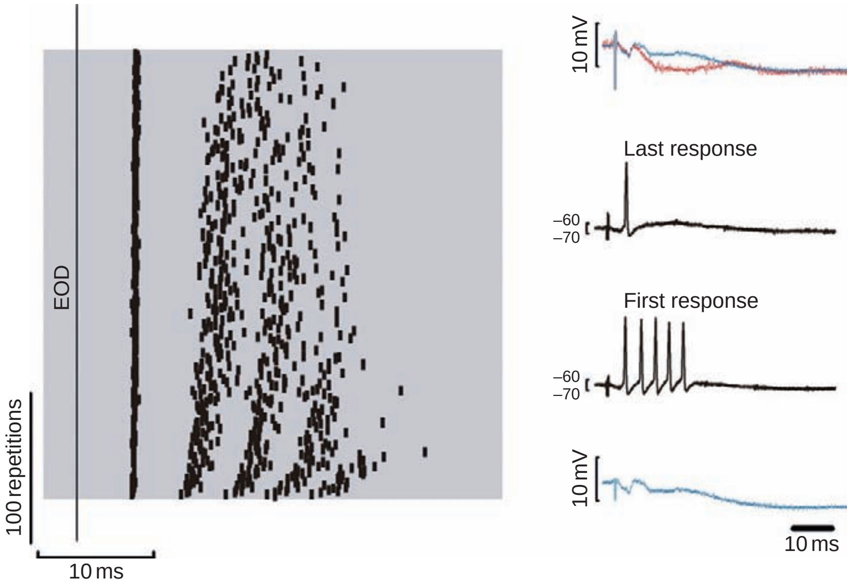

Figure 11 Response of an efferent (LF-cell) neuron of the ELL to the sudden appearance of a small conductive cube. Neuronal spikes are shown in the form of a raster display where the occurrence of each spike is marked by a dot. Experimental time progresses from bottom to top. In the absence of the object, this cell was silent but started spiking heavily on the first presentation of the object (left bottom and first response). After the object was present for a longer time period, the intensity of the sensory response was greatly diminished (left top and last response). This change is due to a change of the corollary discharge input to this cell as is shown on the right. After a certain duration of presenting the object, the corollary discharge input to the cell changes from an initial epsp (blue traces) to an inhibitory postsynaptic potential (ipsp, red trace). Thus, a predictive signal develops which counterbalances the afferent input.

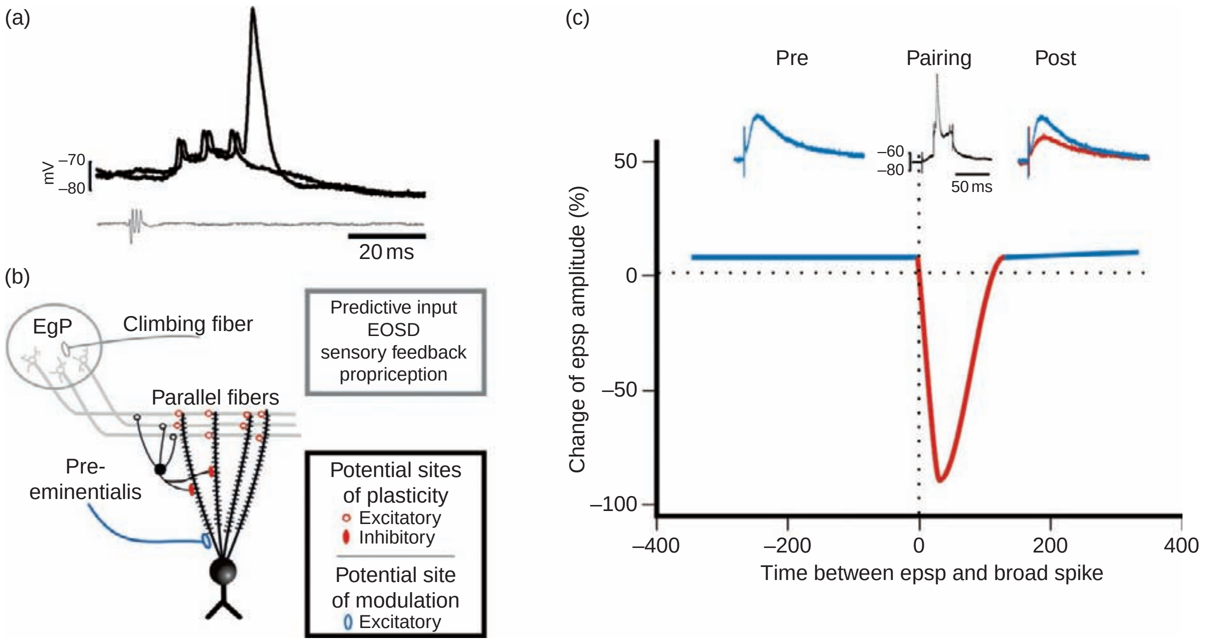

Figure 12 Response properties of medium ganglionic cells and the anti-Hebbian learning rule. (a) Two responses of an MG-cell to the corollary discharge input (in the absence of sensory input). Note that these cells generate axonal spikelets and occasionally complex dendritic broad spikes. (b) Schematic of the connectivity between the climbing fiber/parallel fiber input to the MG-cells and the possible regulatory sites for broad spike generation. (c) Temporal learning rule of MG-cells. Pairing between corollary discharge epsp and broad spikes leads to anti-Hebbian depression of the parallel fiber efficacy (red curve), when the epsp precedes the broad spikes. *In vitro*, additional nonassociative weak potentiation occurs at other times (blue line), but this may be different *in vivo*.

Similar to the complex spikes of the cerebellum, broad spikes can be controlled independently from axonal spikes, most likely by feedback from the preeminential nucleus. This nucleus integrates ELL output with feedback from the midbrain torus semicircularis and thus could provide a source of instructive signals modulating plasticity.

Glossary

Active electrolocation The ability of weakly electric fish to orient and detect objects based on their electric sense.

Carangiform Type of locomotion exhibited by some fish characterized by oscillatory movements of the rear of the body and tail.

Electrocommunication Communication based on electric signals.

Electrocytes Effector cells or syncytium specialized for generating electric fields and located primarily in the tail of electric fish. They generate and control the waveform of the electric organ discharge.

Electromotor neuron Spinal neuron that drives electrocytes to generate an electric field.

Electroreception Sensory modality for the reception and analysis of electric fields.

Fixed action pattern Behavioral sequence that is indivisible and runs to completion. These patterns are invariant and are produced by a commanding neural network in response to external or internal stimuli.

Neural network Circuit of neurons sharing a common control function.

Nodes of Ranvier Gaps in the myelin sheath of axons that create an uninsulated region of the axon where voltage-sensitive ion channels for generating electrical current are located.

Nonspherical topology Any shape of an object that, if inflated, would never achieve a spherical form.

Polyphyletic character A phenotypic character present in multiple taxa that is not present in a common ancestor.

Post-effector mechanisms The passive mechanisms that link effector cells with an external action. The clearest example is the skeleton and connective pulleys that transform muscle contractions into body movements. By analogy, the passive tissues of electric fish transform the fish's body into a distributed electric source.

Size principle States that the threshold of motor neurons grows with the size of the cell body; thus, motor units are recruited according to their size.

Synchronism A relationship among events such that they occur at the same time.

Syncytia (plural of syncytium) A large cell-like structure containing many nuclei derived from the fusion of many individual cells.

Diversity of Electric Organs and Bioelectrogenesis

Electric organs are effectors of the nervous system specialized for emitting electric fields. Bioelectrogenesis has multiple functions. Some electric organs generate strong discharges for use as a weapon. More commonly, electric organs transmit information. In the latter case, the emitted energy carries two types of electrosensory signals. The emitter fish obtains information about surrounding objects by sensing changes in the self-generated electric field (**see also Detection and Generation of Electric Signals**: Active Electrolocation and **Sensory Systems, Perception, and Learning**: Shocking Comments: Electrocommunication in Teleost Fish).

Electrogenesis is found in two orders of Chondrichthyes and four orders of Actinopterygii. The lack of known common electrogenic ancestors suggests that electric organs evolved several times (**Figure 1**). A few basic solutions for electrogenesis have been combined in different ways, yielding a large diversity of electric organs and electric organ discharges (EODs).

One common feature of electric organs is the electrogenic tissue, which is formed by cellular units (called electrocytes) derived from excitable tissue depending on the taxon. Electric organs are classified as neurogenic or myogenic, depending on the cell lineage of the electrocytes. Electrocytes retain a complex repertoire of cell membrane ion channel as the basis of their effector function. They also develop a characteristic geometry and adapt their channel distribution to the organization of the electric organ as a whole (**see also Detection and Generation of Electric Signals**: Development of Electroreceptors and Electric Organs).

Neurogenic organs generate electric fields by the coordinated activation of hundreds of enlargements of electromotor axons running within a connective sheath extended along the fish body. These axons lack a

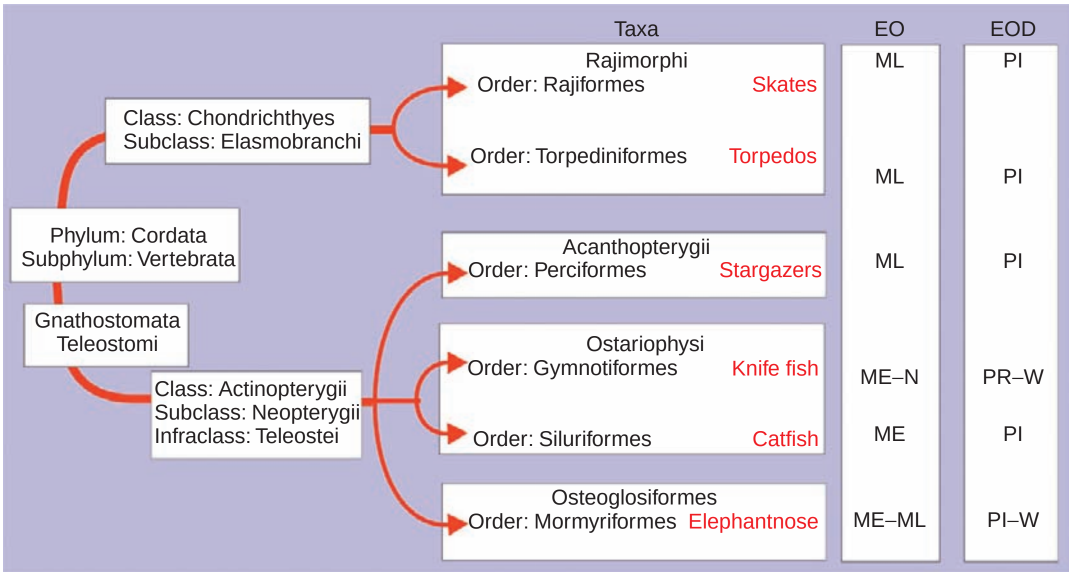

Figure 1 Electrogenesis has been reinvented several times during evolution. Electric organs can be composed of electrocytes of neural (N) or myogenic (M) lineage. Neural organs are extended. Myogenic organs may be localized (ML) or extended (ME) along the fish body and may be driven as a high-frequency continuous wave (W) or in a regular (PR) or irregular (PI) pulsatile manner.

peripheral target and have unique adaptations in their nodes of Ranvier and geometry to maximize current summation.

Myogenic organs are composed of a serial array of electrogenic syncitia derived from the fusion of muscular precursor cells. During development, myogenic electrocytes retain excitability but lose contractile machinery. Depending on the taxon, myogenic electric organs are derived from different muscle groups. Some are localized, either cephalic (stargazers and torpedo rays) or caudal (skates and mormyrids). Other electric organs extend all along the fish body, following the adaptation of body geometry and motor plan for active electroreception (knife fishes).

All these systems conform to a key concept of electrogenesis: relatively large electric fields resulting from the sum of weak currents generated by each electrocyte. Efficient summation of these currents requires the following:

1. A geometric organization allowing a parallel flow of the currents generated by equally oriented patches of membrane.
2. A precise coordination of electrocyte activation by the nervous system. This implies two processes, synchronous activation of identically oriented electrogenic membranes to develop significant amplitude and asynchronous but precisely sequenced activation of opposite-oriented electrogenic membranes to maintain a constant waveform.
3. A post-effector path for electric currents that ultimately integrates the electric organ output and transforms the whole animal body into an electric source.

The activation of the electric organ is repetitive, generally all or none, and follows species-specific spatiotemporal patterns. The timing of the discharge is determined by a command signal generated in the medulla (**see also Detection and Generation of Electric Signals**: Generation of Electric Signals). In pulse fish, the interval between each command is much larger than the duration of the EOD and the electrogenic output consists of a series of discrete pulses of stereotyped waveform characteristic of the species. In wave fish, the discharge interval is regular and similar to the duration of the EOD; the electrogenic output has a continuous sine-wave-like shape with a relatively high frequency (100–1700 Hz). Thus, the rhythms of the neural commands are also characteristic of the species, and, in the case of wave fish, they are also a major determinant of the EOD waveform.

To sum up, electric fish can be schematically grouped as pulse fish having either localized or distributed electric organs and wave fish having electric organs of either neural or muscular lineage (**Figure 1**): (1) Mormyridae, Rajidae, Torpedinidae, and Perciforms have localized organs emitting pulses at irregular intervals; (2) Sternopygydae and Gymnarchidae have myogenic organs emitting continuous waves; (3) Apteronotidae is the only group exhibiting neurogenic organs emitting continuous waves; and (4) Rhamphychthydae, Hypopomidae, and Gymnotidae have more complex electrogenic systems with extended organs emitting complex pulses at regular intervals. Each of these groups exhibits a different combination of mechanisms for waveform generation.

Morphological Organization of Electrogenic Systems and Its Role in Electrogenesis

The individual contribution of electrocytes to the EOD can be either the same or different in amplitude, waveform, and timing. The process of integrating the activity of multiple electrocytes requires a physical path for current summation, as well as a control system. Electrocyte properties (geometry and channel repertoire), neural coordination mechanisms (peripheral wiring, spinal tracts, and motor neuron recruitment), and post-effector mechanisms (connective structures of the electric organ and the fish tissue considered as a current path) have different but complementary roles in determining the waveform of the EOD.

The Electrocytes

The basic rule for understanding electrocyte contribution to the EOD waveform is that active electrocyte membrane patches guide inward currents; the outside of the patch becomes negative and the inside positive. Electrocytes (either from neural or myogenic lineages) show adaptations of their geometry for orienting the external flow of currents and express a channel repertoire whose quality and distribution set the dynamics of their response. As electrocytes are closed surfaces of excitable membrane, only part of the electrocyte must be active at one time to avoid the cancellation of current flow by patches of membrane oriented in opposite directions. Therefore, effective electrogenesis is a subcellular process. In addition, different regions of the electrocyte are activated in a precise sequence to generate multiphasic waveforms. Functionally equivalent regions of different electrocytes have similar ion channels and are oriented in the same direction. Therefore, their synchronous activity generates current flowing in the same direction and each distinct component of the species-specific waveform is generated by a set of functionally equivalent electrocyte regions. As a corollary, membrane patches with opposite orientation are activated in sequence, thereby generating successive wave components with opposite polarity.

Neural electrocytes derive from nerve axons. Unlike most axons, the axons of spinal electromotor neurons of adult Apteronotidae do not have a synaptic target but end as a hairpin-shaped specialization (yellow, **Figure 2(a)**). Neural electrocytes form a plexus running along the body just ventral to the spine. In the electric organ, axons run in a rostral direction for several segments and then turn back in a caudal direction, ending near the point of origin. The thickness of the straight portions of this structure (up to 100 μm in diameter) contrasts with a smaller diameter at the origin, end and turning points. In the regions where the diameter of fiber is small, the nodes of Ranvier are similar to those in typical peripheral nerves. At the thicker portions, the nodes of Ranvier are wide and unexcitable, showing a large number of processes over the entire unmyelinated surface. These nodes have the morphological substrate of a series capacitance that allows a large flow of outward current without firing action potentials. Thus, the action potential running rostrally at the narrow origin of the dorsal branch of the hairpin generates forward currents inside the axon causing a head-positive phase (orange, **Figure 2(b)**). A part of these action currents invades the narrow portion at the turning point, generating a second sink. Action potentials generated there propagate caudally on the ventral arms of the electrocyte, generating the head-negative phase (blue, **Figure 2(b)**).

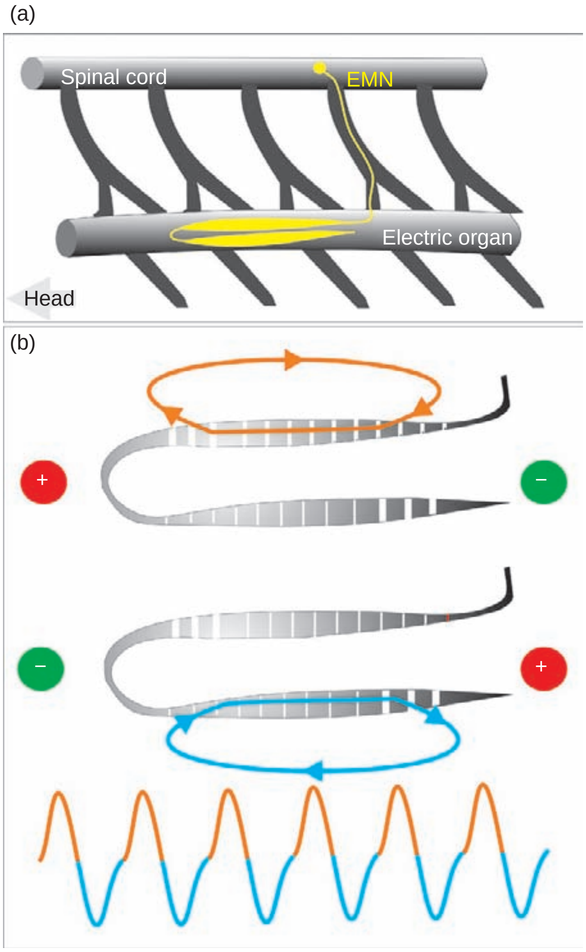

Figure 2 Neural electrocytes. (a) Neural electrocytes consist of two of enlargements of peripheral electromotor axons arranged as a hairpin structure with thick arms and a narrow turning point. (b) Bennett's hypothesis for local wave generation. The action potential running rostrally at the narrow origin of the dorsal branch of the hairpin generates forward currents inside the dilated axon, causing a head-positive phase (orange). A part of these action currents invades the narrow portion, eliciting an action potential at the turning point. This acts as a second sink for action currents that propagate caudally on the ventral arm, generating the head-negative phase (blue).

Myogenic electrocytes are cells under neural control but have different specializations. They respond with monophasic or multiphasic discharges depending on their shape, pattern of innervation, and ion-channel repertoire and distribution. At rest they are a closed, charged, and nonelectrogenic surface (**Figure 3(a)**). This equilibrium is broken by the action of cholinergic synapses on a localized region of each electrocyte that causes an initial external negativity associated with the flow of inward synaptic

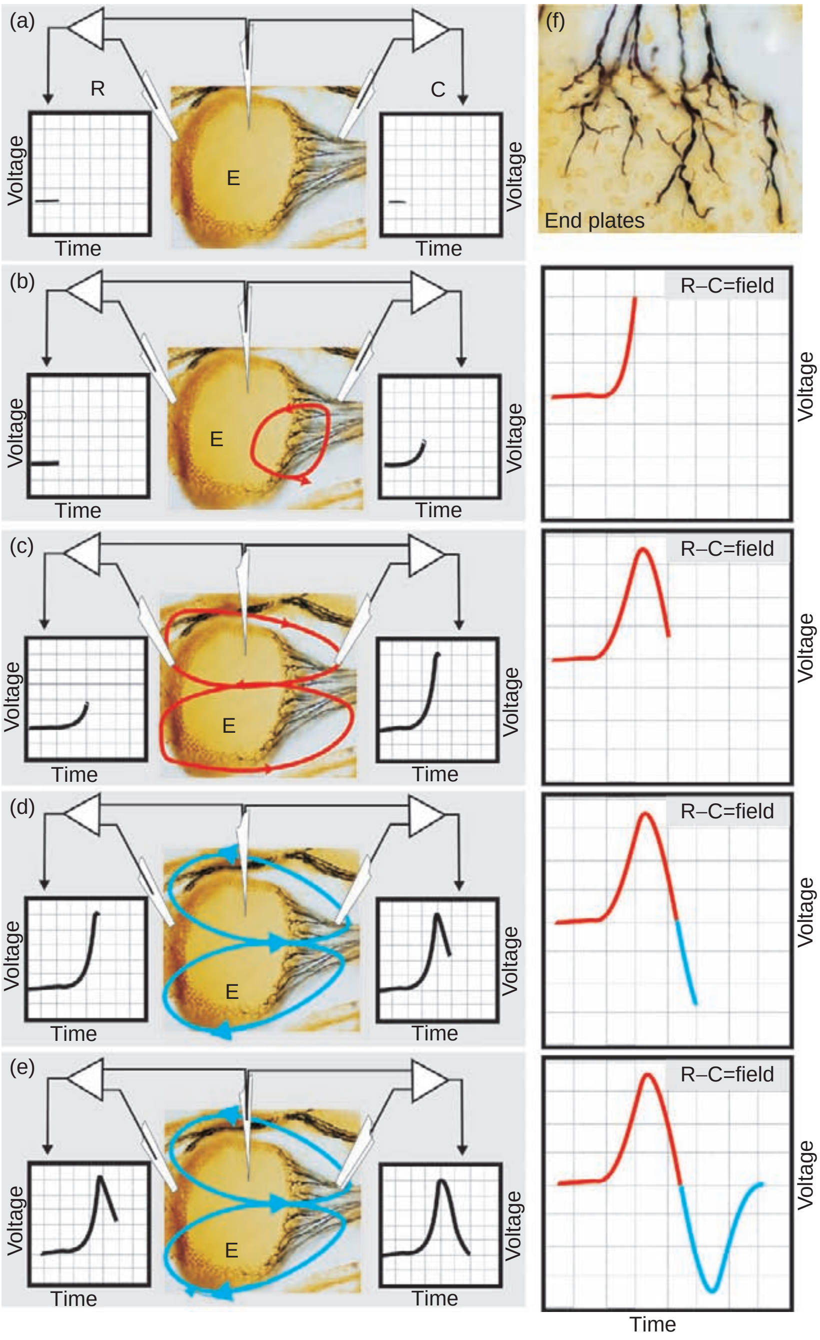

Figure 3 The process of activation of a singly innervated electrocyte. The series of composed figures (a–e) includes a photomicrograph of a singly innervated electrocyte with superimposed schematics representing the flow of currents at five selected times of the EOD as red and blue lines. These currents are associated with changes in the electric field recorded using three microelectrodes (represented as white needles) with their tips placed either inside the electrocyte (E) or outside the electrocyte facing the rostral (R) or the caudal (C) faces, respectively. These electrodes are connected to the differential amplifiers (represented as white triangles) that subtract the potential inside the electrocyte from the potential outside. The time courses of these potential differences (E-R and E-C) are represented in the screens at the rostral and caudal sides of the electrocyte. The time course represented in the right column corresponds to the head-to-tail field (resulting from subtracting R–C) and is the contribution of a single electrocyte to the whole EOD. Color-coding in the traces matches with lines indicating the current flow. (a) At rest, the electrocyte shows a homogeneous internal negativity, but does not generate external fields. (b) Synaptic activity alters the membrane potential locally at the caudal face, generating an inward current (red) that elicits action potentials and consequently caudal sink. (c) Action currents (red) flow outward through the rostral face, generating the head-positive component and exciting the rostral face. (d, e) The consequent secondary sink causes a field of opposite direction that progressively overcomes the head-positive component (red), giving rise to the head-negative component (blue). (f) Synaptic terminals on the surface of the same electrocyte (photomicrograph obtained from another tissue section).

currents (**Figure 3(b)** and inset). These inward currents may also trigger action potentials by exciting adjacent membrane patches, causing an equally oriented and sharper negativity (**Figure 3(c)**). Subsequent activation of the electrocyte membrane may generate additional wave components according to a fixed pattern.

The example in **Figure 3(d)** shows how the opposite face is excited by the action currents generated at the innervated face, resulting in a biphasic discharge. However, electrocyte responses depend on geometry and channel distribution, yielding a large variety of waveforms. In skates, torpedoes, and electric eels, the contribution of electrocytes to the EOD is the simplest. Electrocytes are disk shaped with only one innervated and excitable face. Thus, the EOD consists of a single wave component whose negativity indicates the innervated face. The electrocytes of the African wave fish *Gymnarchus niloticus* combine the activation of the innervated face with a passive response of the opposite face. The activation of caudal faces results in the head-positive crests of a sine-wave-like waveform. Interestingly, in these fish, the time constant of the nonexcitable face matches the frequency of the neural command. Most gymnotiforms show mono-innervated electrocytes on their caudal face, but the rostral face may be excitable or not, depending on the taxon and electrocyte location along the electric organ. *Brachyhypopomus* is a good example of where the innervation is concentrated on a small protrusion of the caudal face (**Figure 4(a)**). Depending on their size and channel repertoire, rostral faces may or may not respond to the depolarizing flow of current generated by the caudal faces. The decrease in size and the inter-electrocyte distance from head-to-tail facilitate the invasion of currents from the caudal to the rostral faces of neighboring electrocytes and, consequently, increase the probability of rostral face firing. As a result, the negative/positive ratio of the locally generated EOD increases from rostral to caudal regions of the fish body (**Figure 5(a)**).

Evolution has led to several solutions for increasing the number of wave components beyond two. In the case of the drum-shaped electrocytes of the tail region of some *Gymnotus* (*G. coropinae*, *G. javari*, *G. carapo*, and other species still not formally described), the channel repertoire of innervated faces allows their re-excitation by the action currents occurring at the opposite face, generating in this way a triphasic waveform (**Figure 4(b)**). Another solution is the sequenced synaptic activation of opposite faces of doubly innervated electrocytes as occurs in the dorsolateral tube of the electric organ of *Gymnotus* and *Rhamphychthys* (**Figure 4(c)**). In common with other gymnotids, their electric organs show several columns of caudally innervated electrocytes generating the main complex of the discharge (**Figures 5(b)** and **5(c)**, red portions of the electric organ and waveform traces). Electrocytes decrease in size and increase in density from head to tail. The regional waveform is monophasic (large rostral electrocytes), biphasic (some *Gymnotus* at the central or caudal regions), or triphasic (*Rhamphychthys* and *Gymnotus* at the tail region). The electric organs of these taxa are characterized by the presence of multiple tubes, each housing electrocytes with different properties (**Figures 5(b)** and **5(c)**, blue and green portions of the electric organ and waveform traces) showing rostrally innervated or doubly innervated electrocytes at some regions of the electric organ. In these electrocytes, synaptic activation in rostral faces occurs earlier than in caudal ones, which in turn occurs synchronously with the activation of caudal faces of singly innervated electrocytes. As a result, a negative component precedes the main complex at the abdominal and central regions of the fish body. Moreover, rostrally innervated faces of abdominal electrocytes are often unable to fire action potentials; this is reflected in fairly smooth negative components generated at the abdominal region (**Figures 5(b)** and **5(c)**, blue portions of the electric organ and waveform traces).

The electrocytes of pulse mormyrids show the largest geometrical refinement. During development, cell fusion occurs according to a precise pattern, creating complex geometries with nonspherical topologies; this means that if an electrocyte were inflated, it would never achieve a spherical form. These electrocytes are fenestrated disks that give rise to finger-like evaginations, which fuse into larger trunks or stalks where the electromotor neurons make synaptic contact. In some species, the stalks traverse electrocyte fenestrations and fuse again with other evaginations on the membrane of the opposite side, acting not only as an electrogenic membrane contributing to the EOD but also as a connecting route between opposite faces (**Figure 4(d)**). Depending on taxa, stalks may go across the electrocyte more than once. These differences in geometry establish the species specificity of the EOD.

Electrocyte shape is not only the expression of genetic traits during early development, but it is also under endocrine control. Sexual differentiation causes changes in the relative areas of excitable and nonexcitable membranes of the electrocytes by adding invaginations of the membrane, and it controls the expression of the ion-channel repertoire. Endocrine signals may also control the expression of channel repertoire at specific regions of the electrocytes, altering the responses of the noninnervated faces in both gymnotids and mormyrids. Interestingly, in the wave fish *Sternopygus*, sex hormones act at the electrocyte level and at the central pacemaker nucleus in such a way that the resulting waveform is a timescaled version of the waveform of nonsexually differentiated fish.

The Bulbospinal and Peripheral Networks

The electric organ of pulse species is commanded either by an irregularly discharging nucleus or by a pacemaker (**see also Detection and Generation of Electric Signals**: Generation of Electric Signals). Command nuclei operate as time integrators, firing irregularly depending on the

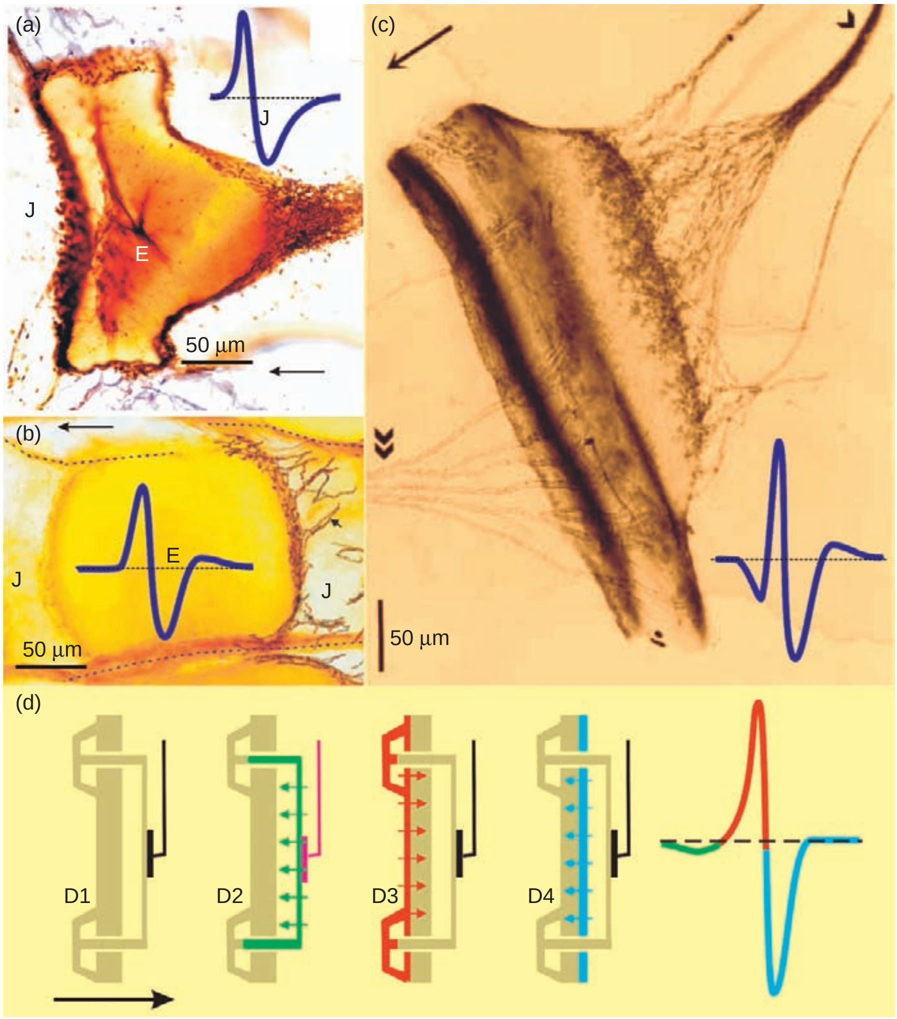

Figure 4 Different types of electrocytes contribute to waveform generation in different ways. (a) Singly innervated electrocyte from *Brachyhypopomus pinnicaudatus.* Nerve terminals contact a caudal protrusion, eliciting the head-positive phase. The negative phase results from current invasion of the rostral face. (b) Caudally innervated electrocytes from the tail region of *Gymnotus carapo* generate a triphasic waveform. Neural activation of caudal faces generates the large initial positive component. Longitudinal currents excite the noninnervated electrocyte face, generating the negative component. The process repeats in the opposite direction, depolarizing again the innervated face to generate the late positive component. (c) Doubly innervated electrocyte from *Rhamphychthys rostratus* shows innervation on the caudal ridge (single thick arrowhead) and also on the marginal zone (double arrowhead). The marginal zone is synaptically activated first, causing the negative phase; next, the synaptic activation of the caudal phase elicits a triphasic complex following a similar sequence as in (c). (d) Schematic of the activation process of a perforated stalked electrocyte from a pulse mormyrid. (D1) Electrocytes have perforant stalks that go through the electrocyte. (D2) Synapses activate the rostral stalks generating a small negative phase at the beginning (green). (D3) Perforant stalks conduct the excitation to the caudal face, generating a head-positive component (red). (D4) Finally, the rostral face is invaded, generating the head-negative component (blue). In all images, the arrow points rostrally.

richness and degree of synchrony of descending motor commands. Pacemaker nuclei generate a regular, frequency-modulated up or down descending motor commands. In all wave species, the electric organs are regularly driven by a pacemaker.

Different control strategies can be described for localized or extended, myogenic or neurogenic types of electric organs:

1. In fish with localized electric organs, the species-specific waveform of the field is based on the synchronous recruitment of similar electrocytes, all generating the same contribution to the external electric field. Thus, in fish with localized myogenic organs, the neural network mainly works as a transmission line to synchronize electrocyte excitation.

In a representative species of Mormyridae, *Gnathonemus petersii*, the electric organ is restricted to the base of the tail and consists of two columns on each side of the midline. In each column, about a 100 electrocytes are enclosed in a tube of connective tissue and are separated by gelatinous tissue. Electrocytes are disk shaped and serially stacked with

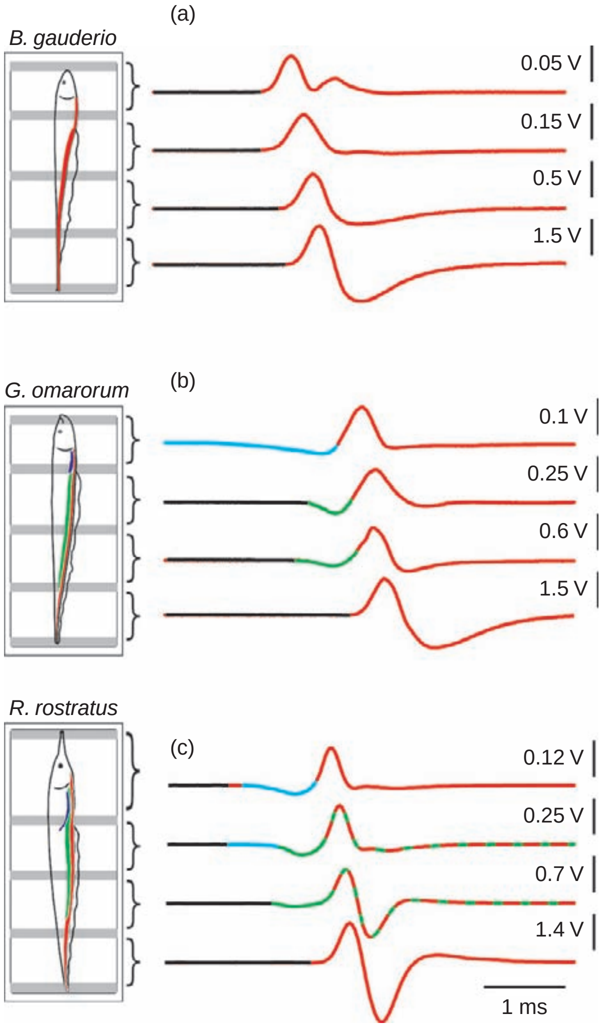

Figure 5 Heterogeneity of electric organs and regional EODs in pulse gymnotids. (a) *Brachyhypopomus pinnicaudatus* shows similar electrocytes all along the electric organ. Due to the decay in size and inter-electrocyte distance, the probability of firing of the rostral faces increases from head to tail, leading to an increase in amplitude of the negative wave (red traces). (b) In addition to the caudally innervated electrocytes generating the main positive–negative complex (red), *G. omarorum* shows two types of doubly innervated electrocytes in one of the tubes composing the electric organ: (1) less-excitable electrocytes at the abdominal region responding to the neural drive with graded potentials reflected in the smoothness of the initial negative wave component (blue) and (2) smaller electrocytes firing action potentials in response to an early command volley on their rostral faces, generating a sharp negative component at the center of the fish body. (c) *Rhamphychthys rostratus* shows three types of electrocytes at the abdominal region: (1) caudally innervated, generating the head-positive component (red), (2) rostrally innervated, generating a smooth negative component (blue) and doubly innervated at the marginal and caudal ridges, generating a triphasic component (green). At the central regions, only caudally innervated and doubly innervated electrocytes are present; and, at the tail region, the entire electrocyte population is caudally innervated. As the electrocytes diminish in size and increase in density toward the tail they become more excitable, leading to tetraphasic contributions of doubly innervated electrocytes and triphasic contributions of caudally innervated electrocytes.

anterior and posterior faces oriented perpendicular to the body axis. They measure about half a millimeter in diameter and are separated by only 50 μm. The current generated by all electrocytes flows along the tube. Thus, the number of electrocytes adds power, but not waveform diversity, and the efficiency of the EOD results from the synchronous activation of the population. To secure this, a synchronized doublet of spikes descends from the command nucleus along the bulbospinal electromotor tract, provoking a synchronized triplet of spikes at the electromotor neuron pool located in the caudal spinal cord. This volley activates the electrocyte stalks provoking in turn the synchronous response of the electrocyte population. The variety of electrocyte shapes, in particular, the number of times that stalks cross the electrocyte body, determines a large variety of EOD waveforms in pulse mormyrids.

2. Extended myogenic electric organs are exhibited by a polyphyletic group of fish formed by species belonging to different evolutionary lines, indicating that this strategy is also a robust solution for active electrolocation and electrocommunication. These types of electric organs generate two types of electric fields: brief pulses of a stereotyped spatiotemporal shape, or continuous quasi-sinusoidal waves shifted in phase along the electric organ. These complex outputs contrast with the input to the electromotor system, which consists of a localized impulse-like pacemaker discharge. Therefore, the nervous system must combine temporal and spatial processing of such simple inputs to achieve a complex electrogenic output.

First, the nervous system synchronizes the activity of electrocytes separated by hundreds of millimeters with 300-μs accuracy. Second, *Rhamphychthidae* and *Gymnotidae* show doubly innervated electrocytes requiring a sequenced recruitment of electromotor neuron pools innervating oppositely oriented membrane patches of the same electrocyte (**Figures 4** and **5**). Thus, in these cases, the neural network works also as a central pattern generator that coordinates the synchronous activation of functionally equivalent membranes and the sequential activation of opposite membranes.

Synchrony and sequence are supported by the synergistic action of neural delay lines implemented in a variety of forms including: (1) different conduction velocities along the spinal cord, (2) different conduction distances in the periphery, and (3) an appropriate distribution of coupling delays (included within this term are the conduction time through fine terminals, synaptic delay, and synaptic efficacy). *Gymnotus omarorum* is a paradigmatic species for illustrating some of these mechanisms.

In the spinal cord of pulse gymnotids, relay axons of different diameters descend through the dorsolateral funiculi (**Figure 6(a)**). Thin and slowly conducting relay fibers end proximally, but most fast conducting fibers end in the caudal portion of the spinal cord. These fibers project on an electromotor neuron layer with somata scattered in a row above the central canal (**Figure 6(b)**). Since electromotor neuron

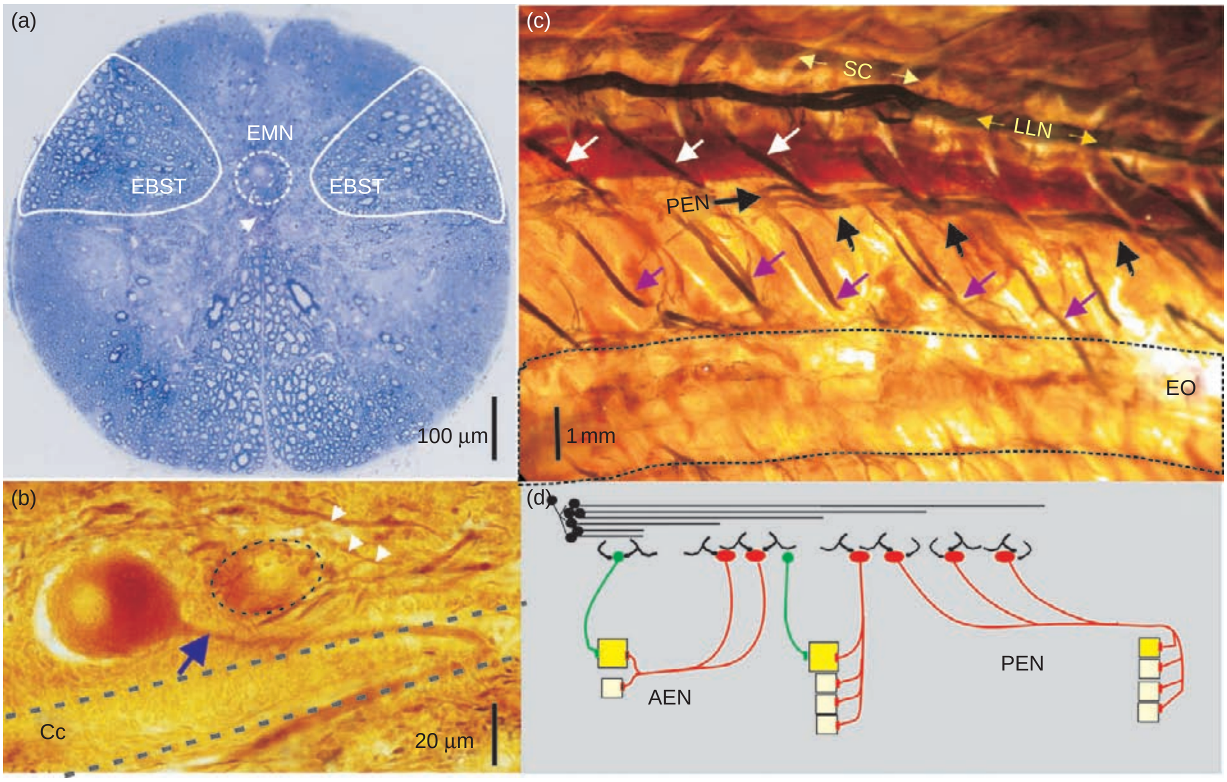

Figure 6 The neural network controlling the electric organ in *G. omarorum*, this network consists of two layers of neurons schematically represented in (d). The relay cell somata form part of the electromotor nucleus at the medulla. Their axons (represented in black in (d)) run along the spinal cord through the dorsolateral funiculi (electromotor bulbar-spinal tract (EBST) enclosed by white contours superimposed on a methylene-blue-stained semi-thin transverse section of the spinal cord in (a)). The terminals of these axons project to electromotor neurons distributed in a row above the central canal (Cc and dotted lines in the silver impregnated section are shown in (b)). Their axons (arrow in (b)) leave the spinal cord through the ventral roots (white arrows in the Osmium-stained material are shown in (c)) and form a neural plexus (PEN black arrows) at the caudal half of the fish's body. From this plexus, segmental nerves project to the electric organ (violet arrows). At the abdominal region, axons innervating the caudal faces of both electrocyte types (doubly and singly innervated) form a recurrent anterior electromotor nerve adding the necessary conduction time to cause their synchronous activation with the rest of the body. (d) At the very caudal regions, the posterior electromotor nerve composed of thick axons projecting to the caudal regions of the electrocytes runs dorsal to the electric organ (d).

activation results from pooled activity of slow and fast fibers, which converge on electromotoneurons in different proportions along the spinal cord, the more caudal the electromotoneuron is located, the more synchronized and faster the activation volley that it receives. In addition, the electric organ has a shortened representation on the spinal cord: in *Gymnotus*, small electromotoneurons projecting to the rostral faces are located on the rostral half of the spinal cord, and large electromotoneurons projecting to caudal faces occupy the central two quarters of the spinal cord (**Figure 6(c)**). Because of the size principle and their proximal location, small neurons projecting to the rostral faces are activated earlier than large neurons projecting to the caudal faces of the same electrocytes. Axons projecting to the rostral faces of the abdominal doubly innervated electrocytes run directly. Conversely, axons projecting to the caudal faces of both doubly and singly innervated electrocytes at the abdominal region are packed as a pair of recurrent nerves (anterior electromotor nerve (AEN), **Figure 6(d)**). This adds a significant conduction distance that delays the caudal activation of caudal faces, separating it from the activation of rostral faces but bringing it close to the activation of caudal faces of electrocytes in the rest of the fish's body. The rest of the axons, projecting to the caudal faces, form a longitudinal plexus referred to as the 'posterior electromotor nerve' (PEN, **Figure 6(d)**). Again, larger fibers projecting to more electrocytes are observed at the tail, shortening the activation time of this region. The activation process of the electric organ of *G. omarorum* is summarized in **Figure 7**.

3. The family Apteronotidae has neural organs. Electromotor neurons respond as forced oscillators driven by a descending tract coming from a pacemaker command nucleus firing at high frequency (about 1000 Hz). Peripheral axons run along a hairpin path showing important changes in diameter (**Figure 2**). At the longitudinal portions they enlarge several times in diameter, increasing the electrogenic area, but their diameter is small at the entry and at the turning

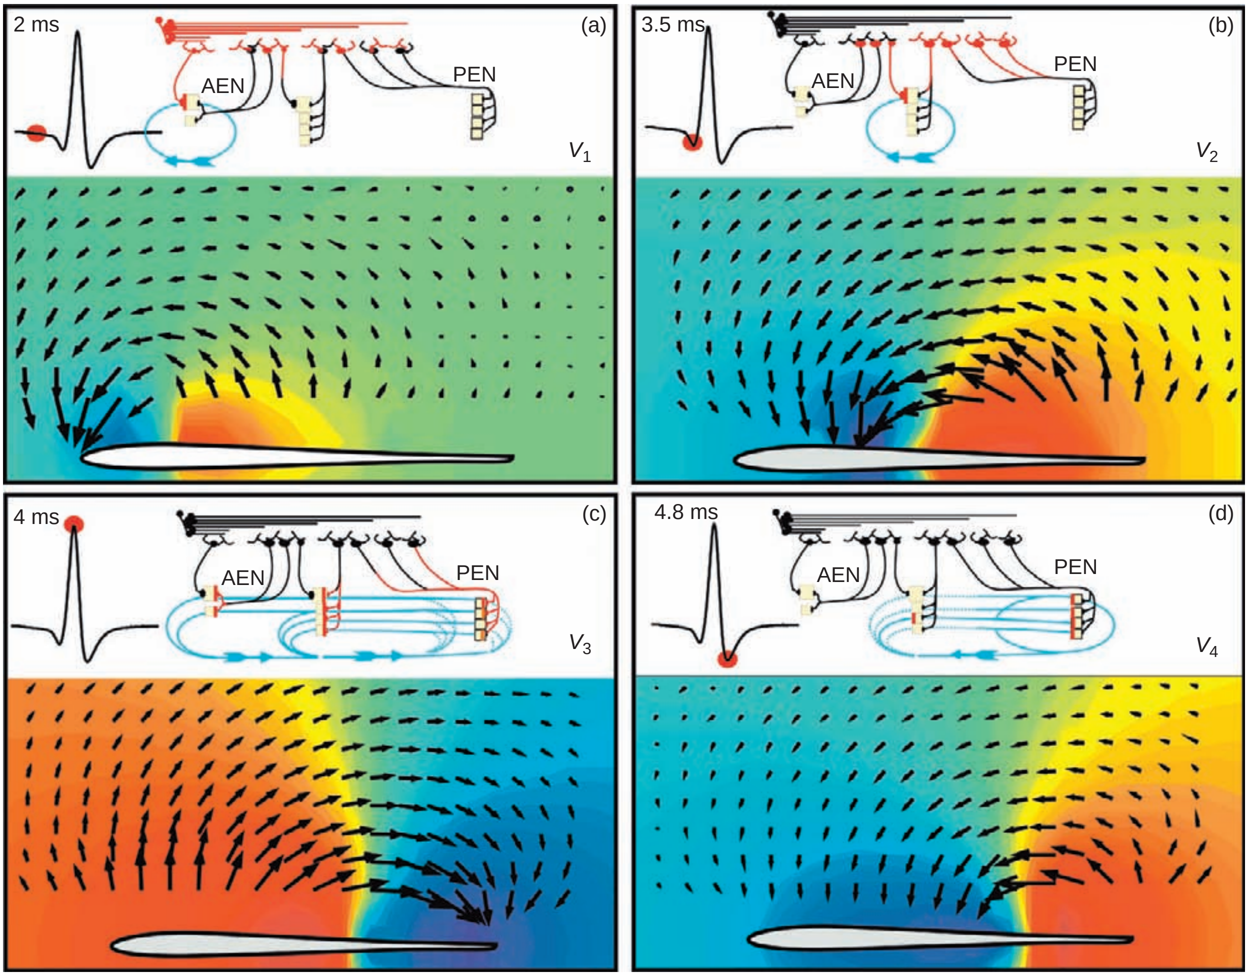

Figure 7 The process of activation of electric organs in *Gymnotus*. Excitation begins with synchronous activation of the central relay nucleus. The descending volley first reaches the small, round electromotor neurons lying in the rostral segments of the cord and projecting to the rostral face of the abdominal electrocytes. (a) After 2 ms, most descending fibers are active at the central portion of the cord. At the same time, the postsynaptic potentials occurring at the rostral face of abdominal electrocytes are generating V_1. (b) Approximately 3.5 ms after the command, small electromotor neurons activate electrocyte rostral faces in the central region, generating V_2. Less-excitable, large, oval electromotor neurons fire later. This, and possibly differential efficacy at peripheral synapses, causes V_3 to occur 0.7 ms after V_2. Axons of large electromotor neurons projecting to the caudal face of abdominal electrocytes follow a recurrent course through the anterior electromotor nerve (AEN), adding an extra delay and compensating for some of the differences in spinal conduction times. (c) Large electromotor neurons occupying the most caudal spinal segments project onto the caudal electric organ through the posterior electromotor nerve (PEN), eliciting V_3 approximately 4.1 ms after the RN discharge. (d) V_4 results when the action potentials generating V_3 propagate to the rostral face of caudally innervated electrocytes about 4.8 ms after the command.

point of the hairpin. Interestingly, the summated duration of these two phases matches the interval between pacemaker discharges. According to the fiber lengths and conduction speeds of the fibers, one can deduce that more than one descending volley has occurred at the descending track and the electromotor axons at the same time. Synchrony is very accurate, but not better than in other gymnotids. Rostral regions of the fish body discharge about 200 μs before the caudal regions (**Figure 8**). However, in high-frequency fish, this phase shift represents up to 20% of the cycle and this phase lag is an important cue for self identification.

Post-Effector Mechanisms

Unitary activities are integrated as an EOD by the passive but no less important action of the electric organ structure and post-effector mechanisms. Electrocytes are packed in series inside connective tubes running parallel along the electric organ, as in the batteries of a hand-held flashlight. This organization maximizes the longitudinal current flow and current summation on the tissue surrounding the electric organ. This flow of current through body tissues of low conductance relative to water transforms the whole fish body into a distributed electrogenic source.

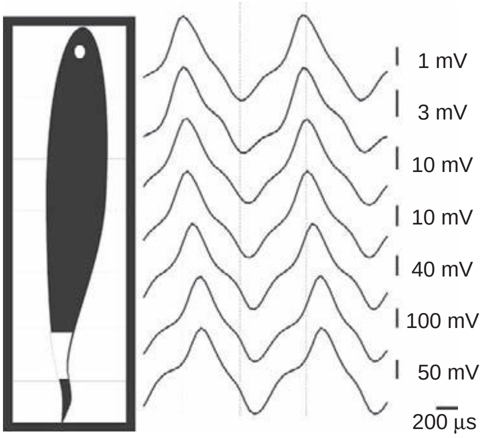

Figure 8 Spatiotemporal pattern of electromotive force generated by *Apteronotus albifroms* recorded with the fish in air. Note that the local waveform is similar but differs in amplitude and phase along the fish's body.

The electrocytes of localized organs often respond to their neural command with a characteristic activation pattern, which determines the waveform of the electric field everywhere in the fish's surroundings. In fish with carangiform locomotion, such as mormyrids, the electric organ is located at the base of the tail but the specialized sensory mosaic is at the head region. The fish's body is a low-conductivity path that connects the cephalic region with the electric organ and also, because of lateral leakage, distributes current for probing the environment. This causes, as an additional effect, an enlargement of the equivalent dipole arm with a consequent increase in 'electrical visibility' of the fish by conspecifics.

Knife fishes optimize these rostral funneling effects with the body geometry by having a long anal fin and a relatively stiff body posture. Furthermore, in pulse knife fishes, the heterogeneous structure of the electric organ determines a different waveform contribution of each region of the electric organ to the integrated output. Thus, for a given time and a given point in the fish surroundings, the local field is a weighted sum of the fields generated at that point by the different portions of the electric organ. The amplitude and polarity as well as the time waveform of the local field strongly depend on the relative position and distance from the electric organ where the field is measured. As a consequence, the field waveform stimulating different regions of the sensory mosaic shows substantial differences from region to region of the skin. In addition, the relatively low conductivity and the knife shape of the fish body cause a rostral funneling of the caudally generated currents, thereby increasing the relative weight of the caudally generated far

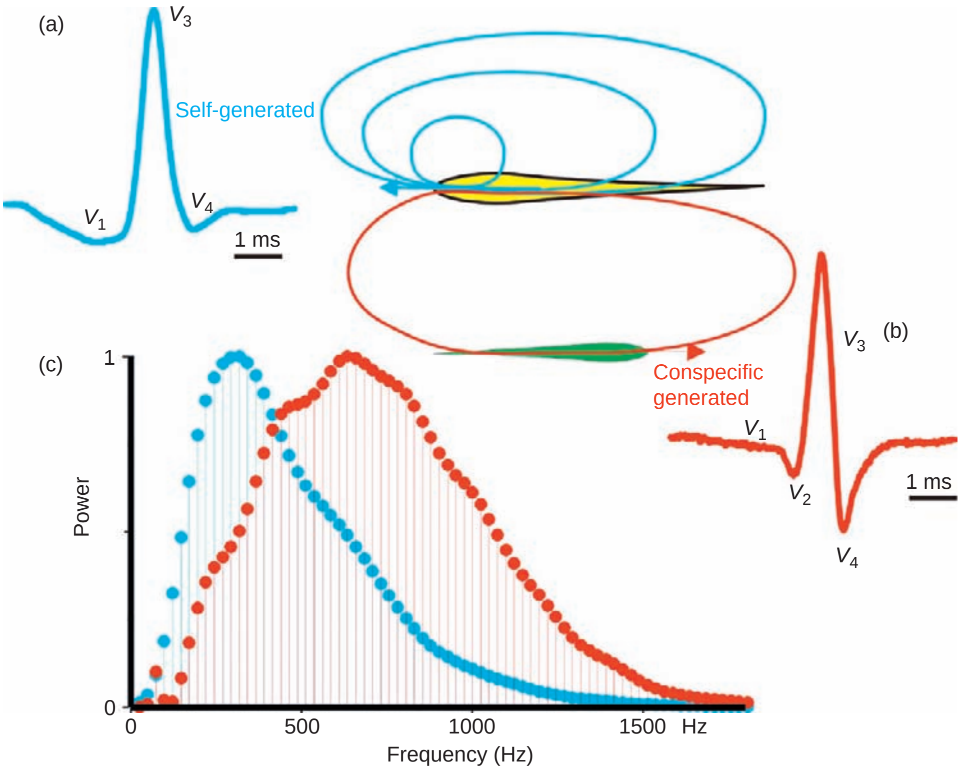

Figure 9 Differences between the self-generated local electric-organ-discharge-associated field (blue) and the conspecific-generated local electric-organ-discharge-associated field at the foveal region of *Gymnotus omarorum* (red). Normalized time waveforms generated by a 22-cm emitting fish (yellow silhouette). Self-generated waveforms show a prominent V_1 (a, blue); the communication signal (b, red) was recorded at the fovea of a parallel 14-cm-long conspecific (green silhouette), 10 cm away. (c) Normalized power spectral density histograms corresponding to the waveforms in (a) (same color-coding). Note the shift in the power spectral density in the self-generated EOD.

field. Here, it is important to recall that these fish, as well as *G. petersii*, have an electrosensory fovea near the oral region. Because of passive filtering, the waveform of the self-generated transcutaneous fields at the rostral region that carry active electrolocation signals is rather different from the fields observed from a distance that carry electrocommunication signals emitted by other fish (**Figure 9**).

Glossary

Action potential A small and transient change of voltage across the cell membrane when the negative resting potential momentarily becomes nearly zero volts and quickly returns to the original level in a few milliseconds. The action potential is possible because of the activity of ion channels, proteins of the cell membrane, selectively allowing certain inorganic ions to pass through their pore.

Central pattern generator Neuronal circuits that generate rhythmic motor output for coordination without the aid of sensory feedback.

Electric organ discharge (EOD) Electrical discharges resulting from the summed excitation of the cells (electrocytes) of the electric organ of electric fishes that function both in communication and in locating nearby objects. Short (100 μs to several tens of milliseconds) electrical pulses of various voltages (a few millivolts to several hundred volts) are generated at various rates (a few to over 1000 times per second).

Gamma-aminobutyric acid (GABA) The most abundant inhibitory neurotransmitter in the vertebrate brain and which usually has an inhibitory influence on the target neuron.

Postsynaptic potential Membrane potential produced by the activities of synapses on an excitable cell. Its amplitude varies depending on the strength of the input signal.

Resting potential The electrical potential inside relative to outside in the resting condition of excitable cells. A few tens of millivolts in amplitude and of negative polarity.

Introduction

Feeble electricity occurs as the by-product of physiological activities of many biological tissues and organs. In contrast, the electric organ of electric fishes produces electricity strong enough to carry out behavioral functions. Electric organs are known only in six taxonomic groups (orders) of fishes: Torpediformes, Rajiformes, Siluriformes, Perciformes, Gymnotiformes, and Mormyriformes (**Figure 1**). The electric organ occurs at various locations in the fishes' body and varies in size and shape depending on the species, but all produce an electric field outside the body (**see also Detection and Generation of Electric Signals**: Electric Organs).

The electrical discharges from the electric organ are called the electric organ discharges (EODs). Each EOD lasts only for a short period of time (100 μs to a few hundred milliseconds depending on species). EODs may be generated in sequence at various inter-EOD intervals. EODs that are separated by relatively long inter-EOD intervals are called pulse-type EODs. Pulse-type fishes may discharge at relatively irregular intervals or rather constant intervals depending on species. Continuous EODs that are separated only by short inter-EOD intervals are called wave-type EODs. Wave-type electric fishes generate EODs uninterrupted day and night throughout their lives for electrolocation.

The strength of EODs differs considerably among electric fishes. The electric eel (*Electrophorus* sp.), electric catfish (*Malapterurus* sp.), electric ray (*Torpedo* sp.), and the electric stargazer (*Astroscopus* sp.) are categorized as strongly electric fishes that generate strong EODs with amplitudes between ~5 and ~800 V. In some *Torpedo* spp., a 50 V peak of an EOD can produce as much as 1 kW of power (20 A of current). These fishes use the strong EODs primarily for defense and stunning prey.

The remaining electric fishes are categorized as weakly electric fishes that generate EODs with amplitudes ranging from a fraction of a volt to several volts. Weakly electric fishes use electricity for electrical behaviors – electrocommunication (**see also Sensory Systems, Perception, and Learning**: Shocking Comments: Electrocommunication in Teleost Fish) and electrolocation (**see also Detection and Generation of Electric Signals**: Active Electrolocation). Though the strongly electric fish were known to ancient humans and demonstrated as electric with the Leyden jar in the

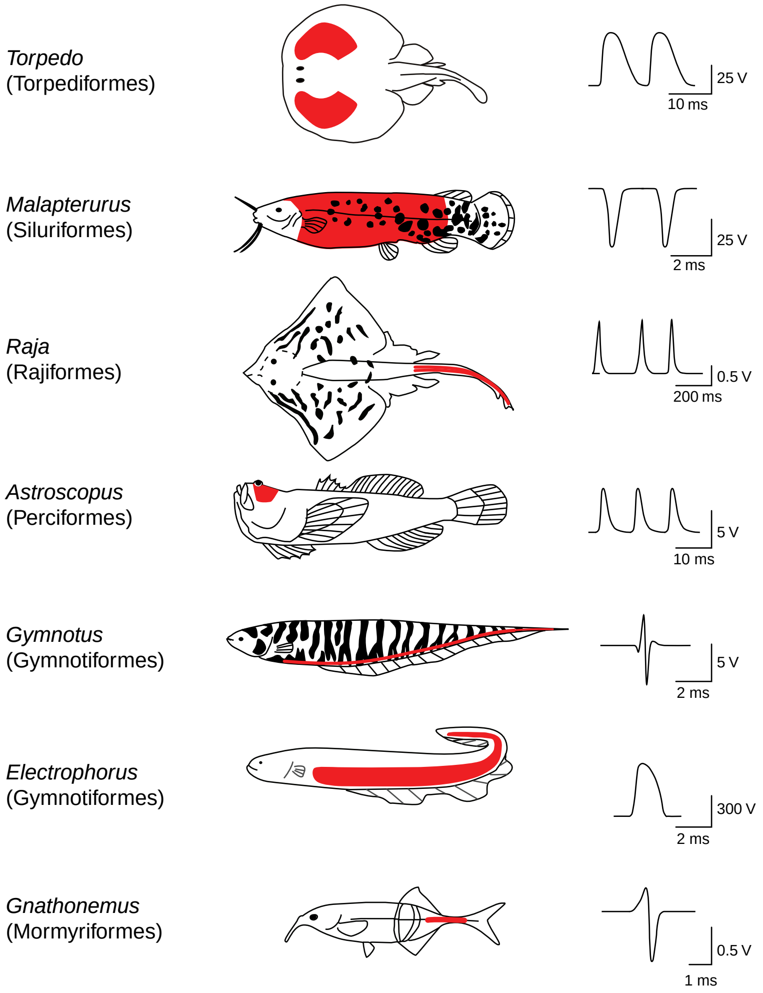

Figure 1 Location of the electric organ (red) and waveform (right) of EODs of representative fish from five major groups of electric fishes. Top view of fish for *Torpedo* and *Raja*, lateral view for other fishes.

sixteenth century, the behavioral functions of low-voltage electricity in weakly electric fishes were recognized only in the 1950s. The phylogeny and ethology of electric fishes, however, indicate that the strongly electric fishes evolved from weakly electric fishes.

The principle of electrical generation is identical for strongly and weakly electric fishes and is based on ionic flow across cell membrane as occurs in ordinary nerve and muscle cells (**see also Detection and Generation of Electric Signals**: Electric Organs). Generating cells in the electric organ are called electrocytes. The electrocytes maintain a charge difference between the inside and outside of the cell (polarization) using ion pumps in the membrane that actively move ions across the membrane. **Figure 2**(**a**) presents the resting state of the electric organ.

An EOD is generated when the polarization is reversed (depolarization) in some part of the membrane due to the activation of spinal electromotor neurons that synapse onto electrocytes (**Figure 2**(**b**)). This asymmetric depolarization results in current flow across the electrocyte and generates approximately 80–150 mV. A large number are arranged serially and stimulated by command signals from the brain that fire all electrocytes in synchrony so that their individual potentials summate. The serially positioned electrocyte columns are often arranged in parallel giving rise to high current. The columns of electrocytes are wrapped with connective tissue with high electrical resistance funneling EOD current flow outside the fish.

The electrophysiological characteristics of electrocytes determine the wave form (time course of voltage change) of each EOD but nerve cells in the brain exclusively control its timing (**Figure 3**). These neurons fire in synchrony and each synchronous firing drives each EOD. In strongly electric fishes, which generate occasional EODs, and in pulse-type weakly electric fishes, which generate irregular EODs, this group of neurons is called the command nucleus because it gathers information from other parts of the brain and makes the decision to fire an EOD. The frequency of EODs in these fishes ranges from approximately 1 to 100 Hz. In wave species and pulse

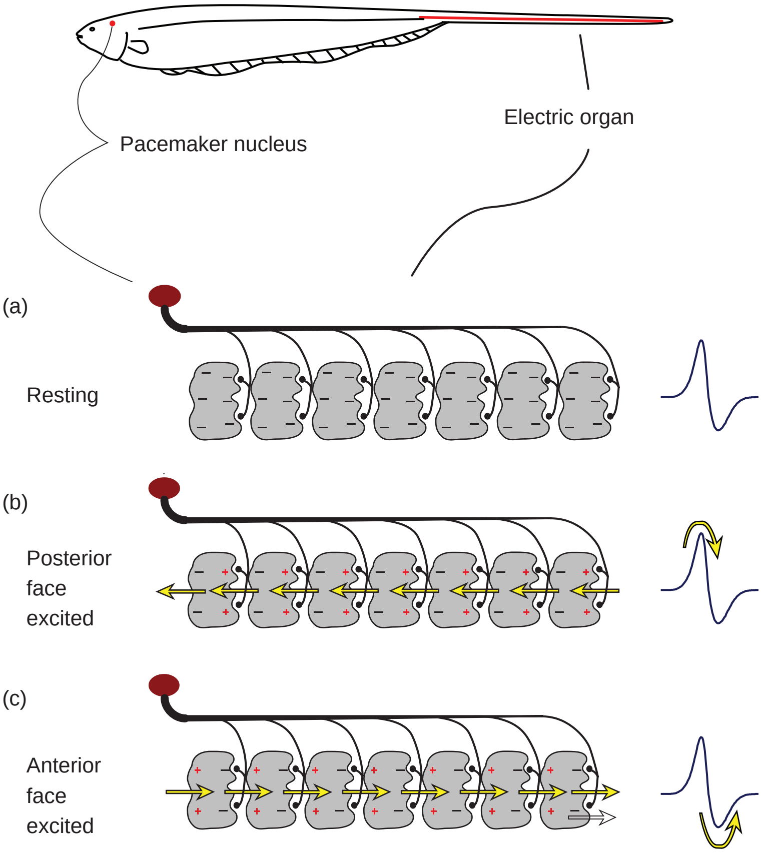

Figure 2 The mechanisms of electric organ discharges (EODs). The inside of electrocytes (gray) has negative charge relative to the outside in the resting state. The pacemaker or command nucleus generates a signal for each EOD. The signal is propagated in the axon of the relay cells that project down the spinal cord. There, the signal stimulates electromotor neurons whose axons innervate each electrocyte. The posterior faces of the electrocytes are excited causing electrical current to flow toward the head. This excitation propagates to the anterior faces causing electrical current to flow toward the tail and the sequential current flow produces the biphasic waveform shown on the right.

species with regularly firing EODs, the brain nucleus is termed the pacemaker nucleus because it intrinsically generates a periodic and regular rhythm of EODs. The frequency of EODs in these fishes ranges from several tens of hertz to as high as ~1500 Hz. A relay station in the brain called the relay nucleus relays the synchronous firing of the command or pacemaker nuclei. Nerve cells in the relay nucleus fire in synchrony following command/pacemaker input and send this information down the spinal cord where the cell bodies of the electromotor neurons further relay the signal to the electrocytes in the electric organ.

Weakly electric fishes that normally generate EODs with a regular rhythm modify their regularity for various behavioral functions. The patterns of modification include gradual increases and decreases in firing frequency, rapid increase of the frequency, brief interruptions (stopping) of the EOD, and random insertion of extra EOD pulses. While regularly discharging EODs are used for electrolocation, these modulations function as social communication signals in contexts such as courtship and aggression (**see also Sensory Systems, Perception, and Learning: Shocking Comments**: Electrocommunication in Teleost Fish) and as jamming avoidance for electrolocation (**see also Detection and Generation of Electric Signals**: Physiology of Tuberous Electrosensory Systems). Such modulations are realized by descending inputs to the command/pacemaker and relay nuclei that modify the regular rhythm of EODs. Several brain nuclei, each dedicated to a particular behavioral pattern, provide these inputs.

Physiological Mechanisms of Electric Organ Discharges

The fundamental mechanism of electrical generation in the electric organ is the movement of ions across the cell membrane of electrocytes. The gradient of chemical and electrical potential across the membrane is the force moving the ions. Membrane ion pumps maintaining the resting potential of the electrocytes create the gradients

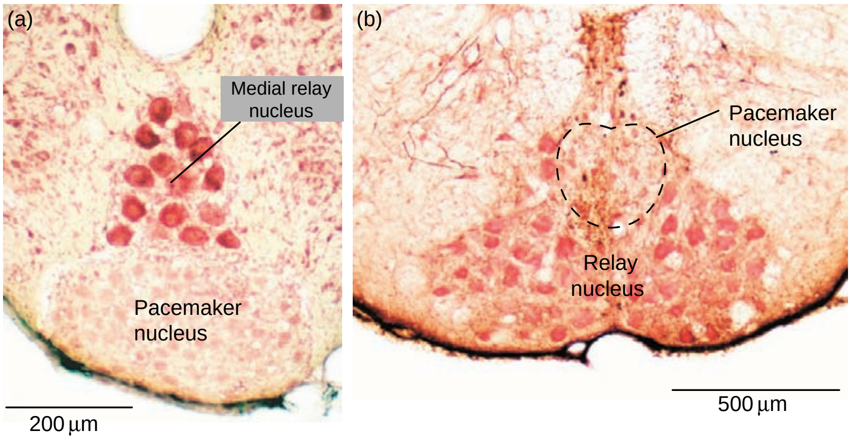

Figure 3 The pacemaker and relay nuclei in *Gymnarchus niloticus* (a) and *Electrophorus electricus* (b). The ventral end of a transverse brain section through the hindbrain is shown in each panel. Large somata (~50 μm in diameter) of relay cells are visible in the dorsal and ventral sides in *G. niloticus* and *Electrophorus electricus*, respectively. The pacemaker nucleus is packed with much smaller pacemaker cells. The lateral relay nucleus is outside of the section in (a).

(**Figure 2**). The axon terminals of electromotor neurons terminate in a part of the electrocyte where they form a chemical synapse. Neurotransmitter substance (acetylcholine) is released there and binds to postsynaptic receptor molecules in the membrane that have a pore through which ions flow. This creates postsynaptic potentials (PSPs) – a change in electrical potential difference between inside and outside the electrocyte at the synapse. PSPs are responsible for the EOD in *Torpedo, Raja*, and *Astroscopus*. In other electric fishes, the PSPs trigger an action potential that results in a short and larger EOD pulse.

Action potentials are a brief change in membrane potential whose time course and amplitude are fixed. They are mediated by voltage-sensitive ion channels for Na^+, Ca^{2+}, or K^+. PSPs or action potentials are created only in a part of electrocyte (active face) that receives innervation from an electromotor neuron (**Figure 2(b)**). The current flow occurring in this part of the electrocyte must exit from other parts of the cell (inactive face). The inactive face may have low resistance and/or high capacitance with a convoluted membrane. As a result of the inward current at the active face and the outward current at the inactive face, at most 150 mV of potential is generated across an electrocyte. The noninnervated face can also be active generating current in the opposite direction creating a negative phase of an EOD in many species (**Figure 2(c)**). A considerable degree of variation exists in the EOD waveform shape. The variation is due to the various morphological specializations of electrocytes, different patterns of innervation and propagation of action potentials within the electrocytes, and the spatial distributions of ion channels within the electrocytes (**see also Detection and Generation of Electric Signals**: Electric Organs).

Synchronous Firing of Electrocytes

A large number of electrocytes are arranged in series and in parallel in the electric organ. In *Torpedo nobiliana*, for example, approximately 1000 electrocytes are stacked in series in one column, and there are 500–1000 columns on each side of the fish. In serially connected electrocytes, the current exiting from the inactive face of a cell tends to enter the active face of the neighboring electrocyte. The direction of this current is inhibitory to the neighboring electrocyte and thus opposes synchronization. All electrocytes must be individually innervated and stimulated at once in order for potentials from all electrocytes to be summed. Synchronous firing of electrocytes is achieved by brain neurons that send a command signal to each electrocytes.

Generation of EOD Commands by Central Nervous System

The simplest command neurons are found in the electric catfish, *Malapterurus electricus*. The somata of two giant electromotor neurons in the anterior segment of the spinal cord are coupled with gap junctions. Each presynaptic fiber to the electromotor neurons bifurcates and terminates on either side for simultaneous stimulation. In most electric fishes, an unpaired command/pacemaker nucleus exists in the medulla (a hindbrain structure) that contains a large number of neurons that fire synchronously. The nucleus is called the command nucleus in mormyrid pulse-type fishes that emit EODs with irregular intervals. It is called the pacemaker nucleus in gymnotiform fishes and mormyriform *Gymnarchus niloticus*, which emit EODs with regular intervals (**Figure 3**). Because neurons in these nuclei show the earliest firing in the brain that is related one to one with EODs, these neurons are considered the decision makers. A short electrical pulse applied to the nucleus resets the phase of its pacemaking activity.

The demand for the precision of synchronization is higher in fishes with high EOD frequencies. In apteronotid electric fishes whose EOD frequencies can be as high as 1500 Hz, an error in timing of firing as little as 0.4–0.5 ms results in total cancellation of output EODs. Reflecting this, species with higher EOD frequencies show tighter electrical coupling and closer apposition among pacemaker neurons. High-frequency wave-type fishes in Gymnotiformes (*Eigenmannia virescens* and *Apteronotus albifrons*) and Mormyriformes (*G. niloticus*) show remarkably stable EOD intervals (jitter = 100 ns to 1 μs). Pacemaker/command signals from these nuclei are sent to the electric organ via one or two intermediate relay nuclei in the brain and electromotor neurons in the spinal cord.

Figure 4 shows the patterns of anatomical connections of the pacemaker/command complex in different fishes. In gymnotiform fishes, the neurons in the pacemaker project to the relay nucleus, an unpaired nucleus in the medulla adjacent to the pacemaker nucleus. Neurons in the relay nucleus extend their axons into the spinal cord where they synapse to the somata of electromotor neurons. The pacemaker neurons in *G. niloticus* project out bilaterally to the lateral relay nuclei, which in turn project to an unpaired midline nucleus, the medial relay nucleus. Although the pacemaker and medial relay nuclei are closely apposed, there is no direct projection from the pacemaker to the relay nucleus. In pulse-type mormyrid electric fishes, the command nucleus projects bilaterally to relay nuclei called the bulbar command-associated nucleus which in turn projects to the medullary relay nucleus as in *G. niloticus*. A difference is that the command neurons also directly connect to the medullary relay nucleus and this projection carries the command signal to the electric organ. The bulbar command-associated nucleus mediates corollary discharges to the upper parts of the brain for gating of sensory information (**see also Detection and Generation of Electric Signals**: Physiology of Tuberous Electrosensory Systems and Active Electrolocation). Neurons in the final relay nuclei of all species extend their axons into the spinal cord where they synapse onto the somata of electromotor neurons. The somata and the axons of the relay nuclei have large diameters for fast conduction of nerve impulses which is believed to contribute to the precise firing of EODs.

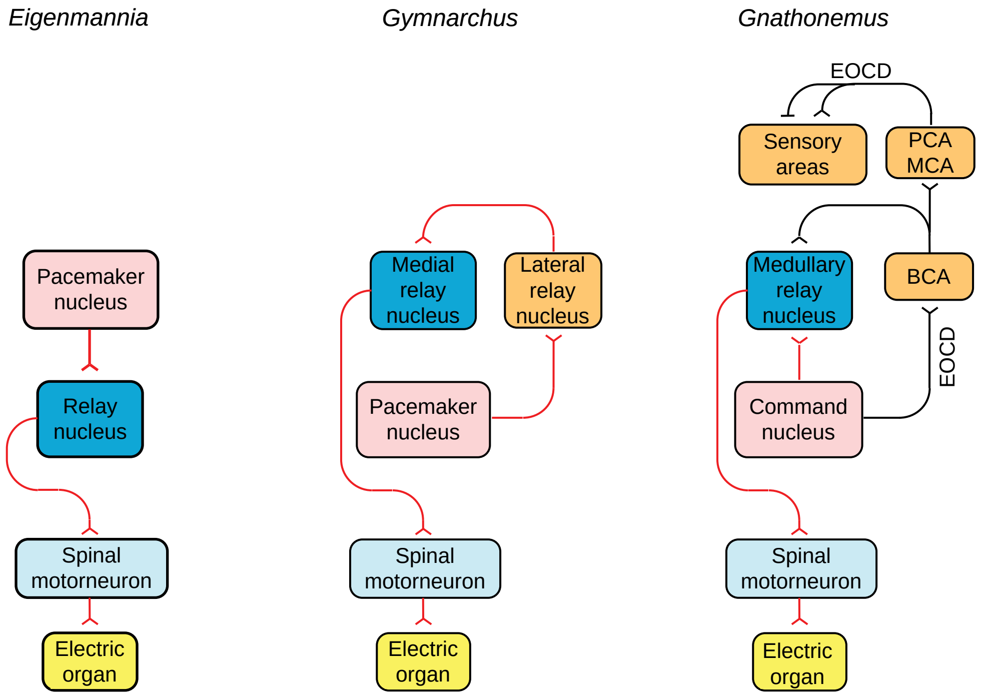

Figure 4 Comparison of central electromotor pathways that drive EODs. *Eigenmannia* (left) represents the pattern of all pulse- and wave-type gymnotiform fishes. A mormyriform pulse-type fish, *Gnathonemus* (right), involves a system for electric organ corollary discharges (EOCDs) that project to sensory areas in the brain. A mormyriform wave species, *Gymnarchus niloticus* (center), has an intermediate complexity. The pacemaker and command nuclei are the site of the EOD generation. Neurons in all the following structures fire one action potential for each EOD. The structures and connections shaded with orange color are actually bilateral but only one side is shown. Note the lack of projection from the pacemaker nucleus to the medial relay nucleus in *G. niloticus*, and the duplicated projections to the medullary relay nucleus in *Gnathonemus*. PCA, paratrigeminal command-associated nucleus; MCA, mesencephalic command-associated nucleus.

Central Control of EOD Time Patterns

Although the command and pacemaker nuclei are responsible for the basic rhythm of EODs at rest, they are by no means uncontrolled generators or oscillators. The time pattern of EODs at rest is modified in various ways for behavioral functions such as electrolocation, courtship, and aggression. The patterns include gradual rises or falls of EOD frequencies that occur over periods of seconds, rapid acceleration or deceleration of EOD timing that occurs within milliseconds, and total cessation of EODs (interruptions) (**Figure 5**). These modulations arise from neuronal inputs to the command/pacemaker and relay nuclei (**Figure 6(a)**). Physiology of the neuronal mechanisms for these modulations has been studied in many species of weakly electric fishes with the following techniques. First, input nuclei were identified by injection of backfill tracers into the pacemaker or relay nucleus. These tracers travel to brain nuclei projecting to the injection site. The nuclei projecting to the pacemaker/relay nuclei were then stimulated electrically or chemically to identify their physiological effects on the pacemaker/relay nucleus and EODs. The projection nuclei are generally found in the diencephalon and midbrain. **Table 1** shows EOD modulation patterns and the brain nuclei responsible for generating them in different genera of weakly electric fishes. The general features of these modulation mechanisms are: (1) the projection nuclei occurring in the diencephalon or the midbrain, (2) labeled line organization in which each projection nucleus serves a specific behavioral output pattern, (3) projections not only to the pacemaker nucleus but also to the relay nucleus, and (4) relatively conserved anatomical connections but functions varying among different species.

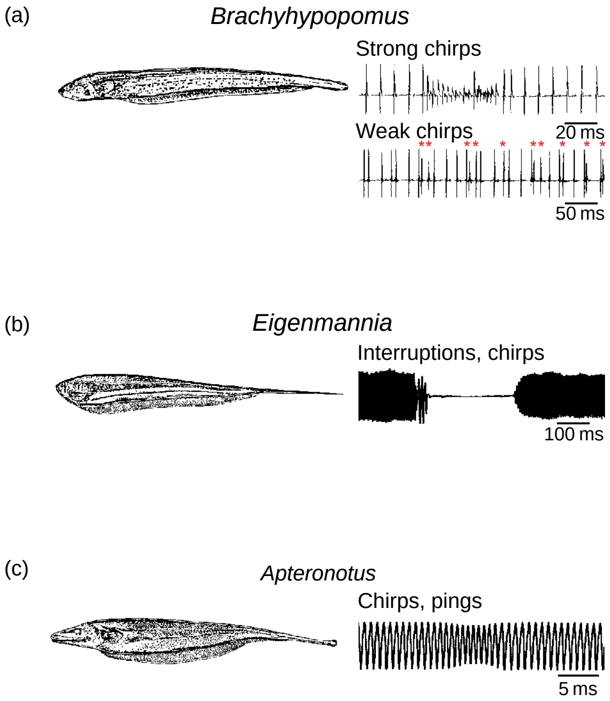

Figure 5 Examples of EOD modulations in gymnotiform electric fishes. (a) Chirps in *Brachyhypopomus brevirostris* consist of extra EOD pulses inserted in the regular train of EOD pulses. A strong chirp interrupts several regular pulses and consists of a sequence of high-frequency small-amplitude pulses. Weak chirps consist of extra pulses inserted without interruption of background EODs. Extra pulses are marked with asterisk. (b) *Eigenmannia* interrupts its wave-type EOD of several hundred hertz for 100–500 ms. The interruption occurs continuously a few tens times per minute in courting males. This behavior also is referred to as chirps. (c) *Apteronotus* rapidly increases its high-discharge frequency (~500–1000 Hz) by a few hundred hertz that lasts for a few tens to a few hundred milliseconds.

Gymnotiform Pulse Fishes

Figure 6(a) shows premotor brain nuclei and their behavioral functions in *Brachyhypopomus brevirostris*. Gradual frequency rises and falls are mediated by the subdivisions of the prepacemaker nucleus (PPn), the PPn-G and the PPn-I, respectively. Neurons from both nuclei project to the pacemaker nucleus and modulate its firing frequency. The inhibitory effects by the PPn-I are mediated by gamma-aminobutyric acid (GABA) and cause total cessation of the pacemaker activity which in turn results in total cessation of relay cells, electromotor neurons, and the electric organ (interruptions). This type of interruption is always preceded by a frequency fall. The sublemniscal prepacemaker nucleus (sPPn) projects to the relay nucleus and steadily depolarizes the membrane potential of relay cells. Due to the depolarization-blocking action potentials through the inactivation of Na^+ channels, the relay cell rejects inputs from the pacemaker nucleus and stops driving the electromotor neurons and electric organ. This type of interruption occurs without any preceding change in EOD frequency because the pacemaker activity is uninterrupted. Chirps are mediated by the PPn-C, which projects to the relay nucleus. Unlike the effects from the sPPn, the excitatory effects from the PPn-C are brief and cause additional spiking in relay neurons which is propagated down to the electric organ to produce extra pulses in between regular EODs (**Figure 5(a)**). Neurotransmitters and their postsynaptic receptor types are known for each of these pathways (**Figures 6(b)**, **6(c)**, and **7**).

Gymnotiform Wave Fishes

Wave-type gymnotiform fishes typically generate EODs at a stable frequency that remains within a few hertz over hours. However, when a fish encounters a neighbor whose EOD frequency is very close (within a few hertz) to the fish's own EOD frequency, it shifts the discharge frequency away from that of the neighbor. *Eigenmannia* increases and decreases the EOD frequency for lower- and higher-frequency neighbors, respectively. *Apteronotus* only increases the frequency in

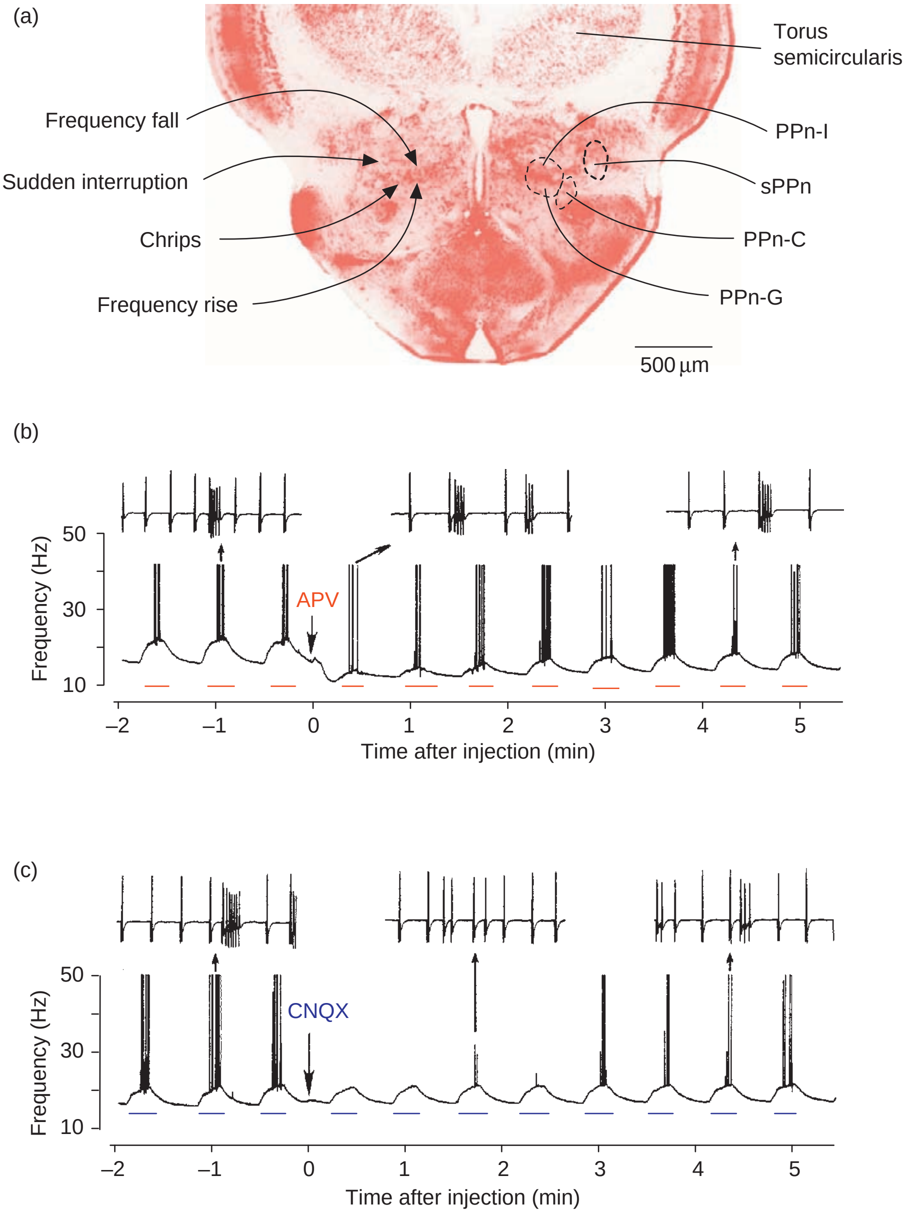

Figure 6 (a) A transverse section of the midbrain of *Brachyhypopomus brevirostris* showing brain nuclei controlling EOD modulation behaviors. Stimulation of small areas indicated with arrows using glutamate iontophoresis modulates the EODs. (b) Selective blocking of frequency-rising behavior by injection of the slow glutamate receptor blocker 2-amino-5-phosphonopentanoic acid (APV) into the pacemaker nucleus (red bars). The PPn-C and PPn-G were stimulated simultaneously to induce chirps and frequency rises, which are seen as spike-like transient increases in frequency and gradual increase in frequency. The three traces above are time-expanded EOD recordings showing chirps. Note that APV injection reduces the frequency-rising behavior but chirping responses are unaffected. (c) Similar experiment as in (b) but a neurotransmitter blocker for the fast type of glutamate receptors, 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), was injected. CNQX injection abolishes chirps but the gradual frequency-rise responses to iontophoretic stimulation of the PPn are unaffected.

response to a low-frequency neighbor but does not respond to a high-frequency neighbor. These frequency changes, called the jamming avoidance responses (JARs), result in expanding frequency differences between the fish and function to avoid mutual jamming of their electrolocation systems (**see also Detection and Generation of Electric Signals**: Physiology of Tuberous Electrosensory Systems). The diencephalic nuclei, the nucleus electrosensorius up (the nE↑) and the nucleus electrosensorius down (nE↓), are involved in frequency-increasing and frequency-decreasing JARs, respectively. Stimulation/lesion of these nuclei affects frequency-increasing and -decreasing JARs, respectively.

The frequency-increasing JAR is mediated by excitatory neuronal input to the pacemaker nucleus from the PPn-G which in turn is stimulated by the nE↑ (**Figure 8**). The frequency-decreasing JAR, however, is not mediated by inhibitory inputs to the pacemaker like the

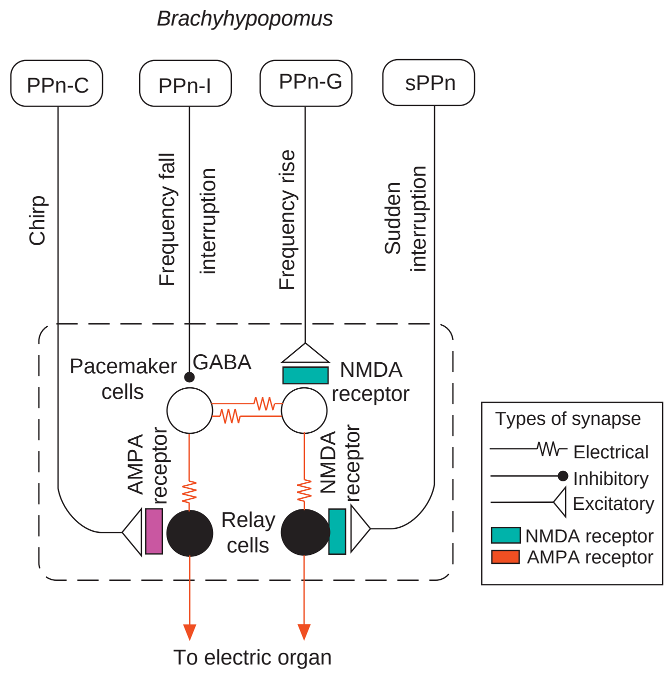

Figure 7 Organization of premotor nuclei and the pacemaker/relay cell complex in gymnotiform pulse fish, *Brachyhypopomus brevirostris*. Stimulation of each subdivision of the prepacemaker nucleus (PPn) induces the EOD behavioral patterns described along the projection lines. Pharmacological experiments as in **Figures 6(b)** and **6(c)** revealed the type of neurotransmitter and receptor subtypes in the pacemaker/relay complex. Red lines are involved in the generation of the basic rhythm; other lines are involved in behavioral modulations.

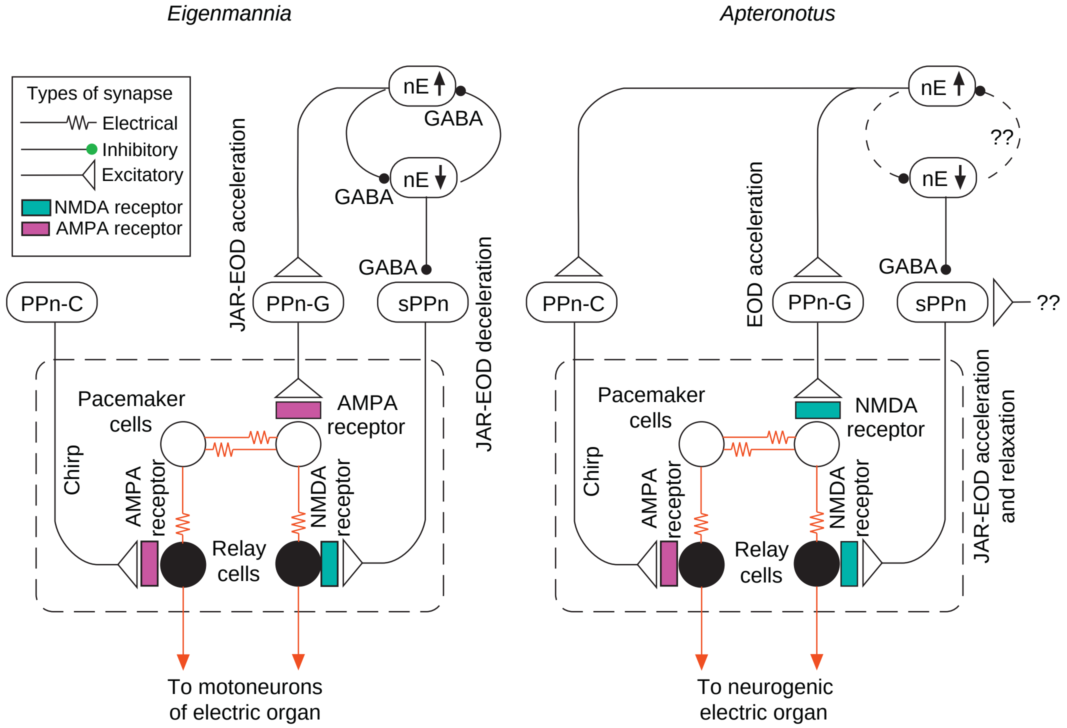

Figure 8 Organization of premotor nuclei and the pacemaker/relay cell complex in gymnotiform wave fishes, *Eigenmannia virescens* and *Apteronotus leptorhynchus*. Stimulation of each subdivision on the prepacemaker nucleus (PPn) induces the EOD behavioral patterns described along the projection lines. Pharmacological experiments as in **Figures 6(b)** and **6(c)** revealed the type of neurotransmitter and receptor subtypes in the pacemaker/relay complex. Red lines are involved in the generation of the basic rhythm; other lines are involved in the behavioral modulations.

frequency-falling behavior in pulse-type *Brachyhypopomus*. Instead, the frequency-decreasing JAR occurs by inhibition from the nE↓ of the sPPn that normally has a constant excitatory effect on the pacemaker nucleus. In *Apteronotus*, anatomical organization of premotor nuclei is similar to that of *Eigenmannia*; their physiological roles are, however, vastly different. The pathway through the nE↑ and PPn-G to the pacemaker nucleus is not involved in the frequency-increasing JAR in *Apteronotus*. Instead, an excitatory effect via sPPn is responsible for the behavior. The nE↑ and nE↓ do exist and have similar anatomical, physiological, and pharmacological connections with the PPn-G and sPPn in *Apteronotus*, but they are not involved in their JAR. Gymnotiform wave fishes show transient EOD modulations that occur within milliseconds during social interactions. These take the form of short interruptions of the EOD in *Eigenmannia*, and rapid frequency rises in *Apteronotus*. These EOD modulations are often called chirps and they are mediated by the PPn-C that projects to the relay nucleus in both genera (**see also Sensory Systems, Perception, and Learning**: Shocking Comments: Electrocommunication in Teleost Fish).

Mormyriform Pulse Fishes

Unlike gymnotiform fishes, mormyrid pulse fishes emit EODs with variable timing. The somewhat irregular EODs are modulated into different EOD patterns in different behavioral situations. The known patterns include cessations (interruptions), accelerations, scallops, and rasps. **Figure 9** shows the organization of premotor nuclei in *Brienomyrus brachyistius*. The command nucleus acts as an integrate-and-fire unit that receives excitatory inputs from various parts of the brain, including the midbrain precommand nucleus (PCN) and thalamic dorsal posterior (DP) nucleus. The output of the command nucleus, while driving the EODs via the relay nucleus, provides corollary discharges to the sensory system for gating of sensory information. The corollary discharge signal also projects to a part of a midbrain nucleus called the ventroposterior nucleus (VPd) that in turn projects to the PCN and the DP nucleus with inhibitory synapses. A simple central pattern generator for their basic EOD rhythm is suggested where the PCN and DP nucleus send constant excitatory inputs to the command nucleus and the corollary discharges

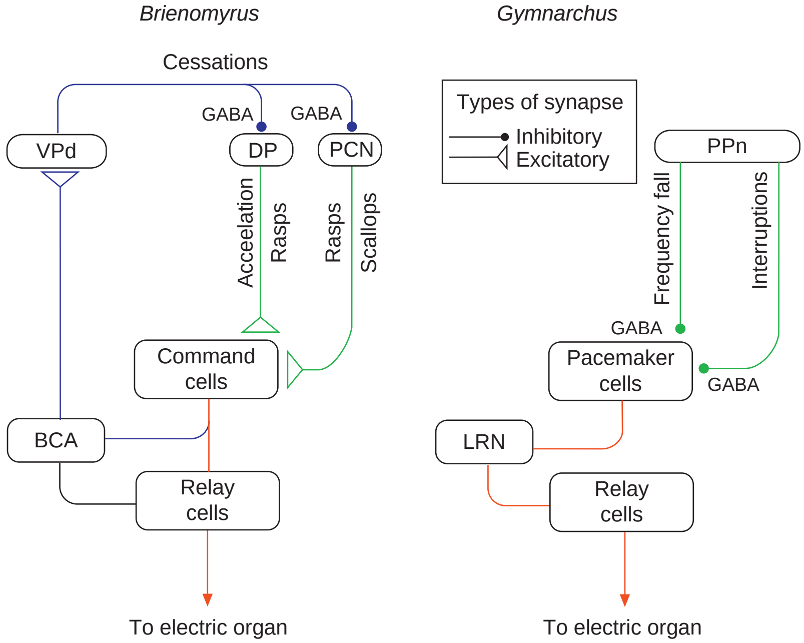

Figure 9 Organization of premotor nuclei and the pacemaker/relay cell complex in a mormyriform pulse fish, *Brienomyrus brachyistius* and a wave fish, *Gymnarchus niloticus*. Stimulation of each premotor nucleus induces the EOD behavioral patterns described along the projection lines (green). Pharmacological experiments as in **Figures 6(b)** and **6(c)** revealed the type of neurotransmitter and receptor subtypes in the pacemaker/relay complex. Red lines are involved in the generation of the basic rhythm; blue lines convey the corollary discharge information; and green lines show the projections for EOD pattern modulation. BCA, the bulbar command-associated nucleus; and LRN, the lateral relay nucleus.

via the VPd cast inhibition back to the DP nucleus and PCN. Stimulation of these premotor nuclei induces specific EOD modulation patterns (**Figure 9**).

Mormyrid Wave Fish *G. niloticus*

G. niloticus, the sole wave-type electric fish of the Mormyriformes, exhibit JARs similar to those of *Eigenmannia* and interruptions as a submissive behavior. Only one diencephalic nucleus has been identified. This PPn casts inhibition to the pacemaker nucleus (**Figure 9**). This projection mediates both frequency-decreasing JARs and interruptions. Premotor nuclei responsible for frequency-increasing JARs are unknown.

Glossary

Ampullary electroreceptors Electroreceptors sensitive to weak electric fields up to about 50 Hz; there are primitive ampullary electroreceptors in cartilaginous and nonteleost fishes and derived ampullary electroreceptors in teleost fishes.

Dorsolateral placodes Localized epidermal thickenings that form within the inner layer of the cephalic ectoderm following neurulation. These placodes give rise to sensory organs of the lateral line system, neuromasts, and ampullary electroreceptor organs.

Epaxial muscle The part of the lateral muscle which is situated dorsal to the vertebral column and the horizontal myoseptum as opposed to the hypaxial muscle lying ventral to the horizontal myoseptum.

Larval electric organ An electric organ that develops during early development in mormyrids and some gymnotiforms; it degenerates later during ontogeny and is replaced by a more derived electric organ.

Myogenic electric organs Electric organs derived from muscle tissue.

Neurogenic electric organs Electric organs formed by the axons of motor neurons.

Tuberous electroreceptors Electroreceptors sensitive to weak electric fields above 50 Hz that occur in teleost fishes possessing electric organs. These receptors are capable of monitoring the weak electric fishes' own discharges and are therefore used in electrocommunication and orientation.

Introduction

Electroreception is the capacity to perceive weak electric fields. The corresponding sensory organs are electroreceptors, which evolved from mucous glands in the case of primitive mammals (Platypus), and from the lateral line system in amphibians, lampreys, and fishes (**Figure 1**; **see also Detection and Generation of Electric Signals**: Morphology of Electroreceptive Sensory Organs).

Superficial electroreceptive organs originated in the common ancestor of lampreys and gnathostomes early in the Palaeozoic and are found in extant lampreys. The electroreceptive organ of cartilaginous fishes and nonteleost bony fishes – lungfishes, coelacanths, bichirs, reedfishes, sturgeons, and paddlefishes – is the ampullary organ, often called the ampullae of Lorenzini. This primitive ampullary organ comprises a hair cell bearing an apical kinocilium, which, however, seems to have been lost with the origin of neopterygian bony fishes (gars, bowfins, and teleosts). The phylogeny of teleost fishes is characterized by repeated, independent evolution (re-invention) of electrosensory systems. Ampullary organs re-evolved three times independently in the African knifefishes (Xenomystinae) and elephantnoses (Mormyriformes), both members of the bony tongues (Osteoglossomorpha), as well as in the catfishes (Siluriformes) and South American knifefishes (Gymnotiformes), members of the Ostariophysi. In addition to these derived, low-frequency-sensitive (up to 50 Hz) ampullary organs with hair cells bearing apical microvilli, high-frequency-sensitive (50 Hz to 2 kHz) tuberous electroreceptors evolved independently in the two teleost taxa, Mormyriformes and Gymnotiformes, concomitantly with electric organs (EOs).

EOs that produce electric fields have been invented at least seven times independently in cartilaginous (Torpedinoids, Rajoids) and teleost fishes (Mormyriformes, Gymnotiformes, Siluriformes, and Uranoscopidae); their anatomy and histology are more diverse than those of electroreceptor organs (**see also Detection and Generation of Electric Signals**: Electric Organs). EOs are derived from muscle tissue or, in one case, nerve fibers (family Apteronotidae of the Gymnotiformes). The electric discharge in strongly electric fish is powerful enough to be used for defense or stunning prey. The weak EOs together

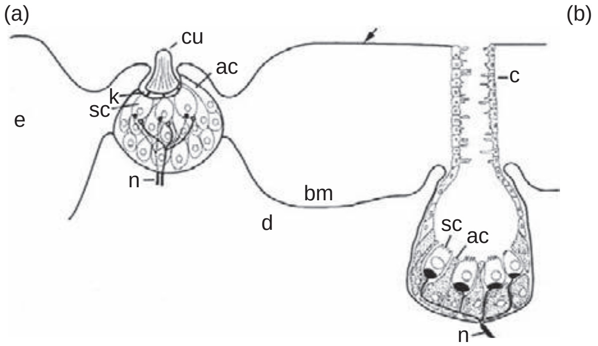

Figure 1 Schematic of a superficial neuromast (a) and a primitive ampullary organ (b). The cupula (cu) of the superficial neuromast comprising polysaccharides protects the sensory cell (sc) from the aquatic environment. The movements of the cupula are transferred to the sensory cells through the kinocils (k). In the ampullary organ, the sensory cells are found at the base of a canal (c) which is embedded in the dermis (d). The canal is filled with electrically conductive polysaccharides that protect the sensory cells from the outer environment. In both organs, the accessory cells (ac) surround the sensory cells. The base of the sensory cells is connected in both organs to afferent sensory nerve fibers (n). In addition, the sensory cells of the neuromast receive efferent input from a motor nerve fiber (dotted lines). bm, basement membrane; arrow, surface of the epidermis.

with the appropriate electroreceptors (electric system) are used for active electrolocation (**see also Detection and Generation of Electric Signals**: Active Electrolocation) and electrocommunication (**see also Sensory Systems, Perception, and Learning**: Shocking Comments: Electrocommunication in Teleost Fish).

Electroreceptor Development

Lampreys (Agnatha)

Ammocoete larvae of lampreys possess multivillous sensory cells, resembling sensory cells belonging to the octavolateralis system. They occur in small groups on the tail and in the gill-vent papillae. They might represent future end buds, the electroreceptor cells of adult lampreys.

Development of the Primitive Ampullary Organ

The primitive ampullary organs are often called the ampullae of Lorenzini. In Chondrichthyes (elasmobranchs and holocephalans), the ampullae of Lorenzini consist of a long canal at the end of which are found the receptor cells. The length and distribution of these canals vary significantly between species and probably reflect niche differences rather than taxonomic positions. The ampullae of many different receptor organs are grouped together in clusters beneath the skin with tubes radiating out from each cluster in many directions. In benthic feeding skates, most of the receptors are on the ventral body surface, whereas many sharks have equal numbers, dorsal and ventral.

The ampullary receptors of the bony fishes (Actinistians, Dipnoi, Polypteriformes, and Chondrostei) consist of a short canal leading to the receptor cells. These organs are predominantly found on the head region and their number varies from one (*Polypterus*) to about 75 000 in *Polyodon* (Chondrostei).

The development has been well studied in elasmobranchs, sturgeons, and paddlefish *(Polyodon spathula)*, and it is quite similar to the development described for amphibians. Early in development, localized epidermal thickenings on the trunk, so-called placodes, form within the inner layer of the cephalic ectoderm. In the beginning, they are covered by an overlying layer of ectoderm. A prominent otic placode gives rise to the inner ear. In general, six pairs of lateral-line placodes develop, three preotic and three postotic placodes that give rise to the lateral line and electrosensory cells located on the head and the trunk, respectively. Below these placodes, neuroblasts of the sensory ganglia of the lateral-line nerve develop and their fibers come into contact with the placodes and apparently induce mitotic activity and enlargement of the placodes. These are termed sensory ridges. The central part of the sensory ridges gives rise to neuromast primordia, and the lateral zones to ampullary primordia which thereafter differentiate into the final ampullary organ composed of sensory cells, supporting cells, and modified epidermal cells (**Figure 1**).

Development of the Derived Ampullary and Tuberous Electroreceptor Organs

Teleostei

Osteoglossomorpha

The osteoglossomorpha are an unusual group of teleost fishes comprising about 250 species of freshwater fishes, most of which are in one family, Mormyridae. The monospecific family Gymnarchidae comprises the large-growing piscivorous aba (*Gymnarchus niloticus*). All species of Mormyridae and Gymnarchidae are weakly electric fishes. They are monophyletic and are grouped into the superfamily Mormyroidea, sometimes considered an order Mormyriformes. They are related to members of the family Notopteridae, of which fishes of the genera *Xenomystus* and *Papyrocranus* (subfamily Xenomystinae) are electroreceptive. The fishes of the subfamily Xenomystinae possess ampullary electroreceptors; their development has not been described to date.

All members of Mormyroidea possess both derived ampullary receptors and two types of tuberous receptors, called knollenorgans and mormyromasts, in Mormyridae and gymnarchomasts in the case of *Gymnarchus*. The knollenorgans serve electrocommunication, whereas the mormyromasts serve active electrolocation. There are no data on the development of electroreceptors in *Gymnarchus*.

Detailed studies have been performed concerning the development of electroreceptors in various species of mormyrids. The electroreceptors start to differentiate at about day 6 after fertilization and they are functional at about day 8. Interestingly, these electroreceptors comprise two distinct larval tuberous electroreceptors, type A and type B (**Figures 2(a)–2(d)**), as well as a larval mormyromast called the promormyromast (**Figure 3**). The larval electroreceptors are predominantly found in the head region (**Figure 4**). In addition to these three types of larval tuberous electroreceptors, the knollenorgans and ampullary organs found in adults develop as well. The two kinds of larval tuberous organs (A and B) degenerate at the onset of the juvenile stage, whereas the promormyromast differentiates at the same time into the more complicated mormyromast found in adults (**Figure 4**). In mormyrids, the various electroreceptors do not seem to develop from placodes or sensory ridges; they apparently develop directly from basal cells of the epidermis.

Siluriformes

There are descriptions on the development of electroreceptors in several species of catfishes. The most detailed study deals with the channel catfish, *Ictalurus nebulosus*. By stage 24, the preotic lateral-line placodes can be recognized, whereas the postotic placodes are not recognized until stage 28 (larva about 2 days old). These placodes, with the exception of the posterior placode, form sensory ridges by stage 34. From these ridges and the posterior placode, neuromast primordia begin to form during stage 37. By stage 45, well-developed superficial neuromasts of the lateral line are present. Ampullary organ primordia develop

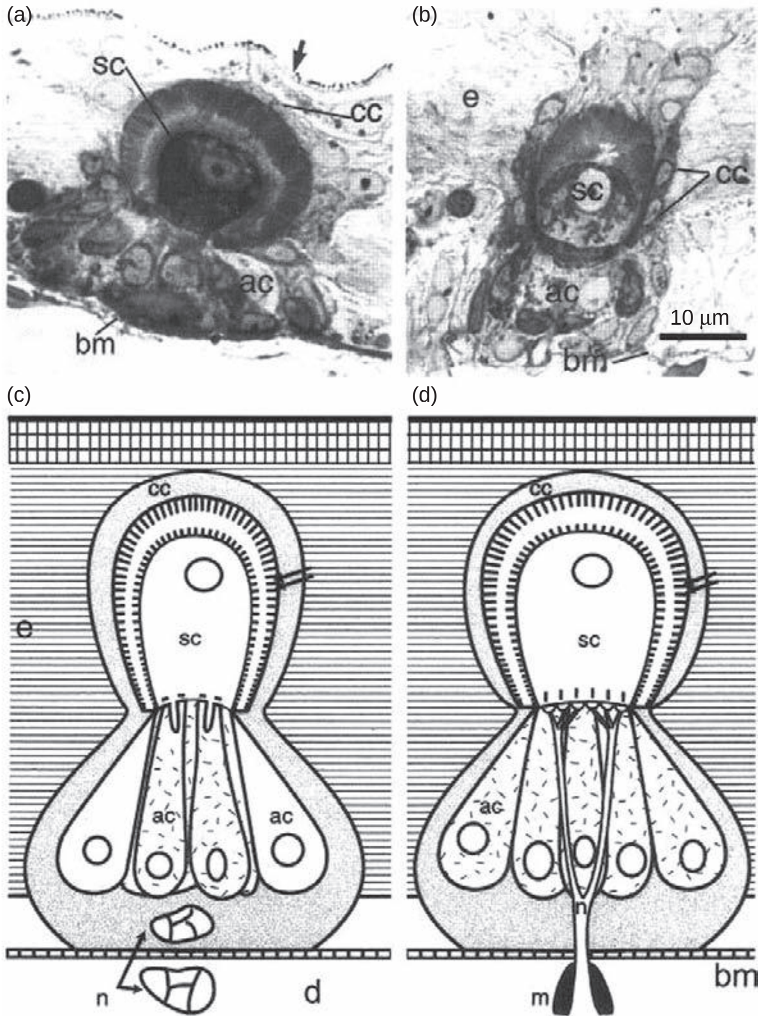

Figure 2 (a–c) Tuberous larval electroreceptors of type A (a, c) and B (b, d) in semithin sections (a, b) and in schematic drawing (c, d) in the epidermis (e) of the head of a 12-day-old larva of *Mormyrus rume proboscirostris*. Each type of organ consists of a single sensory cell (sc) surrounded by microvilli of the surrounding covering cells (cc); the sensory cell sits on a platform of accessory cells (ac); the outer surface of the epidermis is indicated either by a thick arrow (a) or a thick line (c, d). bm, basal membrane; n, nerve; m, myelin sheath. Scale = 10 μm.

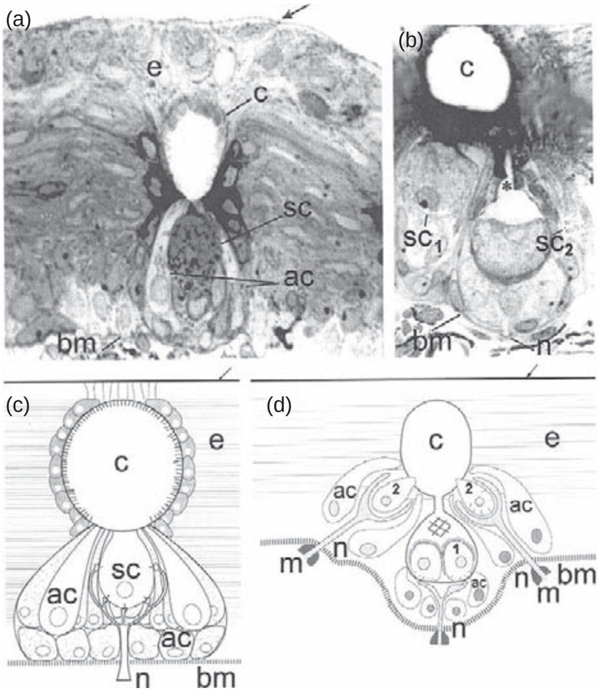

Figure 3 Larval mormyromast (promormyromast) (a, c), and mormyromast (b, d) of mormyrid fish in semithin sections (a, b) and in schematic drawing (c, d). The promormyromast develops into the mormyromast in particular through differentiation of a second type of sensory cell (sc_2 (b), 2 (d)). ac, accessory cells; e, epidermis; bm, basement membrane; n, nerve; sc_1, sensory cell of type 1; sc_2, sensory cell of type 2; m, myelin sheath.

from the sensory ridges around stage 43 (hatching) to 45. At stage 51, both mature ampullary organs and ampullary organ primordia are found on the head of the embryo.

Gymnotiformes

The only detailed study on the development of derived electroreceptors was performed on glass knifefish (*Eigenmannia lineata*). Four days after spawning, most of the lines of neuromasts are formed; the first electroreceptor primordia form on the lateral edges of the neuromast lines. The first differentiated tuberous organs occur on the head on day 7, and the first ampullary organs 1 day later. On the trunk, tuberous and ampullary organs occur 1 day later. The electroreceptor primordia apparently develop from general ectoderm (stratum germinativum) via induction of lateral-line fibers.

Development of EOs

Chondrichthyes

In cartilaginous fishes, EOs have evolved twice independently. In the superfamily Torpedinoidei, strong EOs evolved from branchial muscles and are found in the genera *Torpedo* and *Narcine*. The electric cells (electrocytes) represent disk-shaped structures which are oriented in the ventro-dorsal direction. The EO of electric ray (*Torpedo marmorata*) consists of about 500–1000 parallel columns of about 1000 disk-shaped cells. *T. marmorata* is a live-bearing fish. The EO is already functional before birth. Newborn electric rays (80–90-mm body length) can use their EO discharge (EOD) in prey capture. Differentiation of the electrocytes begins when embryos are 40 mm long, by the horizontal flattening of myotubes. Cell-shape transformation is finished by 55 mm embryo length; the electrocytes have by then acquired their disk-shaped structure. Discharges are first recorded in 60-mm embryos.

Several species of skates (Rajoids) emit weak electric discharges that are probably used for communication. The EO, comprising cup- or disk-shaped electrocytes, is located in the tail in the center of the lateral most bundle of longitudinally running muscle fibers. The EO is spindle shaped and runs most of the length of the tail. The

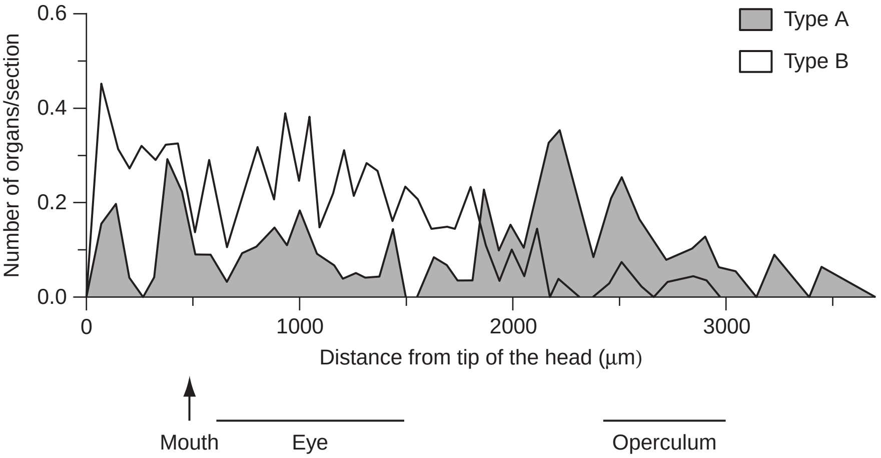

Figure 4 Diagram showing the distribution of the two types (A and B) of larval tuberous organs in the epidermis of an 11-day-old larva of *Campylomormyrus cassaicus* from the tip of the head to the end of the operculum, comprising a total length of 3700 μm, based on analysis of 2-μm-thick sections in the transverse plane. Note the difference in the distribution of the two types of organs.

development of these organs is known for several *Raja* species. The different species apparently represent different steps in the evolution of electrocytes from muscle fibers. In some stages during the differentiation of the electrocytes, myofibrils seem to be capable of contraction. Myofibrils in general are found in various degrees in all the EOs of myogenic origin. However, there has never been an indication of contractile fibers except for the case mentioned above.

Teleostei

Osteoglossomorpha

The development of EO has been described in members of both families of the order Mormyriformes. In *Gymnarchus niloticus*, the electrocytes develop from the medial part of the hypaxial and epaxial muscle. They are quite similar to muscle fibers and they develop directly into the electrocytes of the final organ, which consists of four spindle-like structures extending from the tip of the tail in the axial muscle up to at most the middle of the dorsal fin.

In mormyrids, the ontogeny of the EO has been described in several species. The most detailed description is in the study performed on elephantfish (*Pollimyrus isidori*). Surprisingly, mormyrids possess a larval EO in the axial muscle during the larval phase, which lasts for about 40 days. Thereafter, the adult EO in the caudal peduncle starts to become functional (**Figure 5**). The two organs are connected to the same pacemaker; however, they possess separate populations of electromotor neurons. The larval EO degenerates later during ontogeny. Larval and adult EOs produce different types of EODs. The larval organ possesses many features which indicate its origin from muscle; for example, the early electrocytes are difficult to distinguish from muscle fibers. During development, the adult organ quickly loses the characteristics indicating its origin from muscle, for example,

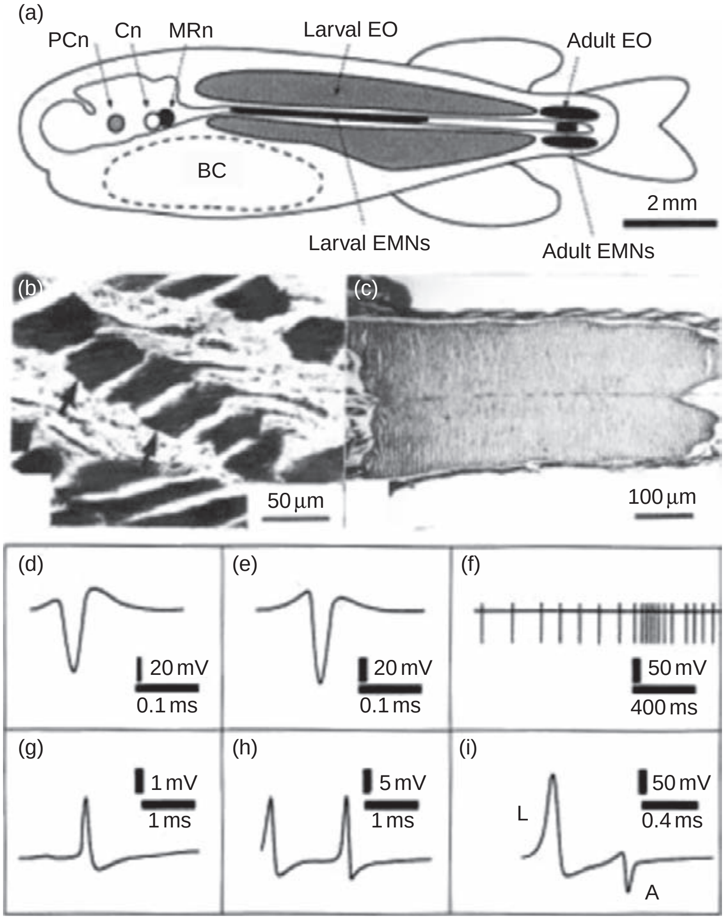

Figure 5 Topographical (a), histological (b, c), and physiological and ontogenetic data (d–i) on the larval and adult electric organs (EOs) in *Pollimyrus isidori*. (a) Topography of larval and adult EOs and electromotor neurons (EMNs) in a 15-mm larva. (b) Rows of larval electrocytes (arrows) from the epaxial muscle. (c) Sagittal section of the caudal peduncle showing the dorsal and ventral part of the adult organ with densely packed electrocytes (about 100 per column). (d–i) Discharge types: male (d), female and juvenile (e); sequence of pulse intervals recorded from an adult fish showing variable inter-pulse interval (f); larval type (g); larvae of approximately 10-mm length and juveniles about 20-mm long produce double pulses (h). In juveniles (i) from 15 mm on, the head-positive larval EOD, L, is followed and clearly separated by a head-negative adult EOD phase, A. BC, body cavity; PCn, pre-command nucleus; Cn, command nucleus; MRn, medullary relay nucleus.

the myotomic arrangement. These two organs therefore represent different steps in the evolution of the EO, interestingly being present in the same extant species.

Siluriformes

The African catfishes of the family Malapteruridae emit strong electric discharges of about 350 V. The EO is located just beneath the skin around the body; the origin of the electrocytes is uncertain. More recently, weak EOs have been recognized in some species of the African catfish families Mochokidae (*Synodontis* spp.) and Clariidae (*Clarias gariepinus*). The origin of the EO of *Synodontis* spp. seems to be the sonic muscle. The ontogenies of these organs are unknown.

Gymnotiformes

The South American electric knifefishes (gymnotiforms) are composed of five families with about 200 recognized species. These fish comprise a strong electric fish, the electric eel (*Electrophorus electricus*), whereas the remaining species all emit weak EODs. The EOs are very diverse in their anatomy, histology, and developmental origin. The EOs are of myogenic origin in species of the families Gymnotidae, Rhamphichthyidae, Hypopomidae, and Sternopygidae, and of neurogenic origin in all fish of the family Apteronotidae. A recent comparative ontogenetic study has demonstrated that there are two general types concerning the ontogenetic origin of the electrocytes. In species of the families Gymnotidae, Rhamphichthyidae, and Hypopomidae, the electrocytes originate below the hypaxial muscle, whereas in fish of the families Sternopygidae and Apteronotidae, the origin lies inside the axial muscle. The development of the organs is a long and complicated process, best exemplified by *Eigenmannia lineata* and (long nosed black ghost) *Apteronotus leptorhynchus* (**Figure 6**). In *Eigenmannia lineata*, the larvae start to emit

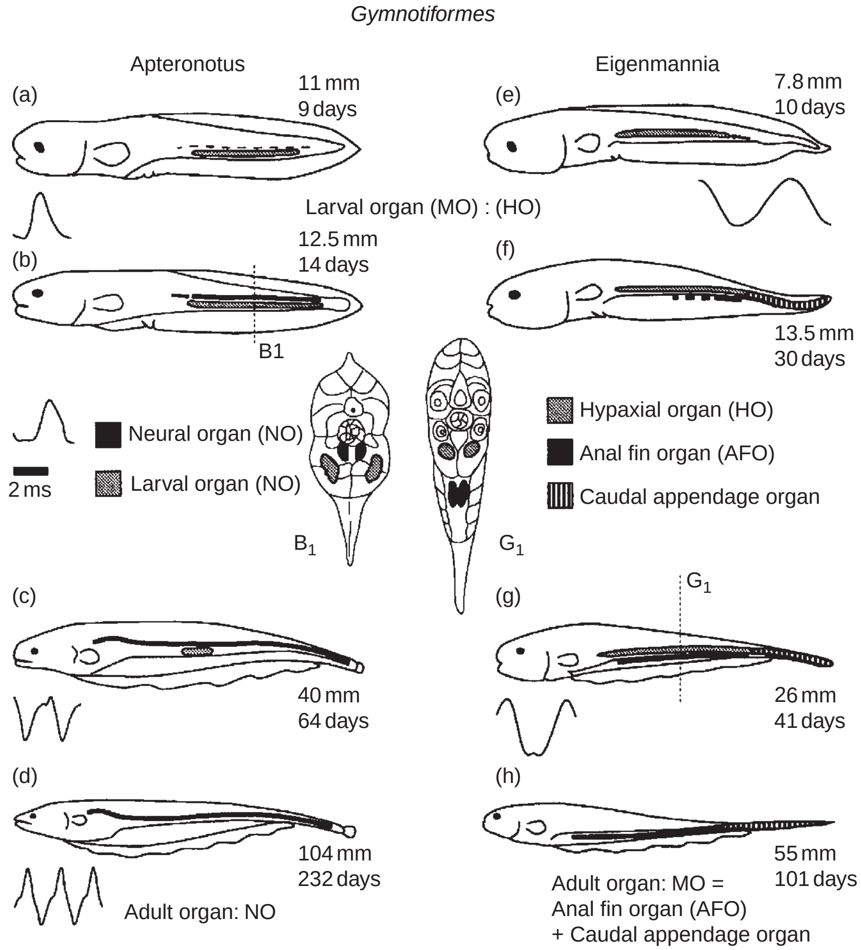

Figure 6 Comparison of the ontogenetic development of electric organs in two gymnotiform species that possess neurogenic (NO, *Apteronotus leptorhynchus* – (a)–(d)) and myogenic organs (MO, *Eigenmannia lineata* – (e)–(h)), respectively. The larval myogenic hypaxial organ is found in both species early during ontogeny; these organs are considered homologous structures. The larval organ eventually is replaced by the neurogenic organ in *Apteronotus*, and by the two myogenic organs in *Eigenmannia*. The larval organ is considered plesiomorphic (similar to that in the primitive ancestral clade), and the adult organs are considered apomorphic structures (structures that distinguish the group).

discharges just before the onset of exogenous feeding, at day 8 after fertilization when they are about 7 mm long. The electrocytes lie in the hypaxial muscle (**Figure 6(e)**) and extend caudally as the fish grows until they have reached the tip of the caudal appendage (**Figure 6(f)**). Then, additional electrocytes develop below the hypaxial muscle in between the muscles controlling movement of the anal fin (**Figure 6(g)**). The last step is the degeneration of the EO in the axial muscle (larval myogenic organ). The adult organ is fully formed by day 101, when juveniles are 55 mm long (**Figure 6(h)**).

Adult *Apteronotus leptorhynchus* possess a neurogenic organ (**Figure 6(d)**). In 9-day-old, 11-mm-long larvae, just at the onset of exogenous feeding, the larvae possess a myogenic organ in the hypaxial muscle (**Figure 6(a)**). This organ degenerates later on (**Figure 6(c)**). In 13-day-old larvae, a neurogenic organ starts to develop dorsal to the myogenic organ in the hypaxial muscle. This organ continuously extends rostrally and caudally (**Figure 6(c)**) and is the only organ present in the adult (**Figure 6(d)**). This ontogenetic sequence suggests that during evolution in apteronotids, first a myogenic and later a neurogenic EO developed. The EOD continuously changes during ontogeny and thus reflects the changing amplitudes of the discharges of both the myogenic and the neurogenic organs.

Comparative study has shown that the electrocytes in all species develop from mononucleated cells (electroblasts) directly into electrocytes. However, myofibrils can always be detected in the developing cells, indicating their myogenic origin. The electrocytes of wave-type species (families Sternopygidae and Apteronotidae) originating in the hypaxial muscle seem to represent more primitive organs compared with those originating below the hypaxial muscle (pulse-type species of the families Gymnotidae, Rhamphichthyidae, and Hypopomidae).

Astroscopidae

In the family Uranoscopidae, some species of the genus *Astroscopus* and *Uranoscopus* possess modified eye muscles emitting strong electric discharges of about 20–30 V. The development of these EOs has not been described to date.

Glossary

Bioluminescence Light produced by a chemical reaction that originates in an organism.

Chromatophores A variety of pigmented cells involved in the coloration of the skin of fish and other vertebrates and invertebrates. In fish, these are melanophores (black or brown), xanthophores (orange or yellow), erythrophores (red), cyanophores (blue), leucophores (whitish), and iridophores (iridescent).

Counter-illumination A defensive measure used by bioluminescent midwater cephalopods, decapod crustaceans, and fishes that camouflages an animal being viewed from below by mimicking downwelling light and reducing their silhouette.

Homology Indicates similarities due to inheritance, and used for homologous structures (e.g., limbs) or homologous gene sequences.

Iridescent Display of lustrous colors, which may vary with the angle of viewing. It is produced by interference of light waves with phase differences, when reflected from outer and inner surfaces of a transparent structure such as a crystal or membrane.

Tessellated cartilage Hyaline-like cartilage ‘tiled’ (tessellated) on the outside with tesserae; a feature of the Elasmobranchii (in contrast with areolar cartilage).

A Brief Historical Perspective on Functional Anatomy of Fishes

The articles in this volume focus on the functional anatomy of fishes, that is, anatomy from the inside out (bones, muscles, and out to skin), with an emphasis on the physiological significance of these structures. Most biologists have at least a cursory knowledge of fish anatomy because most participated, as part of their undergraduate training, in a course in comparative vertebrate anatomy that involved the dissection of a fish, usually a dogfish shark. Moreover, many took a course such as the functional anatomy of fishes taught for many years by Karel Liem at Harvard and which is also taught at many other universities. Of course, many eat cooked fish muscle after first removing the skin and hopefully leaving behind the bones!

Presumably, even cavemen had an idea of the morphology of the animals they ate because some cave drawings illustrate animals including fish. However, it was not until Galen, a Greek physician, who worked in Rome between AD 165 and 200 that there was any substantial written record. Galen wrote a synthesis of what was known about anatomy, but, more importantly, he added to that knowledge by dissecting a variety of animals including fishes, with the intention of discovering their morphology. Many of the names given to bones and muscles by Galen persist to the present day. Galen’s views were essentially dogma until the 1500s. Belon dissected a variety of animals, including fishes, and noted the similarity in the limb bones in all vertebrates. Amazingly, three anatomists published works on fishes at almost the same time: Belon (1553), Rondelet (1554), and Salviani (1554). Lorenzini published a monograph on the anatomy of Torpedo about 100 years later (1678). However, Cuvier is usually considered to be the founder of comparative anatomy. Georges Cuvier (sometimes reported as Georges Leopold Chretien Frederic Dagobert Cuvier and other times as Jean Léopold Nicolas Frédéric Cuvier) Baron de Montbeliard (1769–1832) was an extremely prolific writer. His works include nine volumes on comparative anatomy and the 22-volume *Historie Naturelle des Poissons* (*Natural History of Fishes*). Cuvier focused on the function that different structures performed and how their structure is adapted to their function. His great contribution was that he stressed an important concept that still has resonance: the structure of each and every part of the body is related to the animal's lifestyle; that is, structure and function are interdependent.

In the years that followed Cuvier, there was a struggle between comparative anatomists, especially Richard Owen, who held the view that species were immutable, versus those who supported Darwin, especially T.H. Huxley. Thus, the focus of scientific discussions was distracted away from the actual comparative anatomy and toward the arguments for and against Darwin's ideas about natural selection. In addition, more recently, much of life sciences has been concerned with the role of functional genomics, making it difficult to fund research on functional morphology. The series of articles in the present section show that there remain fascinating questions related to functional anatomy and that important research in the area of functional morphology is still ongoing. The articles in this section show how functional anatomy is just as important as functional genomics in understanding how the bodies of fishes work; it may be perhaps not as topical, but is just as interesting and just as important.

Functional Anatomy of Fishes Today

The following section provides a synthesis of current knowledge concerning the functional anatomy of the skeleton, of muscles, and of skin of fishes.

Skeleton – Bones or No Bones

The Chondrichthyes are considered cartilaginous fishes because the long endoskeletal elements called bones in other vertebrates are made of cartilage instead. Scientists have recognized the gross differences in skeletal material between the Chondrichthyes and other vertebrates for more than two centuries and yet, we have made only short inroads into answering the most basic questions surrounding the evolution and predominance of cartilage in the skeletons of these fishes. Most adult vertebrate animals have bony skeletons, with cartilage mostly restricted to joints and flexible structures. In contrast, the Chondrichthyes (sharks, batoids, and chimaeras) have endoskeletons made entirely of cartilage (**see also The Skeleton**: Cartilaginous Fish Skeletal Anatomy). Moreover, in sharks and batoids, most of the skeletal cartilage is tessellated, covered with mineralized blocks called 'tesserae'. There are several other forms of cartilage found in the bodies of these fishes that likely serve distinct functional and metabolic roles; these are described in a separate article (**see also The Skeleton**: Cartilaginous Fish Skeletal Tissues).

In contrast to the chondrichthyan fishes, most of the skeleton of bony fish becomes calcified during development. The skeleton of bony fishes is composed of hundreds of individual bony and cartilaginous elements that vary considerably in form (**see also The Skeleton**: Bony Fish Skeleton). The details of this variation are the product of functional demands generated by the life history, ecology, and behavior of individual species. Coupled to this are the constraints set in place from the phylogenetic history of each species. It is this combination – phylogeny and function – that makes an understanding and appreciation of the skeleton of fishes central to so many aspects of the evolutionary and ecological biology of fishes.

Muscle

The two articles in this section on muscle compare the cranial muscles of the cartilaginous fishes (**see also The Muscles**: Cartilaginous Fishes Cranial Muscles) with those of the bony fishes (**see also The Muscles**: Bony Fish Cranial Muscles). The cranial muscles of fishes are the actuators of their feeding and respiratory mechanisms, and are thus of great interest regarding vertebrate evolutionary history and functional diversification. The article **The Muscles**: Cartilaginous Fishes Cranial Muscles is a guide to the gross anatomy and function of these muscles in the three main lineages of cartilaginous fishes: sharks (spiny dogfish), batoids (southern guitarfish), and holocephalans (spotted ratfish), and includes a video of these jaw muscles in action. The article **The Muscles**: Bony Fish Cranial Muscles provides a much generalized description of the more common functions performed by or within the head, and those muscles responsible for these functions, including buccal pumping (ventilation), suction feeding, premaxillary protrusion, biting and tearing, and pharyngeal jaw prey processing. Videos of these muscles in action are available in **Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics.

Skin

The integument or skin is the envelope that not only separates and protects a fish from its environment, but also provides the means through which most contacts with the outer world are made (**see also The Skin**: The Many Functions of Fish Integument). It is a large organ and is continuous with the linings of all body openings, and also covers the fins. Fish integument is a multifunctional organ, and its components may serve important roles in protection, communication, sensory perception, locomotion, respiration, ion regulation, excretion, and thermal regulation. The integument consists of two layers (**see also The Skin**: Functional Morphology of the Integumentary System in Fishes): the outer layer and the inner layer. The outer layer, the epidermis, is essentially cellular in structure, comprised of a multilayered epithelium that usually includes specialized cells. The many types of these cells are described in the very well illustrated article **The Skin**: Functional Morphology of the Integumentary System in Fishes. The inner layer, the dermis, is primarily a fibrous structure with relatively few cells, although it may contain scales, nerves, blood vessels, adipose tissue, and pigment cells.

Skin coloration and patterns, and their capacity for change, have important roles in the life of fish, such as camouflage and social signaling (**see also The Skin**: Coloration and Chromatophores in Fishes). A variety of chromatophores (pigmented cells), and skin structural features, provide a physical basis for the wide chromatic variation between and within species. Short-term, physiological, and long-term, morphological, regulation of chromatophores involves the autonomic nervous system, and endocrine, and paracrine factors. Chromatophore-based patterns can result from local variations in the types of these cells, their numerical distribution, and differential control of intracellular pigment movement. Additionally, iridescent coloration may derive from skin structures such as collagen fiber arrays and surface microstructure.

In addition to pigments, many fish are bioluminescent (**see also The Skin**: Bioluminescence in Fishes). Marine teleost fish comprise one of the most diverse groups of luminescent animals with over 45 families and more than 190 genera containing luminescent species. Predominantly, blue light is emitted diffusely through translucent tissues that harbor symbiotic bioluminescent bacteria or discretely form complex photophores equipped with reflectors, lenses, and filters. Light displays can vary from quick flashes to long-lasting glows. Variety in form is matched by diversity in function with luminescence used for predation, defense, and intraspecific signaling. The article **The Skin**: Bioluminescence in Fishes is illustrated with some beautiful examples of bioluminescence in fishes.

Finally, **The Skin**: Hagfish Slime describes a very special function of skin that is present only in the hagfishes – that is, hagfish slime. Hagfish slime is very different from mucus. Hagfish slime is the ultra-dilute material that is formed when hagfishes eject the contents of their slime glands into seawater. The slime consists of two main components, mucin vesicles and thread skeins, which each arise from distinct cells within the slime gland. Deployment of the slime involves swelling of the mucin vesicles when they contact seawater, and their subsequent shearing into long mucin strands when they are acted upon by hydrodynamic mixing. The mucin strands attach to the thread skeins and transduce mixing forces to them, thereby effecting their unraveling. Hagfish slime is believed to function as a defense against gill-breathing predators.

In conclusion, the articles in this section describe how the structural components that make up the skeleton, the muscles, and the skin contribute to the physiology of fishes.

Glossary

Anterior Toward the front or head. In fishes, the term rostral can be substituted for anterior.

Autostyly Jaw condition where palatoquadrate is strongly attached to the ethmoid region and directly fused to the auditory region of the chondrocranium. The hyomandibula does not participate in jaw suspension.

Ceratotrichia Thin, keratinous fin rays, originating from large collagen fibers, and forming the distal-most elements in the fins of cartilaginous fishes (contrast with actinotrichia).

Distal The furthest from the central nervous system, or in the direction away from the central brain. Receptors are the most distal retinal neurons.

Dorsal Toward the top or back of the fish (the dorsal surface).

Endoskeleton The skeletal system formed by all skeletal elements that are nondermal in developmental origin.

Euhyostyly Jaw condition when the palatoquadrate has no ligamentous connection to the chondrocranium and does not contact it anteriorly, but only posteriorly via the hyomandibula (as in batoids).

Extant A species or clade, etc., that is still in existence.

Holostyly Jaw condition when palatoquadrate is fused to chondrocranium (as in Holocephalii).

Hyostyly Jaw condition when the palatoquadrate articulates with the chondrocranium, but is not strongly attached or fused (as in most sharks).

Lateral In a direction away, or a position far from the body's midline (e.g., your eyes are lateral on your face and lateral to your nose).

Medial In a direction toward, or a position near the body's midline (e.g., your nose is medial on your face and medial to your eyes).

Neoselachii A clade of cartilaginous fishes that includes extant sharks and batoids, but not chimaeroids.

Posterior Toward the rear, or behind. In fishes, the term caudal can be substituted for posterior.

Proximal Nearest to the central nervous system, or in the direction toward the central brain. Ganglion cells are the most proximal retinal neurons.

Skeletal element An individual portion in a cartilaginous skeleton, analogous to individual bones in the skeleton of a bony vertebrate.

Spiracle An external opening near the eye in elasmobranch fishes that communicates to the throat, via a passage between the hyomandibula and cranium.

Suspensorium The chain of cartilages, including the hyomandibula that suspends the jaws from the chondrocranium.

Synarcual A series of fused vertebrae.

Ventral Toward the bottom or belly of the fish (the ventral surface).

Introduction

From the outside, for the most part, the members from each of the three major extant groups of the Chondrichthyes look unmistakably distinct; a reef shark could never be confused with a barndoor skate or a white-spotted chimaera. Of course, these differences are reflected broadly in the skeleton; however, certain aspects of skeletal design are conserved among these fishes (**Figures 1** and **2**). The article **The Skeleton:** Cartilaginous Fish Skeletal

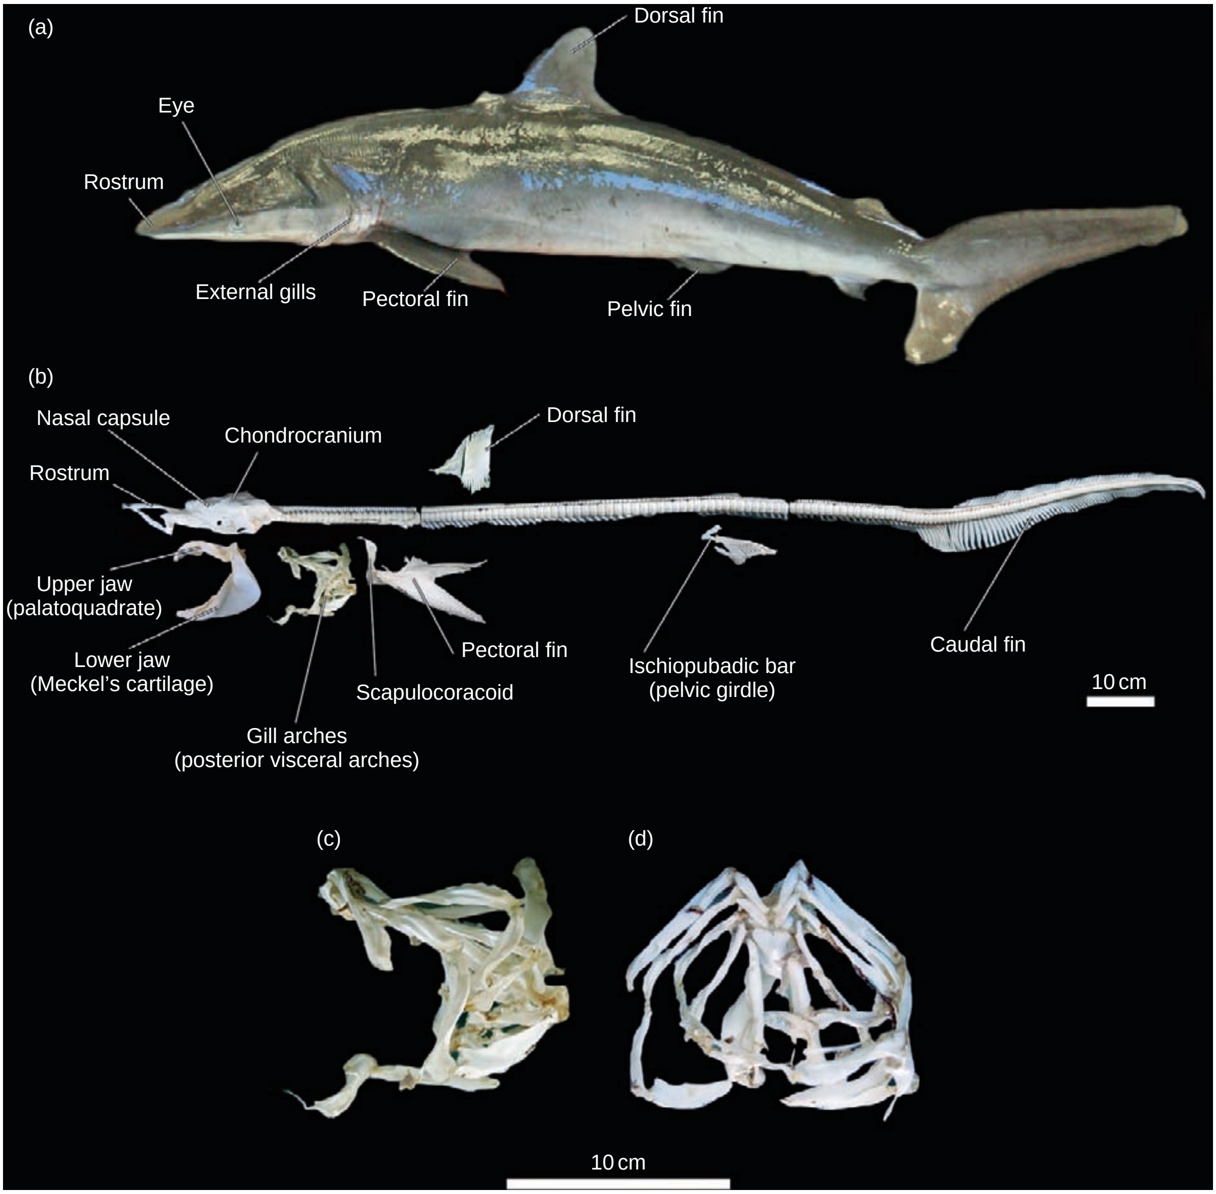

Figure 1 The body plan of sharks: (a) external anatomy of silky shark, *Carcharhinus falciformis*, in lateral view; (b) skeletal anatomy of silky shark, *Carcharhinus falciformis*, in lateral view; (c) closeup of branchial basket in lateral view; and (d) close-up of branchial basket in ventral view. Skeleton was prepared by dissection and maceration before it was dried and mounted. Branchial basket collapsed during drying and is slightly deformed.

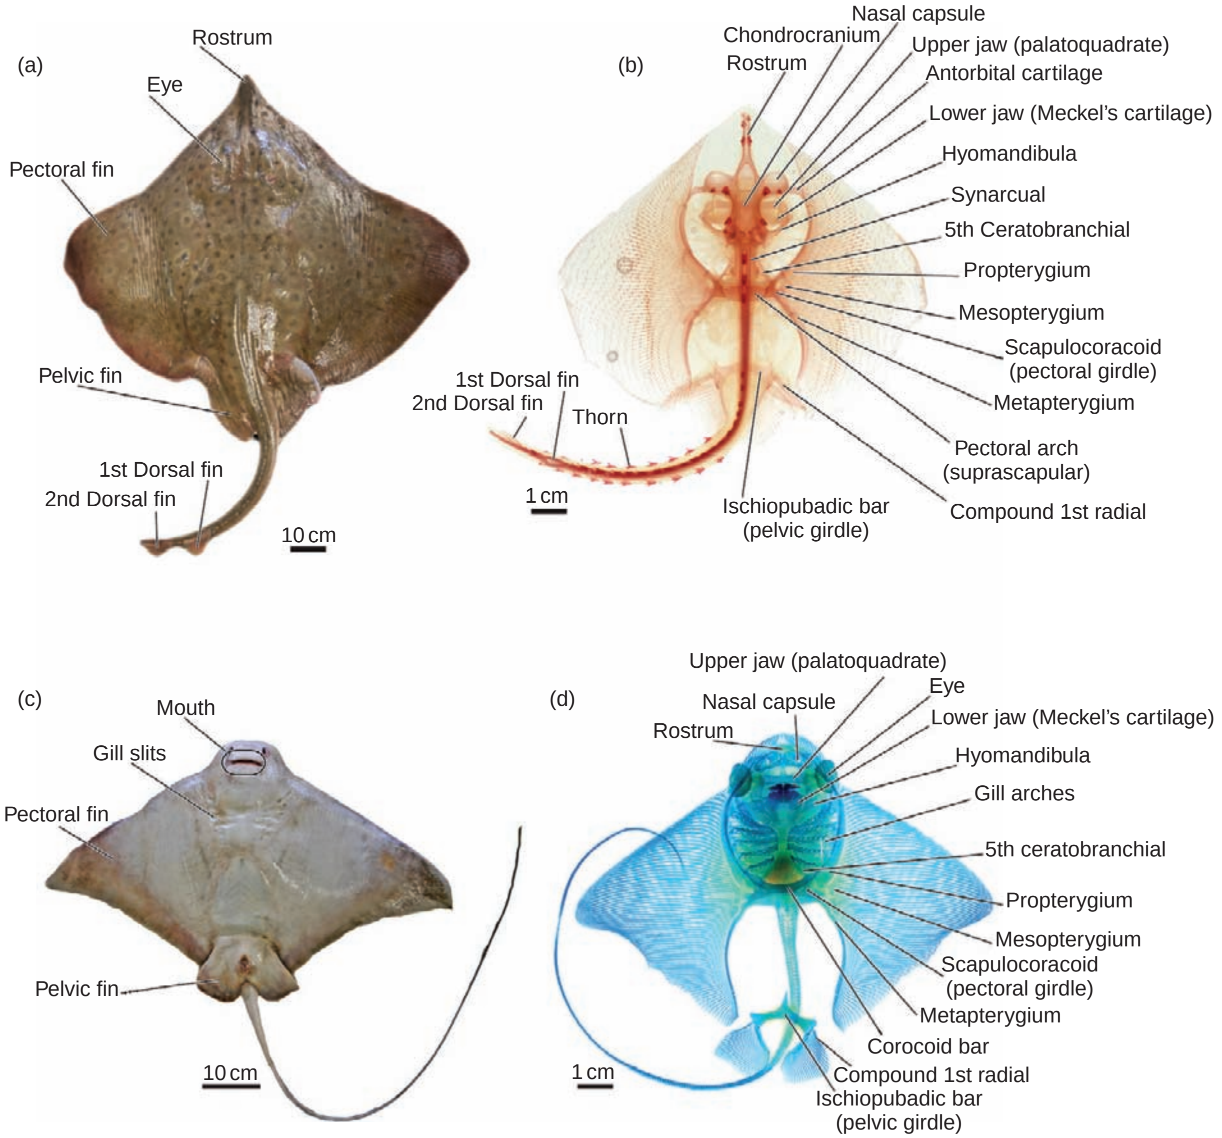

Figure 2 The body plan of batoids: (a) external anatomy of the barndoor skate, *Dipturus laevis*, in dorsal view; (b) skeletal anatomy of a skate, *Raja sp.*, in dorsal view. Skeleton was prepared by clearing and staining. Chemicals are used to digest the muscle fibers and make them clear. Alcian blue stains for uncalcified cartilage and Alizerin red stains for calcified (mineralized and hard) cartilage. The skeleton in this specimen is fairly well developed; (c) external anatomy of the cownose stingray, *Rhinoptera bonasus*; (d) skeletal anatomy of the eagle ray, *Myliobatis sp.* Skeleton was prepared by clearing and staining. This is a young specimen; the skeleton is not very well calcified yet, although all major parts have developed. (b) Courtesy of President and Fellows of Harvard College.

Tissues discusses conservation and variation at the tissue level; here, we show how these different types of cartilages are assembled to form the skeletons of chondrichthyan fishes.

A simplified chondrichthyan skeleton can be divided into three distinct parts – the axial, visceral, and the appendicular skeletons – that are discussed below. To understand the similarities and differences among taxonomic groups, it will help to think about the skeleton in pieces, just do as most anatomists, functional morphologists, and paleontologists. Researchers can compare these pieces through broad taxonomic surveys to gain insight into chondrichthyan evolution and how certain morphologies might be tied to certain ecologies.

General Anatomy

Axial Skeleton

The axial skeleton includes the skull, vertebral column, and ribs. The skull of all chondrichthyan fishes is called the chondrocranium and is essentially a cartilaginous box containing the brain and other important sense organs. Although the adult chondrocranium is a single piece of cartilage with definable regions, it is assembled early in embryonic development through the coalescence of separate cartilages. The embryonic basal and ethmoid plates form the anterior wall and floor of the chondrocranium; the occipital arches form the posterior wall of the chondrocranium; and the orbital cartilages contribute to the lateral walls of the chondrocranium. Although the complete chondrocranium varies in size and shape among species, there are generally identifiable regions that are conserved across the different groups of chondrichthyans and can be used to make broad comparisons among groups. From roughly rostral to caudal, these are the rostrum, nasal capsule, antorbital process, orbital region, otic capsules, and occipital condyles (**Figure 3**).

Posterior to the chondrocranium, the remainder of the axial skeleton is the vertebral column, composed of individuated vertebrae. There are three primary segments of a vertebra in chondrichthyans: dorsally, the paired basidorsals, contributing to the neural arches that protect the spinal cord; ventrally, the paired basiventrals, contributing to hemal arches that house blood vessels; and, in the middle, the centrum. The vertebral centrum is a spool-shaped structure that acts as the primary load-bearing structure and to which the neural and hemal arches that protect the important surrounding soft tissues are attached. Although the arches are made of tessellated cartilage, as in the rest of the skeleton, the centra are areolar cartilage; this is apparently the only place in the body where this tissue is found (**see also The Skeleton:** Cartilaginous Fish Skeletal Tissues). The centra are arranged so that the top and bottom of the spool face rostrally and caudally. Numerous centra are then strung together to form the spinal column, resembling many spools of thread strung together on a string. In the center of each centrum are the remains of the notochord, a stiff but flexible rod that serves as the embryonic foundation for the vertebral column. Among the different elasmobranch taxa, the shape of the persistent notochord in cross section is highly variable in fully developed centra, a result of differential folding as the areolar cartilage grows around it. That shape is consistent within certain groups of elasmobranchs and can be used diagnostically to distinguish between the vertebrae of different groups (e.g., those of sharks and batoids, **Figure 4**).

Visceral Arches

Beneath the chondrocranium is the visceral skeleton, which includes the upper and lower jaws (palatoquadrate and Meckel's cartilage), hyoid, and gill arch cartilages. These collected structures are called the visceral arches and can be thought of as jointed, symmetrical loops/semicircles of cartilaginous elements, arranged in rostrocaudal (anteroposterior) series, and supporting the breathing and feeding structures of the head. The joints

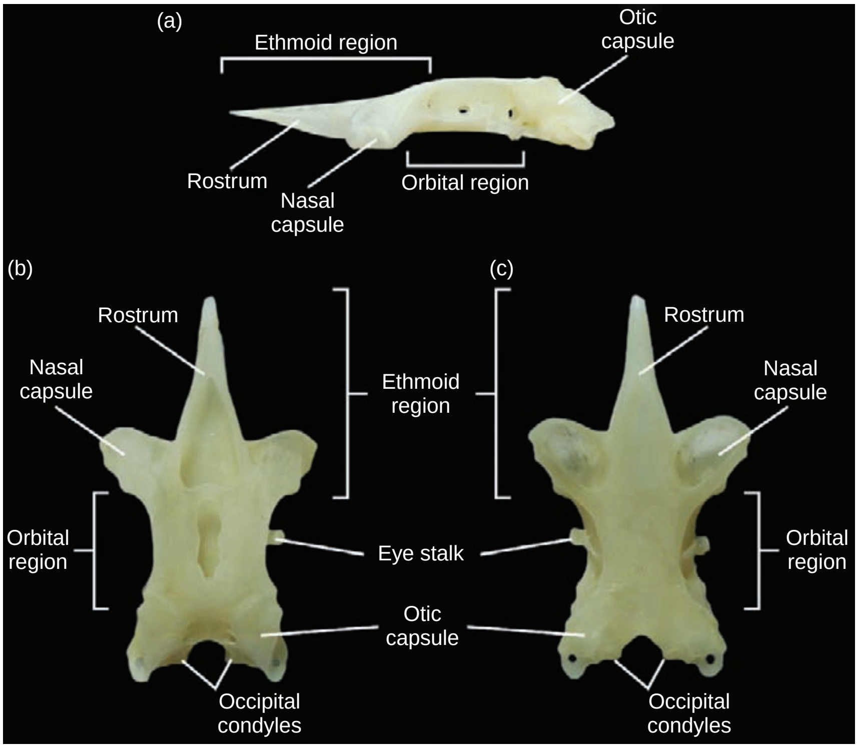

Figure 3 The chondrocranium of a skate, *Leucoraja ocellata*: (a) lateral view; (b) dorsal view; (c) ventral view.

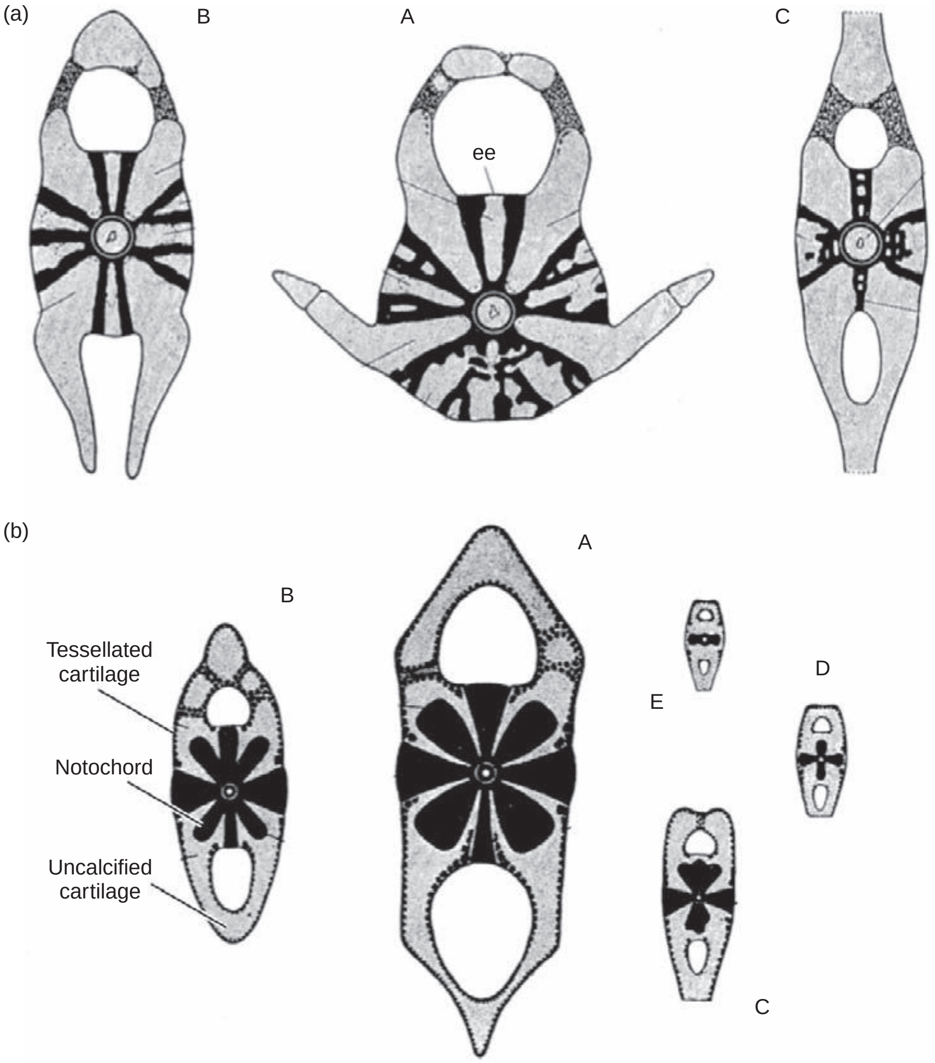

Figure 4 Cross section of vertebrae showing folding pattern of notochord in the centrum: (a) shark vertebrae, *Stegostoma tigrinum*, 660 mm long, ×6 (A, vertebra from region of pectoral girdle; B, vertebra from post-cloacal region; C, vertebra from region half-way along the caudal fin); (b) batoid vertebrae, *Rhinobatos granulatus*, ×3 (A, caudal vertebra, taken a short distance in front of the first dorsal fin; B, vertebra from the base of the caudal fin; C, from half-way between the base of the caudal fin and the extreme caudal end of the vertebral column; D, from half-way between C and the extreme hind end of the vertebral column; E, vertebra, a short distance behind D). Tessellated cartilage crust surrounds uncalcified cartilage. Notochord present as spokes (shark) or clover pattern (batoid). Modified from Ridewood (1921) On the calcification of the vertebral centra in sharks and rays. *Philosophical Transactions of the Royal Society of London, Series B* 210: 311–407.

in the arches allow them to expand and collapse, making breathing and feeding possible.

The mandibular arch (the first visceral arch) forms the jaw in chondrichthyans. It is divided into two parts, the dorsal palatoquadrate (upper jaw) and the ventral Meckel's cartilage (lower jaw). The palatoquadrate and Meckel's cartilage changed shape many times during the evolution of the Chondrichthyes. This is correlated to a change in the way the jaw is attached to the chondrocranium. The earliest chondrichthyans from the Paleozoic had a massive palatoquadrate that was firmly attached to the chondrocranium and was not mobile. In the modern Holocephalii, the jaws are also firmly in place, an arrangement is known as holostyly, which gave the group its name. The holostylic arrangement in Holocephalii is only convergent with the Paleozoic condition, and therefore these similar features are not derived from the same common ancestor. This Paleozoic type of jaw connection is known as autostylic. As chondrichthyans evolved, the palatoquadrate became less firmly connected with the chondrocranium and more mobile. There is evidence that these changes are correlated with the evolution of the variety of feeding styles seen in modern species.

The hyoid arch (the second visceral arch) is posterior to and closely associated with the mandibular arch. It is also divided into dorsal and ventral components. The hyomandibula is the sole dorsal element and the ventral components are the ceratohyal and basihyal. The remainder of the visceral arches are known collectively as the gill arches or branchial basket (**Figures 1**(**c**) and **1**(**d**)). The latter descriptor relates to the shape into which the series of U-shaped arches conform. As they are adjoined by ventral branchial cartilages, they form a structure that looks like the ribcage of a wooden ship, with the longer dorsal elements converging and connecting ventrally. The gill arches are the support system for the soft structures involved in gill ventilation and respiration.

With this knowledge of the relative arrangements of the skeletal structures that support the mouth, throat, and gills, we can now understand the general pathway of water in a breathing shark; this pathway is likely, in general, true for chondrichthyans; however, it has yet to be demonstrated in chimaeroids. The chondrichthyans (as well as other fishes) extract oxygen when they bring water in and pass it over their gills. Water enters the orobranchial chamber through the jaws (visceral arch 1) or the spiracle (bounded posteriorly by visceral arch 2), typically as the floor of the chamber is depressed through ventral movement of the ventral hyoid and branchial arches. This water is pushed or drawn over the gills, and oxygen and carbon dioxide are exchanged across a network of blood vessels found within the soft gill tissues. The water, then oxygen-depleted, passes out of the gill chamber by way of gill slit openings (the spaces between the branchial arches). In the sharks, the gill slits are lateral on the body, whereas in batoids the gill slits are ventral. The gill openings in chimaera are covered by a fleshy operculum with a single posteroventral exit (**see also The Muscles**: Bony Fish Cranial Muscles).

Appendicular Skeleton

The appendicular skeleton includes the cartilages of the paired fins and the limb girdles. In general, skeletal elements are smaller and more flexible the more distal they are in the appendicular skeleton. This is correlated with a tendency for proximal elements to be involved in supporting the more distal elements of the appendicular skeleton, and those distal elements to be more involved in locomotion.

The pectoral (forelimb) and pelvic (hindlimb) girdles are the support structures for the paired fins. The majority of taxa have a U-shaped pectoral girdle, with each arm of the girdle pointing dorsally and comprised of coracoids, scapulae, and suprascapulae. The coracoids and scapulae often fuse into a scapulocoracoid, a term sometimes used in place of pectoral girdle. Suprascapulae are often small and might be absent from some groups. In certain chondrichthyans, the pectoral girdle is tightly associated with the axial skeleton (i.e., the arms of the girdle articulate with the vertebral column). In contrast, the pelvic girdle is composed of a single ischiopubadic bar, is always completely free of the axial skeleton, and is closely associated with the cloaca.

The pectoral and pelvic fins are attached to the ventrolateral edges of their respective girdles. The components of these fins, from proximal to distal, are flat basal pterygial cartilages (two to four in the pectoral fin and two in the pelvic fin), rod-like radial cartilages, and long, parallel fin rays called ceratotrichia. Radial cartilages vary greatly in overall length and number depending on the taxon; for example, they form the majority of the pectoral fins in batoids, which tend to have reduced numbers of ceratotrichia. Fin rays form the jointed and flexible flapping portion of the fin, which are referred to as actinotrichia (a derivation of dermatotrichia) in bony ray-finned fishes. In chondrichthyans, the fin rays are known as ceratotrichia because they are made of elastoidin (not bone), which has properties that are a combination of collagen and elastin. Ceratotrichia are homologous to actinotrichia in bony fishes.

Sharks

The term shark is a common name that refers to a large taxonomic sampling of chondrichthyans (approximately 403 of 970 chondrichthyans, ~41.5%) that are neither batoids nor chimaeroids. In general, sharks have a long body, and the paired fins are relatively short compared with the body (**Figure 1**). However, there is a lot of variation in the shark skeleton. For instance, the goblin shark, *Mitsukurina*, has a skull with an enormous rostrum that protrudes far anteriorly over a highly protrusible mouth while the angel shark, *Squatina*, has a short snout and relatively fixed mouth, but its fins extend anteriorly and resemble wings. In this section, we base our description of a generalized shark skeleton on the common dogfish shark, *Squalus*.

Axial Skeleton

In the ethmoid region of sharks, a short, broad median rostrum is situated anteromedially to the paired nasal capsules, giving many sharks a bullet-shaped body. The nasal capsules are round and situated anteroventrally. Posterior to the nasal capsules are very large orbits, broad cavities in the chondrocranium that house the eyes. The boundaries of the orbit are defined by the antorbital process, supraorbital crest, and postorbital process of the chondrocranium. The orbit is open ventrally. The interorbital space (the space between the eyes on the dorsal surface of the chondrocranium) is slightly narrower than the broad ethmoid region and roughly the same size as the optic region.

Visceral Arches

In most modern sharks, the palatoquadrate articulates with the chondrocranium, but not firmly, a condition called hyostyly. The hyoid cartilages (hyomandibula and ceratohyal) attach to the palatoquadrate and Meckel's cartilage, forming a movable suspensorium. The third hyoid cartilage, a large median basihyal, articulates at its lateral edges with the distal ends of the left and right ceratohyals.

Appendicular Skeleton

The pectoral girdle in sharks includes fused coracoid and scapular cartilages (the scapulocoracoid) and suprascapular cartilages. The ventromedial portion of the scapulocoracoid is the coracoid bar. The scapular process projects posterodorsally from the lateral end of the coracoid bar. The boundary between the coracoid and scapula occurs roughly where the proximal portion of the basal ptergygia of the pectoral fin articulates with the scapulocoracoid. The pectoral fin skeleton is composed of three short basal pterygia: the proptergygium (anteriormost), mesopterygium (medial), and metapterygium (posteriormost). Long radial cartilages extend from the distal ends of all three basal pterygia. Cartilaginous ceratotrichia comprise the distalmost portion of the pectoral fin.

Batoids

Batoids represent over half of the extant species diversity of Neoselachii. Except in a small handful of cases, they are easily distinguished from other chondrichthyans by their flat bodies (**Figure 2**). Compared to the generalized shark body plan, the paired pectoral fins are immense and stretched anteriorly and posteriorly, then effectively joined to the sides of the head; this creates a dorsoventrally flattened body disk anterior to the pelvic girdle. However, within the distinctive depressiform body plan of batoids, there is considerable variation, especially in the shape of the body disk and the stoutness of the tail, which are often representative of swimming mode and ecology. For instance, electric rays are usually nearly circular, a function of the lateral displacement of the pectoral fins by the electric organs. This organization makes their pectoral fins less useful for locomotion; instead they swim by a more shark-like wagging of the tail. Many benthic stingrays also have round body disks, although they lack electric organs; these species locomote along the bottom by undulating the margins of their wings. Some of the largest stingrays, on the other hand, have diamond-shaped bodies with massive, powerful fins for swimming and whip-like, nonpropulsive tails.

Axial Skeleton

Batoids often possess elaborate rostral and/or antorbital cartilages projecting off the anterior ethmoid region of the chondrocranium (**Figure 3**). The rostral and antorbital cartilages are highly variable among batoids and play a large role in determining the overall shape of the body disk. In rajiforms (skates), rhinobatiforms (guitarfishes), and pristioforms (sawfish) there is an anteriorly projecting rostral cartilage that is continuous with the ethmoid region and articulates with one or two rostral appendages distally. In myliobatiforms (stingrays) and torpediniforms (electric rays), the projecting rostral cartilage is absent or miniscule. The antorbital cartilages of torpediniforms, however, are paired and greatly expanded compared to the antorbital cartilages of rajiforms. Antorbital cartilages articulate with the nasal capsule proximally. Nasal capsules are round to oval to kidney-bean shaped and project ventrolaterally. In some batoids, the pectoral fin articulates with the distal margins of the antorbital cartilage. Posterior to the nasal capsule is the orbit. The interorbital space is narrower than the internasal space. The otic capsules are posterior to the orbit and are only slightly wider than the interorbital space.

All batoids share a modified vertebral element known as the synarcual. This is not to be confused with the chimaeroid synarcual (discussed below). The batoid synarcual cartilage is a long tube-like element, hypothesized to be the fusion of the first several vertebrae. Little is known about the synarcual cartilage; however, new research indicates that only neural arches contribute to the tube-like portion in which the spinal cord sits. Anteriorly, the synarcual contacts the chondrocranium. Posteriorly, it is forked and is closely associated with isolated centra made of areolar cartilage. In stingrays, a second, posterior synarcual is present.

Visceral Arches

Batoids share a jaw morphology known as euhyostyly. In this condition, the proximal hyomandibula and distal ceratoyal are still present, as in sharks. However, euhyostyly permits more freedom of movement of the hyomandibula relative to the ceratohyal, and – due to the comparative lack of ligamentous associations – of the jaws relative to the cranium. This type of suspensorium allows a great range of motion in the mouth of rays, with many species able to protrude their jaws up to 50% of their head length and some capable of twice this. The ceratohyal is secondarily free from the suspensorium and contributes to the gill arches. The basihyal, which is large and easily identified in sharks, is fused with the first hypobranchial cartilages in batoids to create a horizontal bar on the floor of the throat, anteromedial to the remaining visceral cartilages. The gill arches are wedged between the pectoral fins and axial skeleton, and are sometimes tightly connected to the synarcual. External gill slits are ventral to the body in batoids.

Appendicular Skeleton

In most batoids, the pectoral girdle and fins form the dominant structures for locomotion; this is in contrast to those species with thick shark-like tails that swim by lateral movements of the tail (e.g., sawfishes, guitarfishes, and electric rays). The different cartilages of the girdle fuse together to create a sturdy U-shaped scapulocoracoid cartilage. Dorsally, the scapulocoracoid articulates with the vertebral column via the suprascapula. This means that the pectoral girdle is the shape of a ring, unlike in other chondrichthyans where the U is not completely closed dorsally. The length of the pectoral fins of *Raja* and other batoids is often half their total body length or more. The cartilages that create the base of the wing-like structure (pro-, meso-, and metapterygia) are expansive, especially the pro- and metapterygia. In some species, the propterygia is so long that it articulates with the antorbital cartilage anteriorly. Pectoral fins of skates and rays consist of a series of parallel radial cartilages that emanate from the basal pterygia of the pectoral girdle. The structural reinforcement of individual radials, as well as the arrangement and bracing of joints between them, is variable among different groups of batoids and is reflective of locomotory life style (e.g., oscillatory vs. undulatory swimming).

Chimaeroids

Chimaeroids have large heads, long snouts, and tube-like bodies that taper to small and sometimes whip-like tails. They are sister group to the elasmobranchs, but externally, they bear little resemblance to their shark and batoid relatives.

Axial Skeleton

If batoid heads are flat (depressiform), those of chimaeroids are narrow (compressiform). Paired lateral rostral rods that lie medial to the nasal capsules extend anteriorly from the ethmoid region. This entire area, anterior to the orbits and surrounding the rostral rods, is packed with soft tissues and as such, the rostrum is soft and flexible. A single median rostral rod is slightly dorsal to the lateral rostral rods, which supports the tip of the nose and is sometimes exceedingly long (e.g., in the Rhinochimaeridae). The nasal capsules are bulbous and project laterally from the anteroventral portion of the ethmoid region. The chimaeroid face is shorter than that of most of the other chondrichthyans: the orbit is posterior to the ethmoid region, anterior to the brain, and dorsal to the paired olfactory tracts. The orbit is bounded ventrally by a suborbital ridge, anteriorly by the antorbital crest, and posteriorly by the postorbital. The left and right orbits are separated by a thin wall of connective tissue, which forms the interorbital septum. Posterior to the orbit in all chimaeroids is the otic region. The semicircular canals of the ear (**see also Hearing and Lateral Line**: The Ear and Hearing in Sharks, Skates, and Rays) bulge on the dorsal surface of the chondrocranium. Posteriorly, the otic region extends to the prominent occipital crest.

Posterior to the chondrocranium is the chimaeroid synarcual. The synarcual is loosely articulated with the occipital region. The synarcual is a cartilaginous plate formed by the fusion of the first 10 vertebral segments. On the dorsal edge of the synarcual is an articulation surface for the basal cartilage of the first dorsal fin and the fin spine. The chimaeroid synarcual is not tightly associated with the suprascapular cartilage and the pectoral girdle, which is in contrast to the condition in batoids.

Visceral Arches

The suspension and morphology of the jaws of chimaeroids is unique among extant Chondrichthyes. Unlike the looser jaw suspensions of the elasmobranch fishes, in chimaeroids the palatoquadrate is fused with the chondrocranium and the hyoid is nonsuspensory (i.e., it does not form a movable suspensorium for the upper and lower jaws). In addition, whereas all other chondrichthyans replace their teeth, the broad, hypermineralized tooth plates of chimaeroids are permanent. The Meckel's cartilage (lower jaw) is fused at the symphysis, forming a single, U-shaped element.

Appendicular Skeleton

The pectoral girdle is positioned just posterior to the neurocranium. The paired halves of the pectoral girdle are fused at the symphysis. The ventralmost portion of the pectoral girdle is the coracoid region. The dorsal portion is the elongate scapular process. This distal portion of the scapular process points anterodorsally to lie lateral to the base of the chimaeroid synarcual. The pectoral fins are dibasal (with two basal cartilages) and articulate with the glenoid fossa on the posterior edge of the coracoid by way of the basal cartilages (propterygium and metapterygium). These pterygia support the radials of the pectoral fin. The pelvic fins lie along the ventral surface of the body. The single basipterygium of the pelvic fin is a flat ovoid cartilage. The anterior margin of the pectoral fin is defined by the basipterygial process, which is formed by the fusion of the proximalmost radials and the basipterygium. Additional radials articulate with the basipterygium and are situated parallel to the basipterygial process.

Glossary

Appositional growth Growth by accretion of tissue at the margins (contrast with interstitial growth).
Areolar calcification/cartilage A weblike form of calcified cartilage found only in the vertebral centra in elasmobranch fishes (cf. tessellated cartilage).
Cap vs. body (prismatic vs. globular calcified cartilage) The two forms of calcified cartilage proposed to comprise tesserae: the prismatic cap is dense and on the perichondral surface, whereas the globular body is found on the underside of tesserae and comprised of coalesced blobs of calcification.
Cellular vs. acellular bone Bone with and without cells, respectively. Acellular bone is much more common in fishes than in mammals.
Chondrocyte Cell type in cartilage that produces extracellular cartilage matrix.
Elastic cartilage Cartilage type found in our epiglottis and ear cartilage that has a high resilience due to its constituent elastin fibers.
Endoskeleton The skeletal system formed by all skeletal elements that are nondermal in developmental origin.
Exoskeleton External support structure of an organism; mineralized exoskeletons were common and extensive in extinct fishes.
Extant A species or clade, etc., that is still in existence.
Extinct A species or clade, etc., that is no longer in existence and typically studied only from fossil forms.
Extracellular matrix (ECM) The polysaccharide- and fiber-rich material that surrounds cells in animal tissues and provides structural support. In hyaline cartilage, the ECM is the glassy, gel-like material that makes up the bulk of the tissue.
Fibrocartilage An intermediate between hyaline cartilage and dense fibrous tissue found in the annulus fibrosus of our intervertebral disks. Fibrocartilage is rich in collagen bundles but has smaller amounts of extracellular matrix.
Hyaline cartilage The most widespread of the three primary cartilage types in mammals, has a comparatively low fibrous- and high matrix-content, and acts most notably as a bearing surface in joints.
Interstitial growth Growth from within a tissue, typically characteristic of nonrigid tissues (contrast with appositional growth).
Intertesseral fibers Collagenous fibers that connect adjacent tesserae.
Lacunae Small space/pit in mineralized/unmineralized matrix in which cartilage/bone cells lie. Lacunae in tesserae are connected by tiny canals called canaliculi.
Neoselachii A clade of cartilaginous fishes that includes extant sharks and batoids, but not chimaeroids.
Perichondral bone A collar of bony tissue that forms in the outer fibrous layer of cartilage (the perichondrium).
Skeletal element An individual portion in a cartilaginous skeleton, analogous to individual bones in the skeleton of a bony vertebrate.
Supernumerary tesseral layers Extra layers of tesserae beneath the subperichondal layer; common in large sharks and species that eat hard prey.
Tessellated cartilage Hyaline-like cartilage tiled (tessellated) on the outside with tesserae; a feature of the Elasmobranchii (cf. areolar cartilage).
Tesserae Mineralized and mostly hexagonal blocks, forming the outer crust of tessellated cartilage.

Introduction

Chondrichthyan fishes – the sharks, rays, and chimaeras – often are described as an evolutionary success story. The group evolved over 400 million years ago and although extant chondrichthyans are not as speciose as bony fishes, they have diverse morphologies and ecologies. The skeletons of chondrichthyans changed tremendously from the earliest-known Paleozoic species to today's extant species. One of the most significant changes is in the material that builds the skeleton: in contrast to extinct forms, all modern chondrichthyan fishes possess endoskeletons fashioned almost entirely of cartilage. This is so characteristic of the group that sharks, rays, and chimaeras are known as the Chondrichthyes or cartilaginous fishes.

Scientists have recognized the gross differences in skeletal material between the Chondrichthyes and other vertebrates for more than two centuries and yet we have made only short in-roads into answering the most basic questions surrounding the evolution and predominance of cartilage in the skeletons of these fishes. How does chondrichthyan cartilage differ from the cartilage of other vertebrates? How many types of cartilage are found in the Chondrichthyes? How do the skeletons of sharks, rays, and chimaeras differ? Are cartilaginous fish skeletons only cartilaginous? By first examining the skeletal materials (this article) and then how these are organized into general body plans (**see also The Skeleton**: Cartilaginous Fish Skeletal Anatomy), we consolidate what is currently known about what it means to have a cartilaginous skeleton and also pinpoint topics demanding further study. This article's focus on cartilage only is a reflection of our scant knowledge of other chondricthyan skeletal tissues; although ligaments and tendons are typically also considered skeletal tissues, little is known of these materials in cartilaginous fishes.

Tissues: *No Bones about It...*

The Chondrichthyes are considered cartilaginous fishes because the long endoskeletal elements called bones in other vertebrates are made of cartilage instead. We are familiar with the distinction between cartilage and bone if we have ever eaten chicken and wrestled with the gristle (cartilage) at the ends of the long bones. The textural difference between these two tissues and the comparatively small amount of cartilage in the adult chicken skeleton is characteristic of nonchondrichthyan vertebrates. Most vertebrates with bony skeletons begin life with uncalcified, comparatively soft cartilaginous skeletons, scaffolds on which their bony version will be patterned. Much of the skeletal cartilage in embryos is systematically invaded by blood vessels, calcified, and then degraded as it is replaced by bone (a process called endochondral ossification). When most vertebrates reach adulthood, endoskeletal uncalcified cartilage typically persists only as articular surfaces in joints and as contour fillers (e.g., in our noses and ears). In this respect, cartilaginous fishes are impressive at the very least for the huge amount of cartilage that persists in the adult skeleton.

A natural question at this point is whether the Chondrichthyes ever possessed bone in their skeletons, and the answer is yes. Early Paleozoic sharks possessed osteonal dentine and acellular bone in association with dorsal spines and other dermal or exoskeletal elements. (The exoskeletal distinction here is important because early chondrichthyans and many other fishes possessed extensive dermal armors that are almost completely absent from the variety of extant groups.) Prismatic cartilage (see below) was preceded by perichondral bone in the endoskeleton, but it appears that by the time the hallmarks of the extant elasmobranch skeleton arose ~400 million years ago, most of the bone in the skeleton was gone. Although many authors debate the presence of bone in the extant chondrichthyan endoskeleton, it is largely accepted that the base of chondrichthyan placoid scales and teeth is comprised of acellular bone. However, no cellular bone has ever been found in any chondrichthyan fish.

Another key distinction between chondrichthyan skeletal cartilage and that of other vertebrates is in the forms that the cartilage takes. Cartilage, in general, is a stiff, gel-like tissue formed by cartilage cells (chondrocytes). The chondrocytes secrete an extracellular matrix rich in proteoglycans (macromolecules with hydrophobic domains that ensure the turgidity of cartilage) and type II collagen, which acts as the tissue's tensile component. Compared with bone, cartilage has a much lower metabolic rate and essentially no blood supply, meaning that cartilage grows slowly and cannot repair itself. In mammals, several primary types of cartilage are recognized, for example, hyaline, elastic, and fibrocartilage. These represent a gradient in the type and proportion of fibrous tissue they contain. Whereas elasmobranch cartilage shares some features with mammalian cartilages, there are several distinct, clade-specific tissue morphologies.

Tessellated Cartilage

In elasmobranch fishes (sharks, rays, and relatives) the majority of skeletal elements are made mostly of an uncalcified, hyaline-like cartilage. The proteoglycan, collagen, and water levels in this cartilage are roughly comparable with mammalian cartilage, although relative proportions of these components vary with species. In all elements except the vertebral centra (**Figure 1** – central schematic), the inner uncalcified tissue is wrapped with an outer layer of mineralization, sandwiched between the uncalcified cartilage core and the fibrous perichondrium that wraps the skeletal elements (**Figures 1**(**a**) and **1**(**b**); although sometimes a layer of uncalcified cartilage is seen intervening between tesserae and perichondrium). Under a microscope (and even sometimes with the naked eye, especially in dried specimens), the mineralized layer looks like the tiled floor of a bathroom: the outer crust of each skeletal element is comprised of thousands of abutting, hexagonal, mineralized blocks called tesserae (**Figure 1**(**a**)). As a result of this distinct outer patterning, this composite of mineralized and unmineralized cartilage

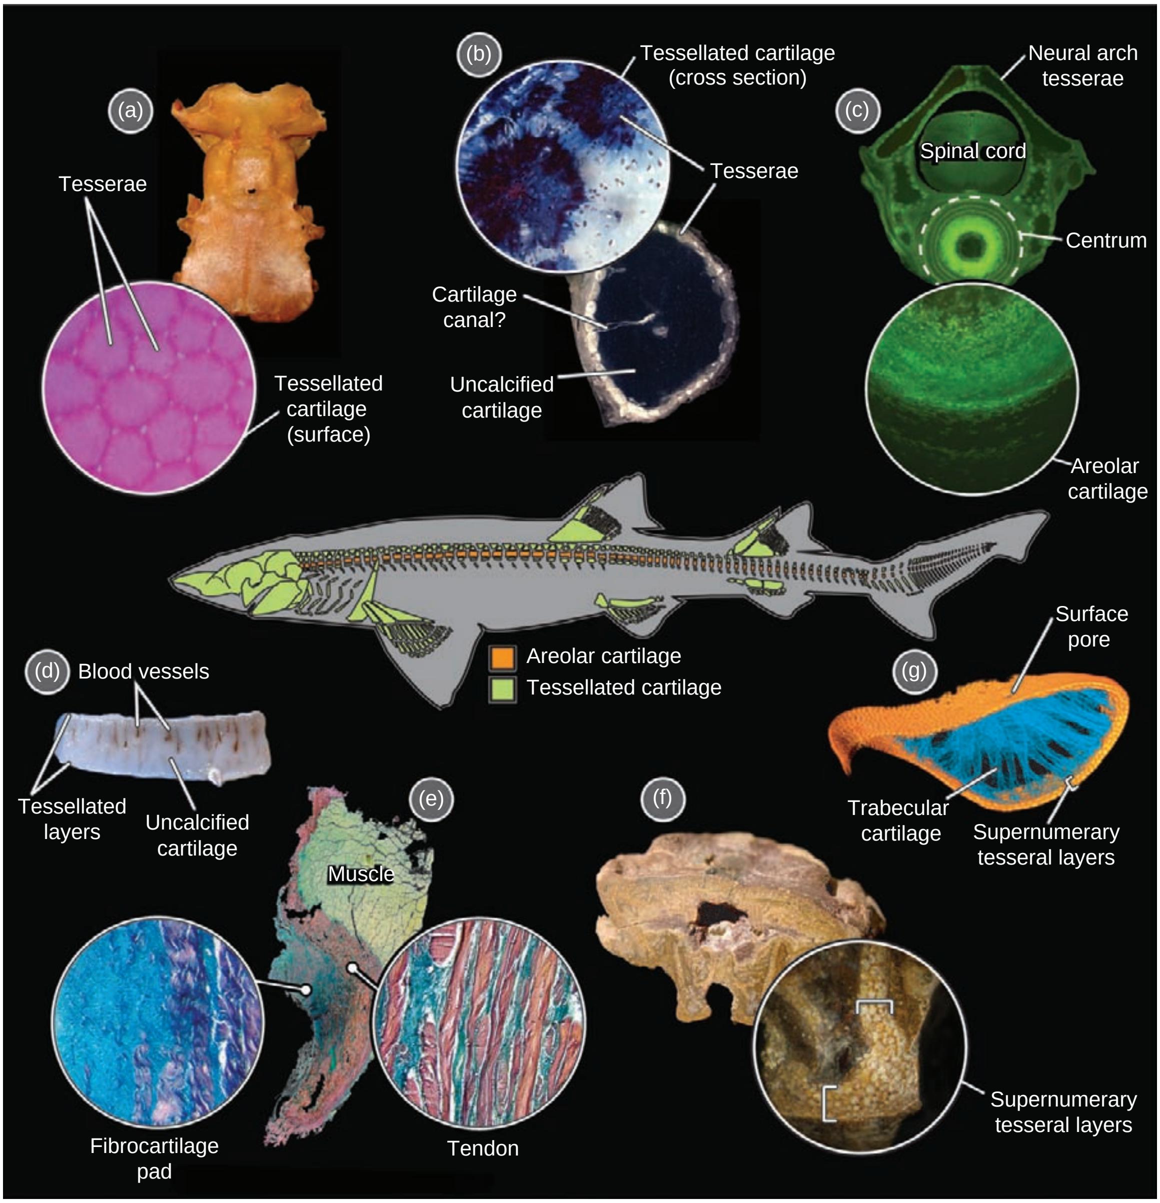

Figure 1 Cartilage types in the skeletons of elasmobranch fishes. The schematic skeleton in the center represents a generalized elasmobranch in lateral view; the images contained in circles are enlargements of the adjacent specimen. The majority of the skeleton is tessellated cartilage ((a) in surface view of a dried angel shark chondrocranium; (b) a cross section of a stingray pelvic girdle), comprised of uncalcified, hyaline-like cartilage tiled by mineralized blocks (tesserae). Areolar cartilage ((c) a cross section of a stingray vertebra, stained with OTC to label active mineral deposition) is found only in the vertebral centra, whereas all the surrounding cartilages are tessellated. Neural arch tesserae may exhibit some features similar to bony tissue. The tissues at the bottom of the figure are modifications of the two primary cartilage types and deserve further study. Although cartilage is considered avascular, some elasmobranch cartilages may exhibit intrinsic vascular tissue ((d) a cross section of a stingray pectoral girdle). Elasmobranch tendons may also be modified in areas of compression to form fibrocartilage ((e) stained stingray adductor muscle and tendon containing fibrocartilage pad). The tessellated layer may be thickened in some areas by supernumerary tesseral layers, especially in the chondrocranium ((f) cross section of a fossilized Paleozoic xenacanthid shark chondrocranium, brackets mark tessellated layers) and the jaws ((g) cross section of a volume-rendered microCT scan of a myliobatid stingray lower jaw). The jaws and other cartilages may also be reinforced by hollow, mineralized struts called trabeculae (g) colored in blue), oriented perpendicular to the tesseral mat. Photo in panel (b): Courtesy of Laura Macesic. All images in panel (e) are from Springer-Verlag; fossil specimen (AMNH7930). Photos in panel (f): Courtesy of the American Museum of Natural History.

is called tessellated (tiled) cartilage. Tessellated cartilage contains a large component of collagenous tissue as well. Each tessera is adjoined to its surrounding tiles by tufts of intertesseral fibers that merge with the overlying perichondrium. As mineralized tissues are typically patterned on fibrous networks, this mesh of collagen probably represents a part of the scaffold on which the whole of the mineralized tissue is organized, but this is yet to be demonstrated.

There are hardly any published data on elasmobranch skeletal material properties, so it is difficult to assess the functional advantages and disadvantages of cartilaginous versus bony skeletons. However, three-dimensional computer models of the jaws of whiteshark *(Carcharodon carcharias)*, modeled in both tessellated cartilage and bone (based on material property data for these tissues), suggest that performance (bite force) is not affected by a change in skeletal tissue. Moreover, although the models show that the cartilaginous jaws would exhibit more strain and deformation than the hypothetical bony ones, the tissue stress levels are considerably lower in tessellated cartilage.

Cells are distributed throughout all phases of the tissue, scattered throughout the unmineralized cartilage, linearly arrayed between the tufts of intertesseral fibers, and housed in mineralized lacunae (lacunar spaces) in the tesserae themselves. Until recently, it was unclear how the intratesseral chondrocytes entombed within tesserae were able to remain alive. High-resolution synchrotron X-ray imaging has revealed a network of tiny canaliculi that likely help distribute nutrients to cells. It is suspected that tesseral cells play a role in mineralization and tesseral growth; materials involved in mineralization may be somehow passed through the canalicular network to tesseral margins, which would explain how tesserae increase in size as animals age. It is important to note that unlike bone, tessellated cartilage cannot repair itself and, unlike mammalian calcified cartilage, elasmobranch calcified cartilage is apparently not ever resorbed. As a result, the mineral that is put into place is there to stay and tesserae can only grow appositionally (i.e., interstitial growth is not possible).

The mechanisms of initiation and regulation of the mineralization process in tessellated cartilage are entirely unknown, although there is evidence that uncalcified matrix proteoglycans are degraded and the enzyme alkaline phosphatase (which also is involved in mammalian cartilage mineralization) is upregulated in areas where tesserae are forming. It was suggested that tesserae are formed in two pieces: an outer cap portion made of very dense prismatic cartilage and an inner body formed by the coalescence of blobs of globular calcified cartilage. Based on these morphological differences and because the cap tends to stain red (like bone) and the body blue (like cartilage) when elasmobranch fishes are cleared and double stained, some authors posit that tesserae are actually blocks of calcified cartilage surmounted by a thin veneer of bone. This concept grew, in part, out of decades of fierce debate over whether elasmobranchs have retained any bone in their endoskeletons.

If this bi-partite tesserae theory is correct, we might expect to see the tiles organized around two different types of collagen, as bone and cartilage are characteristically patterned on type I and type II fibers, respectively. However, the few studies to attempt to type and label elasmobranch collagen have given conflicting results and the answer remains a mystery. These inconsistencies are likely due, in part, to researchers investigating cartilage from different regions of the skeleton; available evidence from numerous techniques suggests that tessellated cartilage in the neural arch of the backbone exhibits distinct structural differences from tessellated tissue elsewhere in the body and may contain a mineralized bone-like (type I-based) tissue (see below).

Immunohistochemical studies localizing and comparing elasmobranch collagens in vertebral and nonvertebral elasmobranch cartilage would be a very useful next step.

Areolar Cartilage

To the best of our knowledge, all calcified endoskeletal elements in elasmobranchs are tessellated with the exception of the centra in the vertebral column, which are comprised of areolar calcified cartilage (**Figure 1**(**c**)). The gross morphology of vertebrae will be considered in more detail in **The Skeleton**: Cartilaginous Fish Skeletal Anatomy – for now, think of the centrum as the central load-bearing part of each vertebra, like a section of the trunk of a tree. As the animal grows, each vertebra's centrum lengthens by adding material appositionally at both (rostral and caudal) ends. This fact has proved extremely convenient for researchers seeking to estimate the ages and growth rates of elasmobranch species: a sagittally sliced centrum reveals the animal's past history, like sedimentary layers in an archaeological dig (rings are visible in the centrum in **Figure 1**(**c**)). Remember that the calcified material in elasmobranch endoskeletons is never resorbed – the number of layers and the distance between them then provide clues to age, growth rate, water temperature, and even surrounding water chemistry.

Areolar cartilage is even less well described than tessellated cartilage. Despite the potential overlap in interests between morphological studies and aging studies (both consider vertebral micro-anatomy), no interdisciplinary study has investigated the ultrastructure of ontogenetic stages in areolar calcified cartilage or the mechanism by which layers are deposited. Morphological work shows areolar calcified cartilage – like the tesserae in tessellated cartilage – to be highly cellular, containing entombed cells in lacunae connected by short canalicular passageways. Cells are arranged concentrically about the centrum's center (where the notochord is found in developing animals; **see also**

The Skeleton: Cartilaginous Fish Skeletal Anatomy) creating laminated cellular rings, with each layer and the cells within layers separated by thin widths of calcified material. The persistent description of areolar cartilage as a web-like calcification likely arose from inorganic sample preparations that destroyed interstitial cells, leaving only this latticework of calcified tissue.

Areolar and tessellated cartilage are the primary cartilages found in the skeleton of elasmobranchs, but anecdotes and results from many studies provide evidence that there may be other types or subtypes. This would hardly be surprising given that vertebrates, and especially fishes, tend to exhibit many intermediate tissues that do not fit easily into the categories of cartilage and bone (see Hall's book for descriptions of the unappreciated variety of vertebrate skeletal tissues). Some options that warrant further organized investigation are as follows:

Neural Arch Cartilage

The cartilage of the neural arch (a skeletal arch on the dorsal side of vertebrae, arching over the spinal cord; **Figure 1**(**c**)) is tessellated, but apparently differs from that in other tessellated cartilage. Neural arch tesserae exhibit more bone-like characters such as tight packing of fibers with strong type I collagen immunoreactivity. Data combined from several sources suggest that neural arch tesserae grow faster than other tesserae; this seems to be the result of disproportionately fast perichondral mineralization in neural arch tesserae, probably related to the mineralization of the stout ligament that lines the spinal cord canal. We suspect that immunohistochemical and ultrastructural comparisons of tesserae from different regions of the body will reveal useful diagnostic differences.

Vascular Cartilage

Cartilage is described as essentially avascular because it contains considerably fewer vessels than bone, and yet cartilage often does contain some blood vessels (**Figure 1**(**d**)). In mammalian cartilage, these are contained in large vascular canals, hundreds of micrometers in diameter, which transport materials between perichondral regions and deep cartilage tissue. Analogous passages have been reported on in elasmobranchs, penetrating the areolar cartilage in vertebral centra and containing a variety of materials (chondrocytes, lymphatic and vascular tissues). Elasmobranch vascular canals are apparently similarly sized to those of mammals (up to 350 μm in diameter) and were found only in those shark species that attain a large maximum size; the small shark and two batoid species examined lacked canals. This phenomenon is likely widespread across cartilage types and species. Vascular canals have been observed in tessellated cartilage, extending beneath the teeth into the uncalcified cartilage of the lower jaw cartilage of blue sharks (*Prionace glauca*) and perforating the pectoral girdles of several batoid species (**Figure 1**(**d**); pers. obs.). Whereas elasmobranch cartilage canals likely play a similar role to those of mammals in nourishing and maintaining cartilage, their association with deep uncalcified cartilage suggests that, unlike mammalian canals, they do not help to mediate mineralization.

Fibrocartilage

The demonstration in cownose rays (*Rhinoptera bonasus*) of a tissue very similar to mammalian fibrocartilage is a further suggestion that elasmobranch skeletal tissue is more varied and plastic than previously believed (**Figure 1**(**e**)). The tissue is found in a tendon that serves to transmit forces between the upper and lower jaw portions of a jaw-closing muscle, which generates the crushing forces needed for eating hard-shelled organisms such as mollusks. Like all tendons, this tissue is loaded in tension, but where it wraps around a calcified process on the lower jaw, it is also subject to compressive forces. In this area, the tendon is modified to contain an uncalcified cartilaginous component that acts to manage the compressive portion of the tendon's load (**Figure 1**(**e**)). These likely represent a common elasmobranch tendon modification in areas of complex loading as cartilaginous plugs have also been observed in the tendons and ligaments connecting the hyomandibula and jaws in batoid species (e.g., those associated with jaw protrusion in the lesser electric ray, *Narcine bancroftii*).

Tessellated Cartilage Reinforcements

Tessellated cartilage can be reinforced in at least two ways: by adding additional layers of tesserae (supernumerary tesseral layers; **Figures 1**(**f**) and **1**(**g**)) or by adding struts (trabeculae; **Figure 1**(**g**)). Unlike maximum tesseral size, which is not associated with animal size – an adult sevengill shark *Notorhynchus* may weigh 100 times more than an adult round stingray *Urobatis*, but both exhibit tesserae up to half a millimeter in width, larger than those of an adult great white shark *Carcharodon* – additional tesseral layers in flat regions of the skeleton are more common in larger species, with some of the biggest sharks exhibiting up to four layers of tesserae. This has also been observed in the cranial structures of extinct sharks and rays. However, we should note that some large coldwater sharks (e.g., sleeper sharks *Somniosus*, sixgill sharks *Hexanchus*; pers. obs.; J. Maisey, personal communication) seem to exhibit the opposite condition; in these species the jaws and crania appear almost entirely unmineralized with only patches of tessellation (e.g., at the basal plate of the chondrocranium in *Hexanchus*). Supernumerary tesseral layers are also found in the jaws of hard prey specialists, such as myliobatid stingrays, supporting the notion that these layers provide mechanical support. In addition to these reinforcements in broad flat areas of the skeleton, the tesseral layer can also exhibit more localized thickening in curved regions, especially those with small radii of curvature (e.g., at the caudal and ventral edges of the jaws). This has been observed in species of all sizes and may represent a general structural constraint of tiling a curved surface.

The second type of tessellated cartilage reinforcement, trabecular cartilage, was first observed in the jaws of myliobatid stingrays, supporting the tissue directly beneath the flat tooth plates that are used to crush mollusks (**Figure 1**(**g**)). Trabecular cartilage is characterized by hollow, apparently tessellated struts (trabeculae) that extend from one tesseral surface through the uncalcified cartilage lumen of the jaws to the opposite tesseral surface. Trabeculae are open at their ends, creating obvious pores in the tesseral mat (**Figure 1**(**g**)); whether these were derived from cartilage canals (see above) or perhaps the intertesseral pores that have been observed in nonmyliobatid stingrays remains to be determined. Trabeculae have also been observed in the visceral arches of *N. bancroftii* – a species of electric ray that excavates buried prey with its jaws – and of some sharks (J. Ramsay, personal communication). The prevalence of trabecular cartilages suggests this type of reinforcement either evolved multiple times or is a plastic response to functional demands on the skeleton, although the latter was shown not to be the case for cownose rays.

It should be reiterated that the types of calcification mentioned above have been described or noted only in elasmobranchs. By comparison, almost nothing is known of the morphology or formation of calcified endoskeletal material in chimaeroids, sister group to the sharks and rays. As far as has been reported, holocephalans (chimaeroids) are the only nontessellated group among the extant Chondrichthyes. One study describes chimaeroid tissue mineralization as 'continuous cartilage calcification' comprised of smooth surface sheets of mineral, but this has, to the best of our knowledge, never been figured in a published article. It is reasonable, however, to assume that the endoskeletons of chimaeroids are much less mineralized than those of elasmobranchs: in CT scans of several species, the only cartilages that appear reinforced are those associated with the jaw joint, the tooth plates, and the occipital joint. Examinations of chimaeroid mineralization and skeletal reinforcement would provide integral knowledge to understand the evolution of chondrichthyan skeletons.

Glossary

Chondral bone Bone that ossifies in association with a cartilage, through either ossification on the surface of a cartilaginous precursor (perichondral bone), as an ossification of the cartilaginous precursor (endochondral bone), or a combination of the two.

Compound bone A bone that is formed by two or more histologically distinct tissues, often the result of fusion during ontogeny.

Dermal bone Bone that ossifies in contact with the dermis.

Durophagy Eating hard-shelled organisms such as coral or mollusks.

Endoskeleton The skeletal system formed by all skeletal elements that are nondermal in developmental origin.

Exoskeleton External support structure of an organism formed by all skeletal elements developed from connection to the dermis, including all dermal bones, teeth, scales, and fin rays; mineralized exoskeletons were common and extensive in extinct fishes.

Membrane bone Bone that ossifies directly within ligaments or other tissue not in contact with the dermis and separate from cartilage.

The skeleton of bony fishes presents a seemingly endless diversity of forms that reflect the varied life history strategies of these organisms. The skeleton provides the architectural support for musculature, while at the same time providing protection for internal organs and sensory systems. The skeleton of bony fishes is composed of hundreds of individual bony and cartilaginous elements that can vary in form, reflective of the function of each element in an organism. A solid understanding of the skeleton and its diversity, therefore, is critical for studies of functional morphology and ecomorphology. In addition, because of the complex nature of the skeleton of bony fishes, it is rich in phylogenetic data and has been fundamental in the formulation of many compelling hypotheses regarding the evolutionary biology of fishes.

This article provides a brief overview of the skeletal structure of actinopterygians and fish-like sarcopterygians. By working from illustrations of three taxa (bowfin, *Amia calva*; goldeye, *Hiodon alosoides*; and Japanese jack mackerel, *Trachurus japonicus*), some of the osteological diversity of bony fishes generally is highlighted. These three taxa represent three phylogenetic levels (i.e., *Amia* is a nonteleostean actinopterygian, *Hiodon* is a basal teleost, and *Trachurus*, an acanthopterygian, is a derived teleost). Although these three taxa serve as exemplars for various phylogenetic levels, as well as different ecological guilds (*Amia* and *Hiodon* as temperate freshwater fishes and *Trachurus* as a temperate/tropical marine form), it must be kept in mind that these are only three out of more than 30 000 species and do not capture the range of variation found in the diversity of bony fishes.

A Hierarchical Approach to the Study of the Skeleton

Because of the complex nature of the skeleton of bony fishes, there are many ways in which one can approach the study of the skeleton. For instance, one can study the exoskeleton as distinct from the endoskeleton. Both the endoskeleton and exoskeleton can be further broken down into various parts, based on variation in the details of their development, for example. The approach adopted here is hierarchical and combines dividing the skeleton into topographic regions and functional units. The primary division of the skeleton is the axial and appendicular regions. Both of these are further divided into regional units (e.g., cranial vs. postcranial portions of the axial skeleton), which themselves are divided into more refined functional units. Other terminology exists for portions of the skull, including the chondrocranium or neurocranium (roughly equivalent to braincase as used here) and the dermatocranium (all dermal bones of the skull, including the skull roof, infraorbital bones, jaws, and the opercular series). However, the dermatocranium comprises elements from many different regions of the skull and is therefore somewhat unwieldy to discuss in the context of functional units. Another complicating factor is that the terminology for individual skeletal elements has changed dramatically over time and there are many synonyms for several elements that are in current use.

Cranial Axial Skeleton

Four major functional units form the skull of bony fishes (**Figure 1**): the braincase, skull roof and infraorbital series, opercular series, and splanchnocranium. Although these are recognizable as discrete units of the skull, the distinction between some of them may be obscured, particularly in derived representatives (e.g., the bones of the braincase and skull roof in teleostean fishes).

As the name suggests, the braincase of bony fishes (**Figure 2**) is the box surrounding the brain and sense organs of the head. The braincase may be divided into four regions (anterior to posterior): the ethmoid, orbital, otic and occipital regions. Early in ontogeny the braincase is entirely cartilaginous, but in most bony fishes the braincase becomes well ossified in the adult (exceptions may include some deep-sea fishes, in which the bony skeleton is reduced generally, and highly pedomorphic taxa, such as the gobioid *Schindleria*). In basal sarcopterygians (e.g., coelacanths), there is an intracranial joint between the ethmosphenoid and the otico-occipital units. Virtually, all of the bones of the braincase are chondral, with the exception of the parasphenoid and vomer, two dermal bones that are tightly associated with the ventral surface of the braincase, and the intercalar, which is a membrane bone in extant taxa. Both the vomer and parasphenoid are primitively toothed bones, although only nonteleostean actinopterygians, osteoglossomorph and elopomorph teleosts, and a few other more derived teleosts have parasphenoid dentition (i.e., in most actinopterygians the parasphenoid is edentulous). In most basal actinopterygians and some basal teleosts, the vomer is a paired element (e.g., in *Hiodon*, during early ontogeny the vomer is paired but is fused to form a median element in the adult, **Figure 2(d)**). The parasphenoid is often the largest bone of the braincase, covering much of its ventral surface. The parasphenoid bears lateral projections (the so-called ascending rami) that often tightly embrace the braincase posterior to the orbit.

The ethmoid region forms the bones and cartilages that surround the nasal capsules. The ethmoid region also forms the articulation point for the anterior portions of the splanchnocranium (in particular the upper jaws and the anterior portions of the palatoquadrate). In lungfishes, the palatoquadrate (forming the upper jaw) is fused to the ethmoid region, forming the so-called autostylic condition of jaw suspension that is reflective of durophagy (other taxa, including holocephalans and tetrapods independently evolved autostyly). The nasal capsule is typically a large concavity in the lateral surface of the ethmoid region that supports the nasal lamellae. The largest bone of the ethmoid region is typically the mesethmoid, which forms in the cartilage separating the left and right nasal capsules. In basal actinopterygians and sarcopterygians, there are sometimes dermal bones that lie anterior or dorsal to the mesethmoid. For instance, the rostral bone forms in the anterior midline of the snout in taxa such as *Polypterus* (bichirs), *Amia*, and the basal teleost genus *Elops* (ladyfishes), and this bone supports the anteriormost portion of the cephalic sensory canal system. In other basal teleosts, there is another dermal bone, the supraethmoid, which develops dorsal to the mesethmoid and does not contain any part of the sensory canal; these bones may fuse to form a compound element (e.g., *Hiodon*). Ventral to, and often tightly sutured to, the mesethmoid is the vomer. Anteriorly, the mesethmoid and (sometimes) the vomer form the articulation surface for the upper jaws. Forming the posterior wall of the nasal capsule and the articulation surface for the palatoquadrate is the lateral ethmoid bone. In nonteleostean actinopterygians, there is a second more anterior pair of ethmoid bones, the preethmoids (e.g., in *Amia*).

The orbital region (which is associated with the eye) is sometimes also called the sphenoid region, in reference to the sphenoid bone of humans, which lies posterior to the ethmoid region and is associated with the orbit. The dominant bone of this region in relatively basal taxa is the orbitosphenoid, which ossifies in the cartilage that forms the septum between the eyes. This bone is paired in basal actinopterygians (e.g., sturgeons, *Amia*), but may be median in the adult (e.g., basal teleosts) or absent (most acanthopterygians, which lack a bony or cartilaginous septum). The other elements that may be considered part of the orbital region include the pterosphenoid, sphenotic, and basisphenoid, all of which are positioned between the orbitosphenoid (if present) and the more posterior otic region. As is the case with the orbitosphenoid, these bones may be lost as independent elements or altogether, particularly in more derived groups of bony fishes.

The otic region is formed by the bones that are in contact with the semicircular canals and ampullae of the inner ear. This region also forms much of the lateral wall of the braincase posterior to the orbit. The largest bone of the otic region typically is the prootic, which forms in association with the foramen or foramina for portions of the trigeminal and facial cranial nerves, in some taxa forming the so-called trigeminofascialis chamber. The pterotic lies dorsal to the prootic, and in most teleosts is

incorporated into the surface of the skull roof. In basal actinopterygians there is an autogenous dermopterotic that is a true dermal skull roofing bone that carries a sensory canal, and is separate from the chondral autopterotic. In teleosts, the autopterotic and dermopterotic are fused to form a compound bone, which is often called the pterotic. In at least some taxa, these two bones are never seen as separate elements during ontogeny, and it is often held as an example of so-called phylogenetic fusion, in which plesiomorphically separate elements form a single

element in derived taxa (this hypothesis however can rarely, if ever, be distinguished from phylogenetic loss).

The bones that interface with the postcranial axial skeleton and its associated musculature comprise the occipital region of the braincase. The median basioccipital lies in the ventral midline of the occipital region. In basal forms, the basioccipital is posteriorly concave, and often resembles a vertebral centrum. This overall similarity in form led to the idea that the occipital region of actinopterygians incorporated the first vertebral centrum into its structure. However, there is little structural or ontogenetic evidence that a centrum is incorporated into the skull in most actinopterygians. A notable exception is in adult *Amia*, in which two centra are fused to the basioccipital during ontogeny. In some teleosts (e.g., *Hiodon*), in particular the acanthomorphs, the articulation between the skull and vertebral column is formed by the basioccipital and the exoccipitals, a pair of bones that form on either side of the foramen magnum. In lungfishes, the exoccipital is the only chondral bone of the braincase. The exoccipital can be readily identified across taxa because it typically contains or defines the foramen for the vagal nerve. Dorsolateral to the exoccipital are two paired bones, the epioccipital and the intercalar. The epioccipital is often called the epiotic because it houses the posterior semicircular canal of the inner ear. However, it has been shown that at least in extant teleosts, this bone forms in association with cartilage derived from the occipital arch of early developmental stages. Nonteleostean actinopterygians (e.g., sturgeon, gars, and *Amia*) do, however, have an epiotic bone. The intercalar is found ventral to the epioccipital (in teleosts) or epiotic (in *Amia*) and in older literature this bone is termed the opisthotic. In *Amia* and extant teleosts, the intercalar is composed only of membrane bone. The remaining bone of the occipital region in teleostean fishes is the supraoccipital (not present in nonteleostean actinopterygians or sarcopterygians). This chondral bone forms in the posterior midline on the dorsal surface of the braincase and may form part of the skull roof. The supraoccipital often bears a median crest that extends posteriorly.

The skull roof of bony fishes is formed by those bones visible in dorsal view of the skull. By this definition bones such as the supraoccipital and the mesethmoid would be considered as part of the skull roof. Plesiomorphically, the skull roof comprises only those dermal bones that form the dorsal surface of the skull, and that cover the cartilage and chondral bones of the braincase. There is a trend across the evolution of fishes toward the sinking of the skull roofing bones (i.e., in most basal taxa the bones of the skull roof are at the surface and are covered by only a thin layer of skin, whereas the bones are deeper and covered by muscle and skin in more derived fishes). In virtually all actinopterygian fishes, these dermal bones include (anterior to posterior) the nasals (which may be reduced to mere tubes surrounding the sensory canal), the frontals, the parietals, and the extrascapulars (as with the nasals, these may be little more than tubular bones). The frontal typically is the largest of the skull roofing bones, followed by the parietal. In fish-like sarcopterygian fishes, there is an additional pair of bones, which has, in part, led to controversy regarding the identity of the skull roofing bones between actinopterygians and sarcopterygians. In sarcopterygians, there are paired frontals, parietals, and postparietals. Based on the pattern and association of the bones to the sensory canals and their topographic position (relative to the pineal organ), it has been proposed that the bones commonly termed (and which is followed here) the frontals and parietals in actinopterygians are homologous to the parietals and postparietals, respectively, of sarcopterygians. A change of terminology for actinopterygians has been suggested but has not yet been widely adopted.

The infraorbital series of bones (=circumorbital bones) is associated with the skull roof by housing the infraorbital sensory canal, a ventral branch from the supratemporal sensory canal (contained in the pterotic). The infraorbital bones define the orbit and are numbered sequentially (anterior to posterior), although certain elements of the series are given particular names (e.g., infraorbital 1, which is often enlarged, is called the lachrymal, and the posteriormost infraorbital, which contains the branching between the infraorbital canal and the dorsal supraorbital canal, is called the dermosphenotic). In addition, the elements that are positioned under the eye are sometimes termed the suborbitals and those posterior to the eye are the postorbitals. Basal actinopterygians also have an antorbital bone, which lies anterior to the orbit. There is variably a supraorbital bone, which lies dorsal to the orbit, although this bone does not generally have a connection to the sensory canal system.

The opercular series forms the bones of the gill-cover and functions in both feeding and respiration. In virtually all bony fishes, the largest bone of the opercular series is the opercle, which is typically also the dorsal-most of the series. The only exception is in extant sturgeons and paddlefishes in which the opercle is lost and the large bone forming the support for the gill cover is the subopercle (the opercle is present in close fossil relatives, but is greatly reduced in size compared to the subopercle). Typically, the subopercle is smaller and positioned ventral to the opercle, and bridges the gap between the opercle and the branchiostegals, which form the supports for the ventral portion of the opercular flap. In basal actinopterygians, including the basal teleosts of the family Elopidae (ladyfishes and tarpons), there is a gular plate, which forms between the left and right lower jaws. This gular is medial in most actinopterygians in which it is present, but is paired in *Polypterus* and coelacanths. The interopercle develops in the interoperculomandibular ligament and is found only in *Amia* and teleosts among extant fishes. This bone, which forms a linkage between the opercular series and the lower jaw, is important for transmission of force during jaw opening. The preopercle carries the dorsal cephalic sensory canal to the lower jaw. In sarcopterygians (e.g., coelacanths), there are also other bones of the cheek that carry sensory canals (e.g., the squamosal).

The splanchnocranium includes all the bones and cartilages of the visceral arches, which include the mandibular, hyoid, and branchial arches (oral jaws, hyoid, and gill arches, respectively) as well as the palatoquadrate (the roof of the mouth). Therefore, although they are all part of an integrated unit, they are all treated as distinct portions of this region of the skull. The oral jaws (upper and lower) most frequently bear teeth, although entire orders of fishes (e.g., Cypriniformes) may be edentulous. The form of the teeth, as that of the bones of the jaws themselves, reflects the ecology and diet of fishes (e.g., piscivorous fishes often have sharply pointed teeth set in relatively narrow jaws, whereas durophagous fishes have more robust jaws and often have molariform teeth). The upper jaw (**Figures 1** and **3**) is

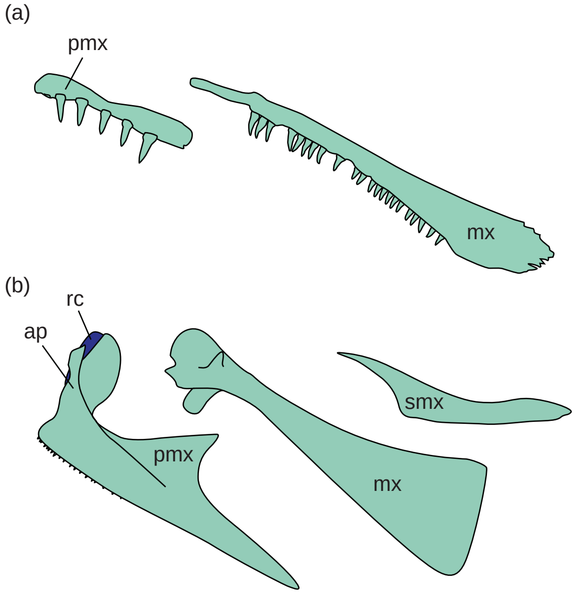

Figure 3 Bones of the upper jaw of *Hiodon* (a) and *Trachurus* (b) in lateral view. Cartilage is shown in dark blue and dermal bone in light green. Abbreviations: ap, ascending process; mx, maxilla; pmx, premaxilla; rc, rostral cartilage; smx, supramaxilla. Modified from Hilton EJ (2002) Osteology of the extant North American fishes of the genus *Hiodon* Lesueur, 1818 (Teleostei: Osteoglossomorpha: Hiodontiformes). *Fieldiana (Zoology) new series* 100: 1–142 and Suda Y (1996) Osteology and muscular attachments of the Japanese jack mackerel, *Trachurus japonicus*. *Bulletin of Marine Science* 58: 438–493.

formed by a series of bones: the premaxilla, maxilla, and supramaxilla (there are sometimes more than one supramaxillae positioned along the posterodorsal margin of the maxilla). The premaxilla is the anteriormost of the series and articulates with the ethmoid region of the braincase. In basal forms (e.g., nonteleostean actinopterygians and basal teleosts), the premaxilla is rigidly articulated with the braincase and is relatively small in comparison to the maxilla. In these basal forms, the maxilla is the main tooth-bearing bone of the upper jaw, while the premaxilla is restricted to the anterior margin of the jaw. Also in many early actinopterygians (e.g., *Polypterus*, palaeoniscoids) and sarcopterygians, the maxilla is firmly attached to the other bones of the cheek. In other nonteleostean actinopterygians and basal teleosts, the maxilla is freed from the cheek and rotates forward during feeding, forming a mouth that is more round in cross section. Across the evolution of the teleosts, the premaxilla becomes the dominant bone of the upper jaw, and the maxilla becomes an edentulous bone that is excluded from the margin of the jaw. With the premaxilla becoming as the primary bone of the upper jaw, exemplified by Acanthomorpha, also comes the development of a large ascending process of the premaxilla. The left and right premaxillae meet in the midline of the jaw, and the ascending processes surround the rostral cartilage, a median cartilage that articulates with the ethmoid region of the braincase and serves to support the upper jaw during jaw protrusion. In fact, all of the modifications of the upper jaw seen across the evolution of teleosts can be correlated to the development of jaw protrusion, which is extremely well developed in acanthomorph teleosts.

The lower jaw of bony fishes is a complex of dermal, chondral, compound and membrane-bone elements (**Figures 1** and **4**). The chondral bones include ossifications of Meckel's cartilage, which runs along much of the length of the jaw; in some taxa, it is regressed in adults. These chondral bones include the mentomeckelian, near the anterior tip of the jaw, and the articular and retroarticular bones at the posterior end of the jaw (there is typically a single articular; *Amia* is unique in having two articular bones). The articular forms the articulation surface for the lower jaw with the quadrate, and the retroarticular serves as the attachment site for the interoperculomandibular ligament, which contributes to the jaw opening mechanism. On the dorsal surface of Meckel's cartilage is the coronomeckelian, which is a membrane bone that forms in the tendon of the adductor mandibulae muscle where it attaches to the lower jaw. Surrounding the chondral portions of the lower jaw is a series of dermal elements. Two of these, the angular (posterior) and the dentary (anterior), are sensory canal-bearing bones. In most extant teleosts, the angular is fused to either the articular or the retroarticular bone. In most extant fishes, the dentary is the only tooth-bearing bone and is typically the largest bone of the lower jaw. In nonteleostean fishes, there are additional dermal bones, which include the surangular on the external surface, the prearticular on the internal surface (covering much of the posterior region of Meckel's cartilage), and a series of coronoid bones, which are small tooth-bearing elements. Therefore, there is a general trend toward loss of bones in the lower jaw across actinopterygian fishes.

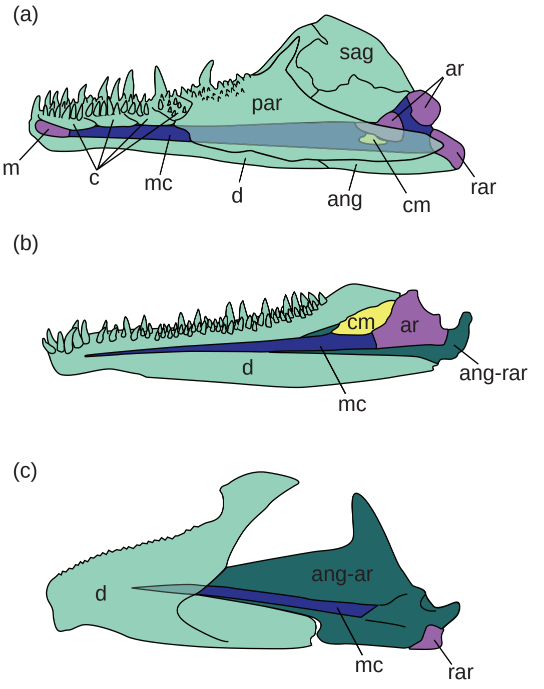

Figure 4 Lower jaw of *Amia* (a), *Hiodon* (b), and *Trachurus* (c) in medial view. Cartilage is shown in dark blue, chondral bone in purple, dermal bone in light green, compound bone in dark green, and membrane bone in yellow. Abbreviations: ang, angular; ang-ar, anguloarticular; ang-rar, anguloretroarticular; ar, articular; c, coronoid; cm, coronomeckelian; d, dentary; m, mentomeckelian; mc, Meckel's cartilage; par, prearticular; rar, retroarticular; sag, surangular. Modified from Grande L and Bemis WE (1998) A comprehensive phylogenetic study of amiid fishes (Amiidae) based on comparative skeletal anatomy. An empirical search for interconnected patterns of natural history. *Society of Vertebrate Paleontology, Memoir* 4: 1–690; Hilton EJ (2002) Osteology of the extant North American fishes of the genus *Hiodon* Lesueur, 1818 (Teleostei: Osteoglossomorpha: Hiodontiformes). *Fieldiana (Zoology) new series* 100: 1–142; and Suda Y (1996) Osteology and muscular attachments of the Japanese jack mackerel, *Trachurus japonicus*. *Bulletin of Marine Science* 58: 438–493.

The dorsal portions of the hyoid arch (i.e., the hyosymplectic cartilage and its ossifications, the hyomandibila and the symplectic), together with the palatoquadrate and its ossifications (palatine, ectopterygoid, endopterygoid, metapterygoid, and quadrate), form the suspensorium or the roof of the mouth (**Figure 5**). The palatine, ectopterygoid, and endopterygoid may bear teeth, particularly in relatively basal forms. In nonteleostean and basal teleostean actinopterygians, there are

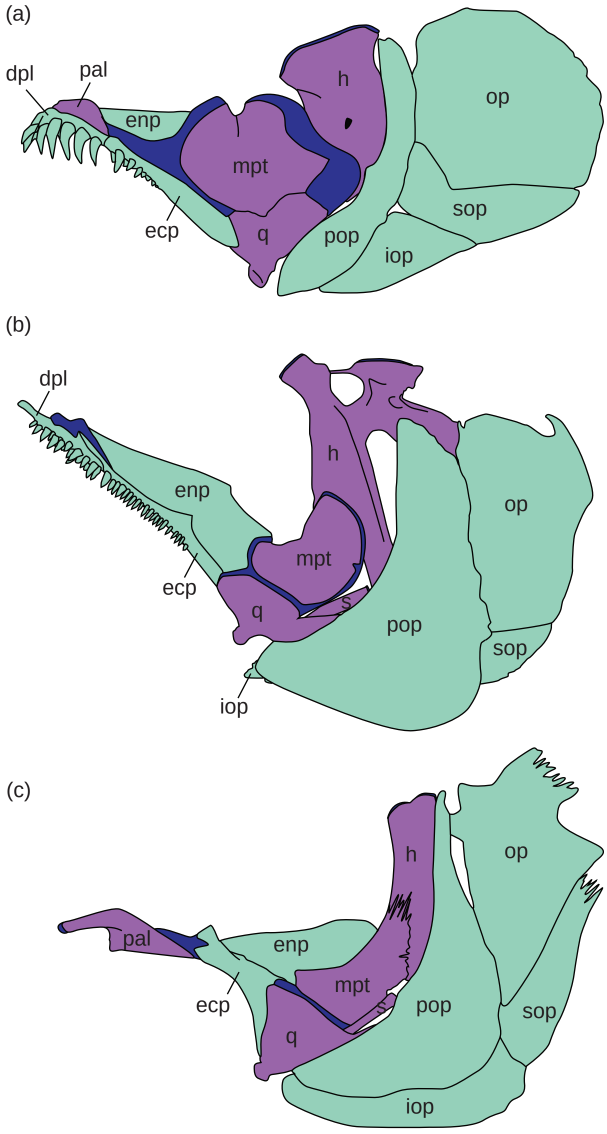

Figure 5 Suspensorium and opercular bones of *Amia* (a), *Hiodon* (b) and *Trachurus* (c) in lateral view. Cartilage in dark blue, chondral bone in purple, and dermal bone in light green. Abbreviations: dpl, dermopalatine; ecp, ectopterygoid; enp, endopterygoid; h, hyomandibula; iop, interopercle; mpt, metapterygoid; op, opercle; pal, palatine; pop, preopercle; q, quadrate; s, symplectic; sop, subopercle. Modified from Grande L and Bemis WE (1998) A comprehensive phylogenetic study of amiid fishes (Amiidae) based on comparative skeletal anatomy. An empirical search for interconnected patterns of natural history. *Society of Vertebrate Paleontology, Memoir* 4: 1–690; Hilton EJ (2002) Osteology of the extant North American fishes of the genus *Hiodon* Lesueur, 1818 (Teleostei: Osteoglossomorpha: Hiodontiformes). *Fieldiana (Zoology) new series* 100: 1–142; and and Suda Y (1996) Osteology and muscular attachments of the Japanese jack mackerel, *Trachurus japonicus*. *Bulletin of Marine Science* 58: 438–493.

toothed dermopalatines of varying number. These are distinct from the palatine (also called the autopalatine), which is a chondral bone at the anteriormost extent of the palatoquadrate cartilage that forms the anterior articulation of the suspensorium with the ethmoid region of the braincase. The ectopterygoid and endopterygoid are dermal bones that form in association with the palatoquadrate, and form the major bones of the roof of the mouth. The metapterygoid and quadrate are posterior ossifications of the palatoquadrate cartilage. The quadrate bears a distinct head for the articulation with the lower jaw. In teleosts, it also bears a distinct posteroventral process that is often tightly associated with the symplectic, which is often a stick-like or wedge-like bone that forms in the ventralmost part of the hyosymplectic cartilage. The hyomandibula is the dorsal ossification of the hyosymplectic cartilage and is typically the largest bone of the hyoid arch. This bone forms the posterior articulation of the suspensorium with the neurocranium as well as the articulation point for the opercle.

The ventral portions of the hyoid arch bridge the elements of the suspensorium with the branchial arches (**Figure 6**). Articulating directly with the suspensorium (typically near the symplectic) is the interhyal, which also articulates with the posterior certatohyal. The anterior and posterior ceratohyal ossify in a single cartilage, and serve to support the branchiostegals. One (basal taxa) or two (most teleosts) hypohyal bones lie anteriorly, and these articulate with the bones and cartilages of the branchial arches. In *Polypterus* and teleosts (convergence), there is an urohyal bone, which is a membrane bone that forms in the tendon of the sternohyoideus muscle. The urohyal serves to strengthen the attachment of this muscle to the branchial arches, which contributes to the rapid jaw opening that is necessary for suction feeding.

In the midline of the mouth is a series of median elements: the basihyal, which is in series with the hyoid arch, and the basibranchials, which are in series with the branchial arches. The basibranchials ossify in an anterior basibranchial cartilage (copula) and are numbered anterior to posterior based on their associated branchial arch; a separate posterior cartilage found in most actinopterygians represents the fourth basibranchial. All of these elements may bear toothplates. The ventral portions of the branchial arches follow the same pattern as the hyoid arch. There is a series of hypobranchial elements that articulate directly with the basibranchials, and a more distal series of five certaobranchials. There are five ceratobranchials. The fifth ceratobranchial often does not have a dorsal counterpart (i.e., in most fishes there are only four epibranchials) and often exhibits extreme modifications in association with the development of the so-called pharyngeal jaws, including hypertrophy and robust molariform dentition in durophagous fishes (e.g., some members of the family Sciaenidae). In many fishes, these modifications of the fifth ceratobranchial are matched by similar modifications of the dorsal branchial elements as well.

In some nonteleostean (e.g., sturgeons) and some basal teleostean fishes (e.g., *Elops*), there are three series of

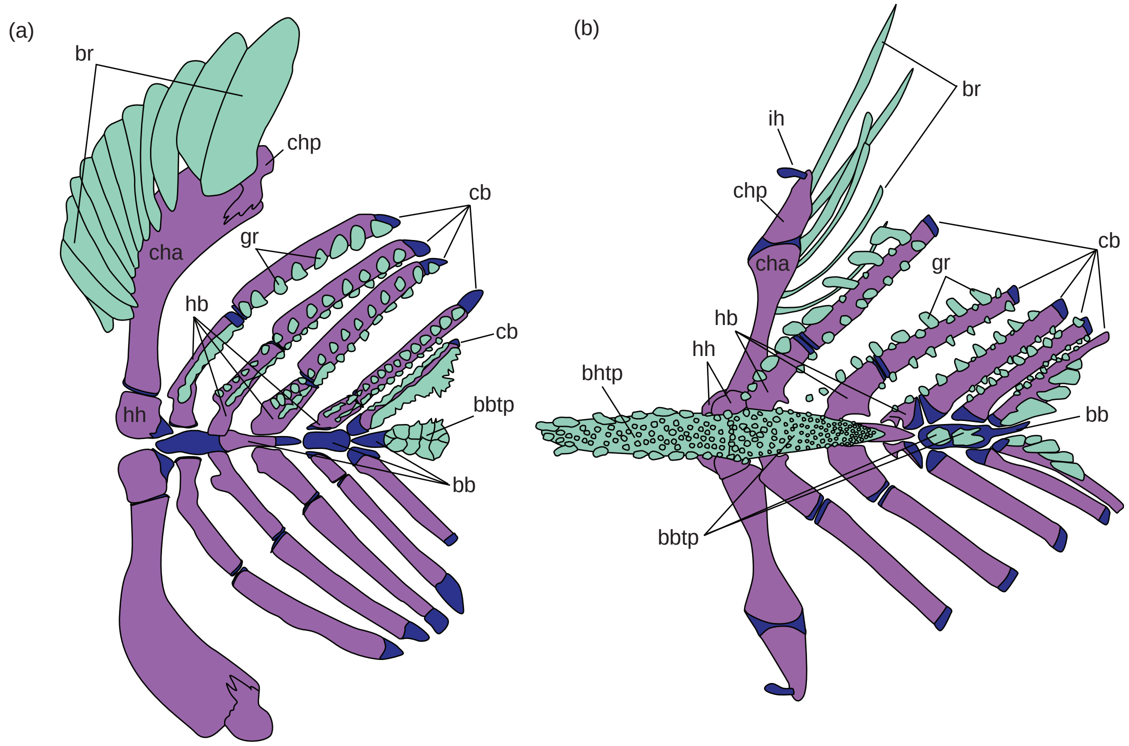

Figure 6 Ventral portion of the hyoid and branchial arches of *Amia* (a) and *Hiodon* (b) in dorsal (oral) view. Cartilage is shown in dark blue, chondral bone in purple, and dermal bone in light green. Modified from Grande L and Bemis WE (1998) A comprehensive phylogenetic study of amiid fishes (Amiidae) based on comparative skeletal anatomy. An empirical search for interconnected patterns of natural history. *Society of Vertebrate Paleontology, Memoir* 4: 1–690 and Hilton EJ (2002) Osteology of the extant North American fishes of the genus *Hiodon* Lesueur, 1818 (Teleostei: Osteoglossomorpha: Hiodontiformes). *Fieldiana (Zoology) new series* 100: 1–142.

elements in the dorsal portions of the branchial arches: the suprapharyngobranchials, infrapharyngobranchials, and the epibranchials, which articulate distally with the ceratobranchials. In these taxa, the supra- and/or infrapharyngobranchials articulate with the neurocranium. In most extant teleosts (**Figure** 7), the suprapharyngobranchial

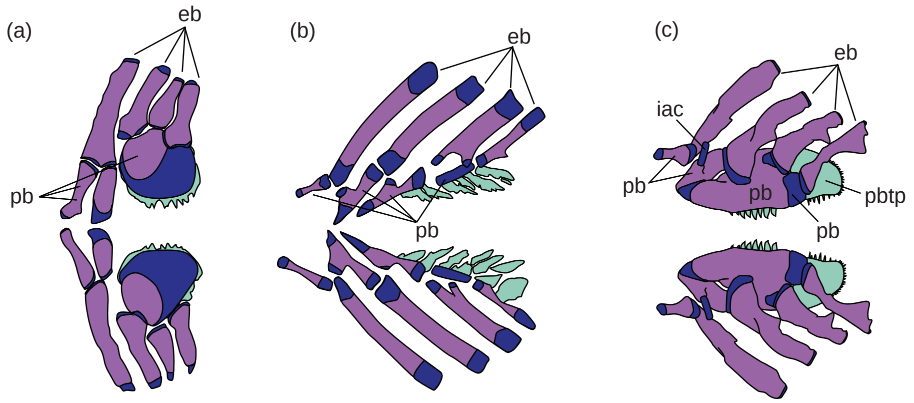

Figure 7 Dorsal portion of the branchial arches of *Amia* (a), *Hiodon* (b), and *Trachurus* (c) in dorsal view. Cartilage is shown in dark blue, chondral bone in purple, and dermal bone in light green. Abbreviations: eb, epibranchial; iac, interarcual cartilage; pb, pharyngobranchial; pbtp, pharyngobranchial toothplate. Modified from Grande L and Bemis WE (1998) A comprehensive phylogenetic study of amiid fishes (Amiidae) based on comparative skeletal anatomy. An empirical search for interconnected patterns of natural history. *Society of Vertebrate Paleontology, Memoir* 4: 1–690; Hilton EJ (2002) Osteology of the extant North American fishes of the genus *Hiodon* Lesueur, 1818 (Teleostei: Osteoglossomorpha: Hiodontiformes). *Fieldiana (Zoology) new series* 100: 1–142; and and Suda Y (1996) Osteology and muscular attachments of the Japanese jack mackerel, *Trachurus japonicus*. *Bulletin of Marine Science* 58: 438–493.

series is absent, and the infrapharyngobranchials (often termed simply 'pharyngobranchials') suspend the branchial basket from the neurocranium.

All elements of the branchial arches may support toothplates and gill-rakers, which form series on both the leading and trailing edges of the arch and function to keep the gill tissue clear, and they serve to sieve the water column to collect food in some filter-feeding taxa (e.g., many Clupeidae). The number and arrangement of the toothplates, particularly on the dorsal branchial arch skeleton, often have significant phylogenetic and functional significance. The structure of the branchial arches generally can inform greatly about the ecology of fishes and is rich in phylogenetically informative character data.

Postcranial Axial Skeleton

The postcranial axial skeleton of fishes comprises three basic units – the scale jacket, the vertebral skeleton, and the median fins and their supporting skeletal elements. The scales of fishes are widely varied in their structure. These range from the large, bony cosmoid scales of most fossil fish-like sarcopterygians, which contain a layer of cosmine (lost in extant sarcopterygians), to the thin, flexible cycloid scales found in most teleostean fishes. Some teleosts have so-called ctenoid scales, which are similar to cycloid scales, but which have small spines (cteni) on the exposed posterior field of the scale. Basal sarcopterygians and basal actinopterygians (e.g., *Polypterus*, gars) have thick, interlocking ganoid scales that are coated with ganoine (enamel and dentine). Scales (or in some cases other dermal ossifications) support the lateral sensory canal (if present) and serve to protect the fish. If the scales are reduced in size, there may be other functional protecting layers that are developed (e.g., the greatly thickened dermis of the ocean sunfish, *Mola mola*). Scales and the dermis itself may also store energy used during locomotion and respiration. More broadly speaking, the scale jacket may also include other bony structures, such as scutes (bony plates serially arranged along the body, as in sturgeons, some catfishes, and carangid fishes) and fulcra (scales typically associated with the leading edge of fins).

The vertebral column can be divided into abdominal and caudal regions, with the caudal region further divided into the preural and ural regions. The number, form, and modifications of the vertebrae (e.g., zygapophyses, which may lock together sequential vertebrae in groups such as some billfishes) greatly affect the flexibility of the body, and therefore have significant functional correlations. The abdominal region is defined as that region posterior to the skull with vertebrae bearing parapophyses (**Figures 8**(**a**) and 8(**b**)). The parapophyses are ossifications of paired cartilages (basiventrals) found ventrally along the length of the notochord in early stages of development. The parapophyses are matched by the neural arches, which are ossifications of the basidorsals (which form on either side of the spinal cord). In basal forms (e.g., sturgeons), irregularly shaped cartilaginous elements – interdorsals and interventrals – are intercalated between adjacent basidorsals and basiventrals, respectively. Both neural arches and parapophyses may fuse to the centra, which typically ossify within the notochordal sheath (although there is substantial variation in the mode of ossification of centra, e.g., some parts of a centrum ossify in conjunction with the basidorsals and basiventrals in addition to the notochord). In some basal actinopterygians (e.g., sturgeons) and fish-like sarcopterygians (coelacanths and lungfishes), the centra do not ossify (the so-called unconstricted notochord), although the other elements of the vertebrae are present.

In actinopterygians, the neural arches extend dorsally, forming the neural spine. In derived teleosts, most neural and haemal spines are not preformed in cartilage but are membrane bone. The left and right neural spines typically fuse forming a median structure, although the two may remain separate in basal actinopterygians. Intercalated between the neural spines anterior to the dorsal fin is a series of supraneural bones. The centra and neural arches of the abdominal region continue into the caudal region (**Figures 8**(**c**) and 8(**d**)). The parapohyses, on the other hand, end at the abdominal–caudal division and are replaced by the haemal arches and spines. Like the parapophyses, these structures develop from the basiventrals, but are similar in form to the neural arches. The hemal arches surround the major blood vessels of the caudal region.

Intermuscular bones are associated with the other elements of the vertebrae of teleosts, and these bones are widely regarded as a synapomorphy for the Teleostei. These bones form in the ligaments of the myosepta, and are thought to help stiffen the body and provide more attachment sites for transmission of force. Only relatively basal teleosts (e.g., elopomorphs and clupeomorphs) have a complete set of intermuscular bones (i.e., epineurals, epicentrals, epipleurals, and myorhabdoi, a naming based on which fold of the myosepta they are found within), and their presence, absence, and positioning are phylogenetically informative.

The elements of the vertebral column continue posteriorly into the ural region (defined as the region posterior to the vertebra that includes the parhypural, which is the last element that has a hemal arch surrounding the blood vessels; i.e., the first ural vertebrae is associated with hypural 1), which contains most of the supports for the caudal fin (**Figure 9**). The caudal fin and its supports are the source of many phylogenetically informative

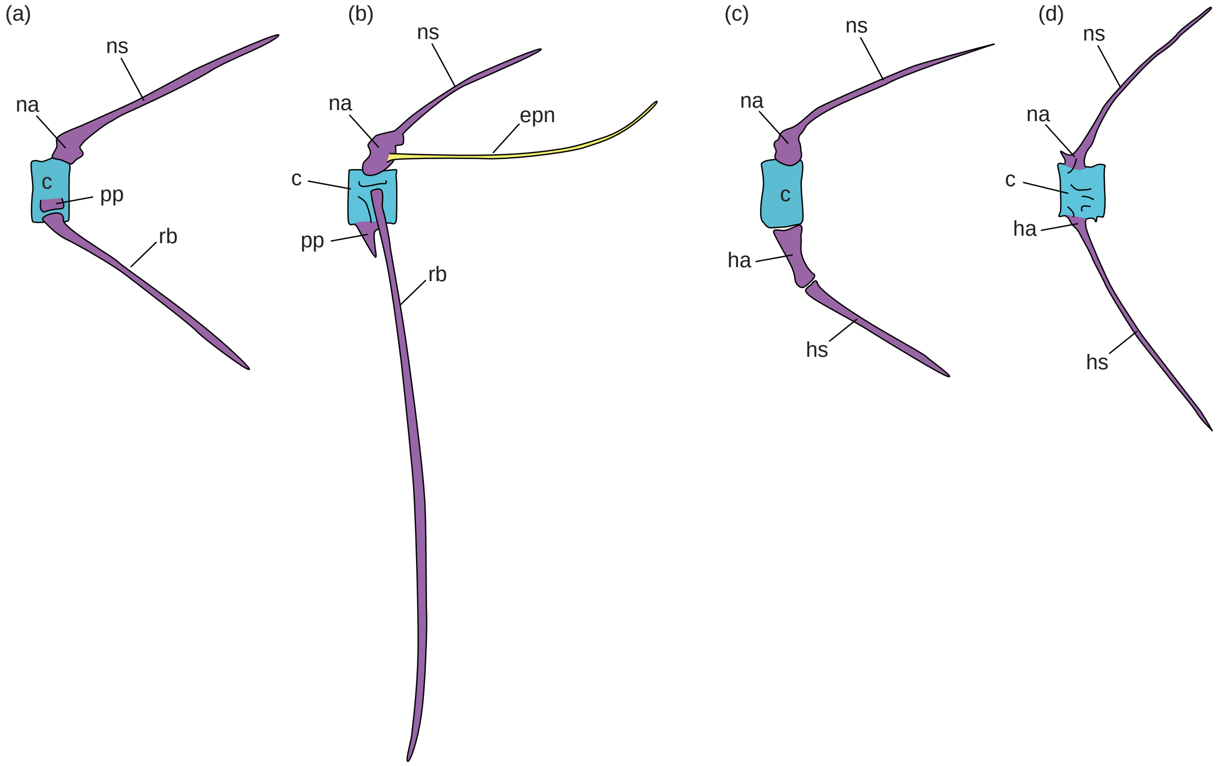

Figure 8 Abdominal (a, b) and caudal (c, d) vertebrae of *Amia* (a, c) and *Hiodon* (b, d) in lateral view. Chondral bone is shown in purple, membrane bone in yellow, and perichordal bone in light blue. Abbreviations: c, centrum; epn, epineural intermuscular bone; ha, hemal arch; hs, hemal spine; na, neural arch; ns, neural spine; pp, parapophysis; rb, rib. Modified from Grande L and Bemis WE (1998) A comprehensive phylogenetic study of amiid fishes (Amiidae) based on comparative skeletal anatomy. An empirical search for interconnected patterns of natural history. *Society of Vertebrate Paleontology, Memoir* 4: 1–690; and Hilton EJ (2002) Osteology of the extant North American fishes of the genus *Hiodon* Lesueur, 1818 (Teleostei: Osteoglossomorpha: Hiodontiformes). *Fieldiana (Zoology) new series* 100: 1–142.

characters and is perhaps the most-studied region of the skeleton.

In basal sarcopterygians and nonteleostean actinopterygians, the caudal fin is heterocercal, in which the vertebral supports bend slightly dorsally, and the ventral skeletal supports (the hypurals, the serial homologues of the haemal spines) extend to the very tip of the notochord. The fin rays are almost entirely hypaxial, and produce an internally and externally asymmetrical, shark-like caudal fin. Nonteleostean actinopterygians (e.g., gars, *Amia*) have an abbreviated heterocercal caudal skeleton. This is in contrast to the condition seen in teleosts, in which the notochord has a sharp bend at its posterior end, causing the hypurals to be directed posteriorly. The fin itself is symmetrical, although the internal supporting elements are asymmetrical, forming the so-called homocercal caudal fin. Most notable in the asymmetry of the internal skeleton is the presence of uroneurals, which are the homologs to the neural arches of ural vertebrae that have become separated from their vertebrae and modified into stabilizing struts that serve to stiffen the vertebrae of the posterior caudal skeleton. The presence of uroneurals is a key synapomorphy of the Teleostei. In derived teleosts, the uroneurals may fuse to the terminal centrum (which is thought to incorporate preural centrum 1 and all ural centra; **Figure 9(c)**). There are significant functional consequences to the various patterns found in the caudal skeletons and fins of fishes, although both heterocercal and homocercal tails appear to function asymmetrically (perhaps through active control by species with homocercal tails). Therefore, even fishes with a broad diversity of tail forms all may produce asymmetrical patterns of thrust and lift, which are matched to ecological and behavioral necessities.

The dorsal and anal fins have a similar overall structure and arrangement (**Figure 10**). In both fins the skeletal supports for the fin rays, collectively called the pterygiophores, are composed of a series of radial elements termed the proximal, middle, and distal radials. The proximal radials are typically the longest of the series. In most derived teleosts, the proximal and middle radials are fused, forming the so-called proximal-middle radial. The distal radials are typically the smallest elements of a pterygiophore, and are embraced by the bases of the fin rays. In neopterygians (gars, bowfins, and teleosts), the fin rays are about equal in number to the number

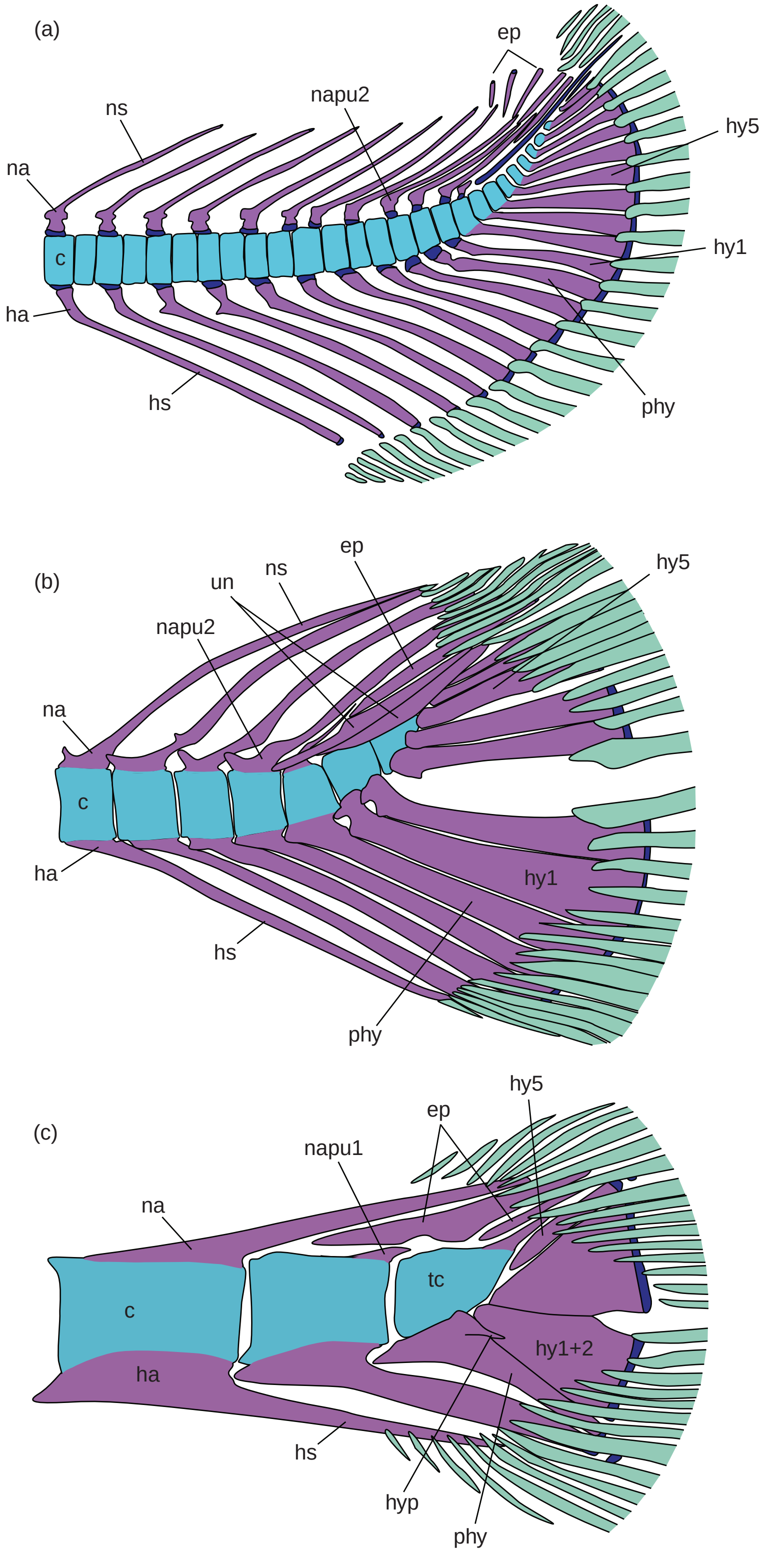

Figure 9 Caudal skeletons of *Amia* (a), *Hiodon* (b), and *Trachurus* (c) in lateral view. Modified from Grande L and Bemis WE (1998) A comprehensive phylogenetic study of amiid fishes (Amiidae) based on comparative skeletal anatomy. An empirical search for interconnected patterns of natural history. *Society of Vertebrate Paleontology, Memoir* 4: 1–690 and Suda Y (1996) Osteology and muscular attachments of the Japanese jack mackerel, *Trachurus japonicus*. *Bulletin of Marine Science* 58: 438–493.

of pterygiophores, which stands in contrast to more basal actinopterygians (e.g., sturgeons), in which the fin rays greatly outnumber the pterygiophores. The fin rays (lepidotrichia) of nonacanthomorph teleosts are all soft rays formed by paired hemilepidotrichia, with the exception of catfishes and some cyprinids, which have leading spine-like fin rays. In Acanthomorpha, a series of true, unsegmented median spines precede the soft rays of both the dorsal and anal fins, and may form a separate spinous dorsal fin.

Appendicular Skeleton

The pectoral girdle of most actinopterygian fishes (**Figure 11**) is unique among vertebrates in having a direct and often strong attachment to the posterior region of the skull. This connection is achieved through the posttemporal bone. The posttemporal most often bears dorsal limb that contacts the posterodorsal portion of the skull roof or the braincase (e.g., with the extrascapular or the epioccipital) and a ventral limb that contacts or braces against the skull (often at the intercalar) through ligament or direct bony articulation. Ventral to the posttemporal is the supracleithrum, which is attached to the axial skeleton (either the basioccipital or an anterior vertebra) through the so-called Baudelot's ligament. The supracleithrum and the posttemporal carry the trunk lateral sensory canal to the skull. The largest dermal bone of the pectoral girdle is the cleithrum, which is typically a J-shaped bone that provides much of the surface area for muscular attachment in the pectoral girdle. In basal actinopterygians and in sarcopterygians, there is also a clavicle that is positioned anteroventral to the cleithrum. The clavicles are lost in gars and all teleosts. In the bowfin, *Amia*, there are two small plates that are superficial to the sternohyoideus muscle that have been homologized with the clavicles of more basal actinopterygians. Also in basal actinopterygians and sarcopterygians, there is a median dermal interclavicle intercalated between the clavicles; this bone is lost in Neopterygii. Posteriorly, there is a series of postcleithra (often one to three elements, but

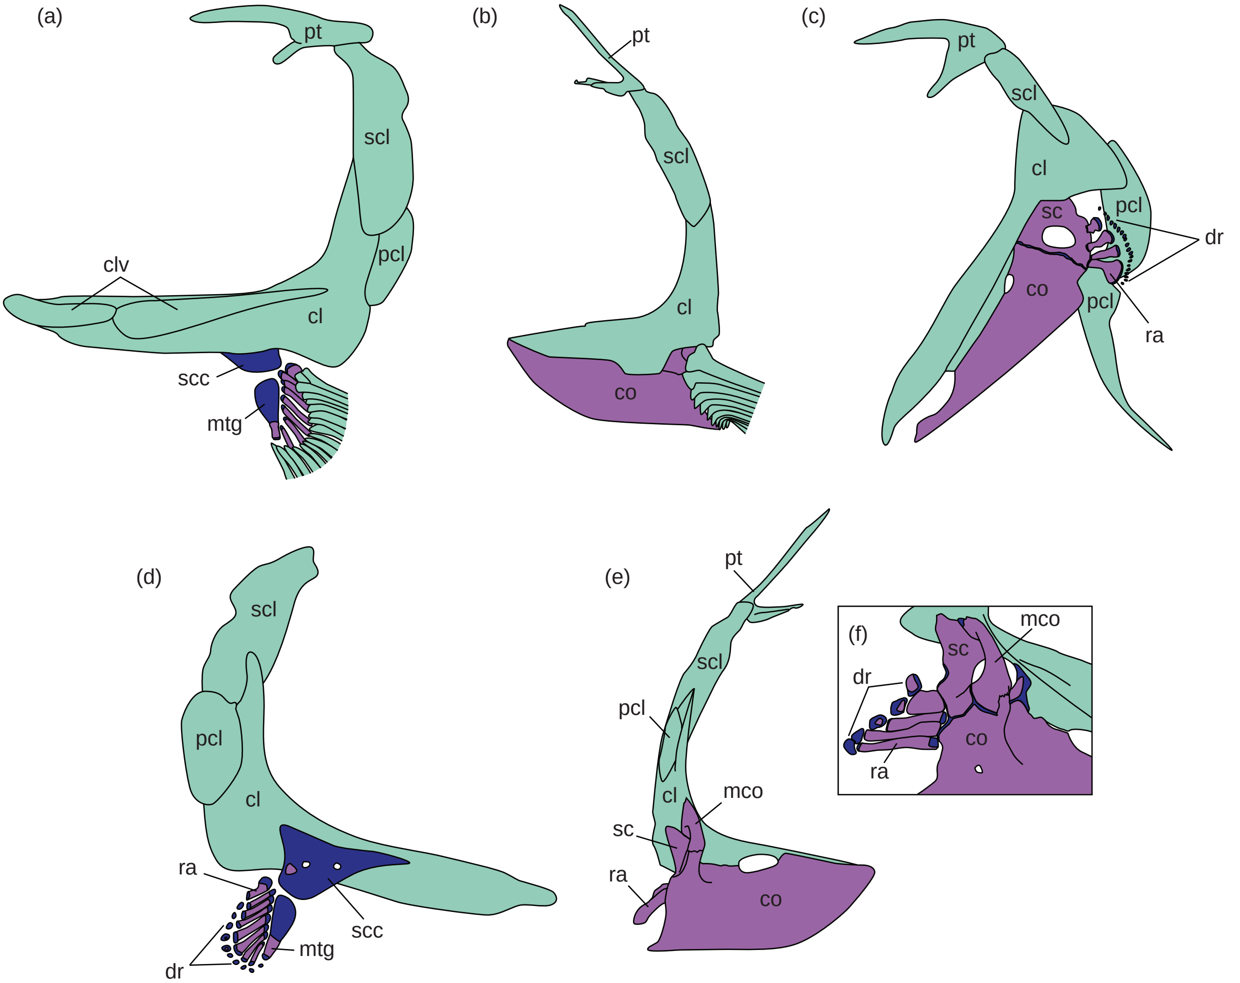

Figure 11 Pectoral girdle of *Amia* (a, d), *Hiodon* (b, e, f), and *Trachurus* (c) in lateral (a–c) and medial (d–f) views. Abbreviations: cl, cleithrum; clv, clavicle; co, coracoid; dr, distal radial; mco, mesocoracoid; mtg, metapterygium; pcl, postcleithrum; pt, posttemporal; ra, radial; sc, scapula; scc, scapulocoracoid cartilage; scl, supracleithrum. Modified from Grande L and Bemis WE (1998) A comprehensive phylogenetic study of amiid fishes (Amiidae) based on comparative skeletal anatomy. An empirical search for interconnected patterns of natural history. *Society of Vertebrate Paleontology, Memoir* 4: 1–690; Hilton EJ (2002) Osteology of the extant North American fishes of the genus *Hiodon* Lesueur, 1818 (Teleostei: Osteoglossomorpha: Hiodontiformes). *Fieldiana (Zoology) new series* 100: 1–142; and Suda Y (1996) Osteology and muscular attachments of the Japanese jack mackerel, *Trachurus japonicus*. *Bulletin of Marine Science* 58: 438–493.

sometimes more or less), which extend posteroventrally from the supracleithrum–cleithrum joint. In many teleosts the posteriormost postcleithrum is greatly elongated and rib-like in its form. In sarcopterygians, the shoulder girdle is often separate from the skull (e.g., coelacanths and lungfishes), but may have additional dermal bones (e.g., the anocleithrum and extracleithrum of coelacanths).

The internal chondral portion of the pectoral girdle of bony fishes is formed by the scapulocoracoid cartilage and its ossifications, and the radial elements that directly support the fin rays. In some taxa, there may be additional neomorphic elements that are synapomorphies for these groups (e.g., the supracleithral cartilage of sturgeons, family Acipenseridae). Three endochondral bones are present in nonteleostean and basal teleostean actinopterygians: the scapula, the coracoid, and the mesocoracoid. The scapula ossifies dorsally, surrounding the scapular foramen, whereas the coracoid ossifies ventrally within the scapulocoracoid cartilage. The mesocoracoid ossifies in a medial arch of the scapulocoracoid cartilage that braces against the medial surface of the cleithrum. The mesocoracoid is lost in advanced teleostean fishes. In Sarcopterygii, a single element articulates with the scapulocoracoid, forming the so-called monobasal fin. The proximal radials of the pectoral fin of most actinopterygians articulate with the scapula and the coracoid and extend distally to support the fin rays. Typically, there are four or more proximal radials (=actinosts) that ossify and a single propterygium that often becomes fused to the leading fin ray. In nonteleostean actinopterygians, there is

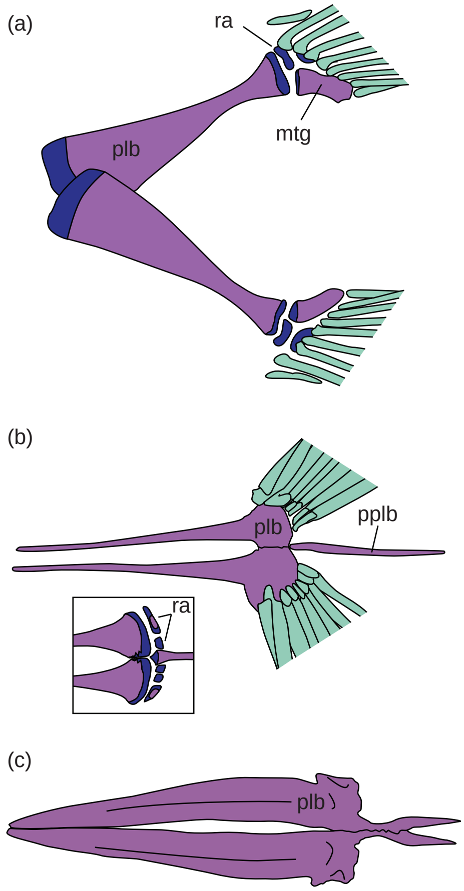

Figure 12 Pelvic girdle of *Amia* (a), *Hiodon* (b), and *Trachurus* (c) in dorsal view (inset in (b) shows base of pelvic bone and radials with fin rays removed). Cartilage is shown in dark blue, chondral bone in purple, and dermal bone in green. Abbreviations: mtg, metapterygium; plb, pelvic bone; pplb, postpelvic bone; ra, radial. Modified from Grande L and Bemis WE (1998) A comprehensive phylogenetic study of amiid fishes (Amiidae) based on comparative skeletal anatomy. An empirical search for interconnected patterns of natural history. *Society of Vertebrate Paleontology, Memoir* 4: 1–690; Hilton EJ (2002) Osteology of the extant North American fishes of the genus Hiodon Lesueur, 1818 (Teleostei: Osteoglossomorpha: Hiodontiformes). *Fieldiana (Zoology) new series* 100: 1–142; and Suda Y (1996) Osteology and muscular attachments of the Japanese jack mackerel, *Trachurus japonicus. Bulletin of Marine Science* 58: 438–493.

also a posteriorly positioned, elongated metapterygoid that contributes to the support of the proximal radials. Finally, there is a series of distal radials, which are entirely surrounded by the bases of the fin rays of the pectoral fin. In sturgeons, there is a pectoral fin spine that is formed by the fusion of adjacent fin rays. In catfishes, the pectoral fin also has a pectoral fin spine formed by the fusion of the segments of the leading fin ray. In these spines, the posterior margin may be serrated.

The pelvic fin of basal taxa is positioned posteriorly on the ventral portion of the abdominal region. In derived teleostean fishes (e.g., Acanthomorpha), the position of the pelvic fin is shifted forward on the body, and in many acanthomorphs, the pelvic fins may be anterior to the pectoral fins. The migration of the pelvic fin has both phylogenetic (e.g., occurs as a derived state) as well as functional significance, and seems to be correlated with increased maneuverability and control during locomotion. In Acanthopterygii the soft fin rays of the pelvic fin are preceded by a stout fin spine.

The largest element of the pelvic girdle of most bony fishes is the pelvic bone (basipterygium), which forms a large plate-like element that serves to support the pelvic fin musculature (**Figure 12**). In nonteleostean fishes, the anterior ends of the left and right basipterygia contact or slightly overlap one another. In sturgeons and paddlefishes, the left and right pelvic girdles are widely separated, each embedded in the hypaxial musculature of the body wall. In most teleosts, the posterior regions of the basipterygia are in contact with the midline. Pelvic radials are lost in the adults of derived acanthomorphs.

Conclusion

Collectively, the skeletons of fishes display a complex and diverse array of forms. The details of this variation, which are merely hinted at in this chapter, are the product of functional demands generated by the life history, ecology, and behavior of individual species. Coupled to this are the constraints set in place from the phylogenetic history of each species. It is this combination – phylogeny and function – that makes an understanding and appreciation of the skeleton of fishes central to so many aspects of the evolutionary and ecological biology of fishes.

Glossary

Branchiomeric Pertaining to muscles originating between the dorsal and ventral elements of the visceral arches of the skeleton.

Chondrocranium Cartilaginous cranium of the chondrichthyan fishes.

Epibranchial Pertaining to muscles lying dorsal to the branchial arches.

Hypobranchial Pertaining to muscles lying ventral to the branchial arches.

Meckel's cartilage Lower jaw of the chondrichthyan fishes.

Palatoquadrate Upper jaw of the chondrichthyan fishes.

Raphe A seam-like union between two halves of an anatomical structure having a sheet of connective tissue at the septum.

Scapulocoracoid Pectoral girdle of the chondrichthyan fishes.

Introduction

Study of the cranial musculature of the cartilaginous fishes has a long history owing to both the phylogenetic position of this clade and the dynamic nature of their predatory endeavors. Basal gnathostomes diverged from a common ancestor with the Teleostomi over 400 million years ago and thus the study of their cranial musculature promises insight into the proximate mechanisms underlying the transition of the anterior visceral arches from respiratory structures into those involved in active predation. While early studies focused on describing the cranial muscles and their relation to the visceral arches as a means of codifying the evolutionary history of jawed vertebrates, later studies focused on the range of function enabled by the diverse morphologies of the various chondrichthyan feeding (**see also Chondrichthyes**: Physiology of Sharks, Skates, and Rays, **Food Acquisition and Digestion:** Energetics of Prey Capture: From Foraging Theory to Functional Morphology, and **The Reproductive Organs and Processes:** Anatomy and Histology of Fish Testis) and respiratory mechanisms (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics).

Although taxonomically few, cartilaginous fishes possess a remarkable diversity of feeding mechanisms (six jaw suspension types, ram/biting/suction/filter feeding, jaw protrusion). While their respiratory mechanisms are not as diverse, they represent both predominant systems found in aquatic vertebrates, the suction-force pump and ram ventilation. The cranial muscles serve as the actuators of these mechanisms. Thus, studying their functional diversity provides critical links in our understanding of the relationship between the morphology, behavior and ecology in cartilaginous fishes, and the reconstruction of vertebrate evolutionary history. The following information is a basic guide to the cranial musculature of the three major radiations of extant cartilaginous fishes. Among the elasmobranchs, sharks are represented by the spiny dogfish *Squalus acanthias* and batoids by the southern guitarfish *Rhinobatos percellens*. The holocephalans are represented by the spotted ratfish *Hydrolagus colliei*. Hypobranchial and pharyngeal muscles are described in addition to cranial muscles, as these structures are also involved in feeding and respiration.

Shark Musculature

The muscles involved in feeding and respiration in cartilaginous fishes can be broadly categorized as epibranchial, branchiomeric, or hypobranchial. The epibranchial muscles form a cranial extension of the epaxial musculature, and as such retain the myomeric structure typical of the trunk. The epibranchial muscles originate on the epaxial muscle mass, insert onto the otic capsule of the chondrocranium, and elevate the cranium during prey capture (**Figures 1** and **2**, and **Table 2**).

The branchiomeric muscles adduct the dorsal and ventral elements of the visceral arches. As the visceral arches (I–VII) differentiated from respiratory structures into those suited for respiration and feeding (mandibular, hyoid, and branchial arches I–V), a concomitant differentiation of the branchiomeric muscles occurred. Branchiomeric muscles associated with the mandibular arch include the adductor mandibulae, preorbitalis, levator palatoquadrati, intermandibularis, and spiracularis. The adductor mandibulae originates on the palatoquadrate (upper jaw), inserts onto Meckel's cartilage (lower jaw), has multiple divisions, and is the primary jaw adductor in all cartilaginous fishes (**Figures 1–5** and **Table 2**). The preorbitalis originates on the chondrocranium, posterior to the nasal capsule, and inserts onto the median raphe, separating the dorsal and ventral divisions of the adductor mandibulae (**Figures 1** and **2**, and **Table 2**). It elevates the lower jaw, protrudes the upper jaw, and depresses the cranium.

The levator palatoquadrati originates on the otic capsule of the chondrocranium and inserts onto the palatoquadrate (**Figures 1**, **2**, and **4**, and **Table 2**). It elevates the upper jaw into its resting position during the recovery phase of the gape cycle after the upper and lower jaws have been adducted. The intermandibularis is a thin sheet of muscle lying between the two halves of the lower jaw, with its right and left portions inserted upon the midventral raphe. It elevates the floor of the mouth during feeding and respiration, facilitating hydraulic transport through the oropharyngeal cavity (**Figure 3** and **Table 2**). Lastly, the spiracularis originates on the lateral wall of the chondrocranium, posterior to the levator palatoquadrati, and inserts onto and closes the spiracle (**Figures 1**, **2**, and **4**).

Branchiomeric muscles of the hyoid arch include the interhyoideus, dorsal and ventral hyoid constrictors, hyoid trematic constrictor, and levator hyomandibulae. The interhyoideus is a thin muscle sheet lying dorsal to the intermandibularis. It originates on the ceratohyal cartilages of the hyoid arch, inserts onto the midventral raphe, and elevates the floor of the mouth (**Figures 2**

EHC	Epihyal cartilage	VC	Vertebral column
GR	Gill rays		

Table 2 Origins, insertions, and actions of the cranial muscles of sharks

Muscle	*Origin*	*Insertion*	*Action*
Adductor mandibulae	Palatoquadrate cartilage	Meckel's cartilage	Adduct lower jaw
Branchial adductor	Epibranchial cartilage	Ceratobranchial cartilage	Adduct gill arch
Branchial trematic constrictor	Tendinous sheath of gill slit	Gill slit	Compress gill pouch
Constrictor hyoideus dorsalis	Chondrocranium, cucullaris	Tendinous sheath of hyomandibular cartilage	Compress first gill pouch
Constrictor hyoideus ventrails	Raphe of first gill slit	Tendinous sheath of hyomandibular cartilage	Compress first gill pouch
Coracoarcualis	Scapulocoracoid cartilage	Coracomandibularis, corachyoideus	Expand oropharyngeal cavity
Coracobranchialis	Coracoarcualis, pectoral girdle	Basihyal, hypobranchial, and basibranchial cartilages	Abduct hyoid and branchial arches
Coracohyoideus	Coracoarcualis	Basihyal cartilage	Abduct hyoid arch
Coracomandibularis	Coracoarcualis	Meckel's cartilages	Abduct lower jaw
Cucullaris	Epibranchial	Pectoral girdle	Elevate pectoral girdle
Dorsal interarcual	Pharyngobranchial cartilage	Pharyngobranchial cartilage	Adduct gill arch
Dorsal oblique	Chondrocranium	Eyeball	Rotate eyeball
Dorsal rectus	Chondrocranium	Eyeball	Rotate eyeball
Dorsal superficial branchial constrictor	Cucullaris	Tendinous sheaths of gill slits	Compress gill pouches
Epibranchial	Epaxialis	Chondrocranium	Elevate chondrocranium
Hyoid trematic constrictor	Tendinous sheath of hyomandibular cartilage	First gill slit	Compress first gill pouch
Interbranchial	Gill rays	Gill rays	Adduct gill arches, move interbranchial septa
Interhyoideus	Ceratohyal cartilage	Midventral raphe	Elevate floor of mouth
Intermandibularis	Meckel's cartilage	Midventral raphe	Elevate floor of mouth
Lateral interarcual	Pharyngobranchial cartilage	Epibranchial cartilage	Adduct gill arch
Lateral rectus	Chondrocranium	Eyeball	Rotate eyeball
Levator hyomandibulae	Chondrocranium, epibranchial muscles	Hyomandibular cartilage	Elevate hyomandibular cartilage
Levator palatoquadrati	Chondrocranium	Palatoquadrate cartilage	Elevates upper jaw
Medial rectus	Chondrocranium	Eyeball	Rotate eyeball
Preorbitalis	Chondrocranium	Adductor mandibulae	Adduct lower jaw, protrude upper jaw
Spiracularis	Chondrocranium	Spiracle	Close spiracular valve
Ventral oblique	Chondrocranium	Eyeball	Rotate eyeball
Ventral rectus	Chondrocranium	Eyeball	Rotate eyeball
Ventral superficial branchial constrictor	Coracoarcualis	Tendinous sheaths of gill slits	Compress gill pouches

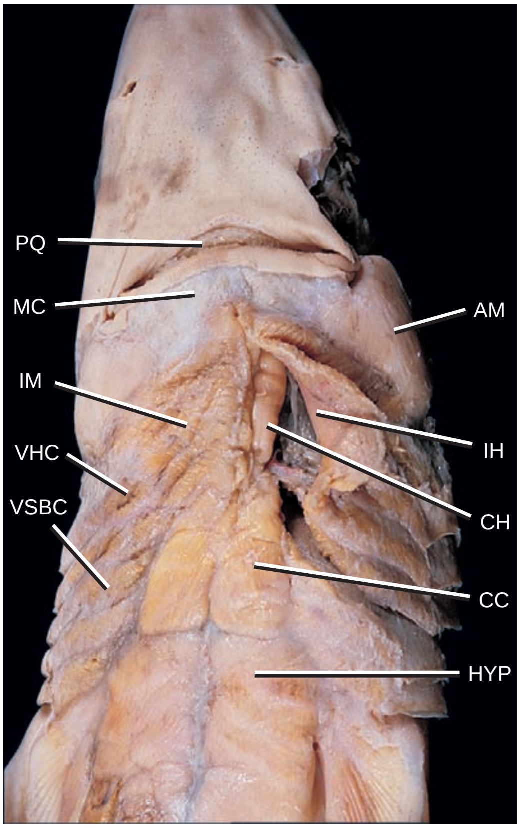

Figure 3 Branchiomeric and hypobranchial cranial muscles of the spiny dogfish *Squalus acanthias* in ventral view. The intermandibularis and interhyoideus have been partially reflected to show the coracohyoideus. See **Table 1** for abbreviated terms. Modified from Fishbeck DW and Sebastiani AS (2008) *Manual of Vertebrate Dissection: Comparative Anatomy*, 2nd edn. Englewood, CO: Morton Publishing.

and **3**, and **Table 2**). The dorsal and ventral hyoid constrictors as well as the hyoid trematic constrictor compress the first gill pouch, assisting in hydraulic transport during respiration and feeding. Both the dorsal and ventral hyoid constrictors insert onto the tendinous sheath overlying the hyomandibular cartilages. The former originates from the otic capsule of the chondrocranium and cucullaris muscle, whereas the latter originates adjacent to the interhyoideus along the raphe of the first gill slit (**Figures 1–4** and **Table 2**). The hyoid trematic constrictor originates on the tendinous sheath overlying the hyomandibular cartilages and inserts onto the first gill slit (**Figure 1** and **Table 2**). The levator hyomandibulae originates on the otic capsule of the chondrocranium and epibranchial musculature, inserts onto the hyomandibular cartilages, and elevates these cartilages following a gape or respiratory cycle (**Figures 1** and **2**, and **Table 2**).

The branchiomeric muscles of the branchial arches include the dorsal and ventral superficial branchial constrictors, branchial trematic constrictors, dorsal and lateral interarcual, branchial adductor, interbranchial, and cucullaris muscles. The dorsal and ventral superficial branchial constrictors lie above and below the gill slits in positions comparable to the respective hyoid constrictors. The dorsal superficial branchial constrictor originates on the cucullaris and extends downward to meet its ventral counterpart at a series of tendinous intersections on each gill slit. The ventral division originates on the fascia of the coracoarcualis muscle (**Figures 1** and **3–5**, and **Table 2**). The branchial trematic constrictor muscles originate on the

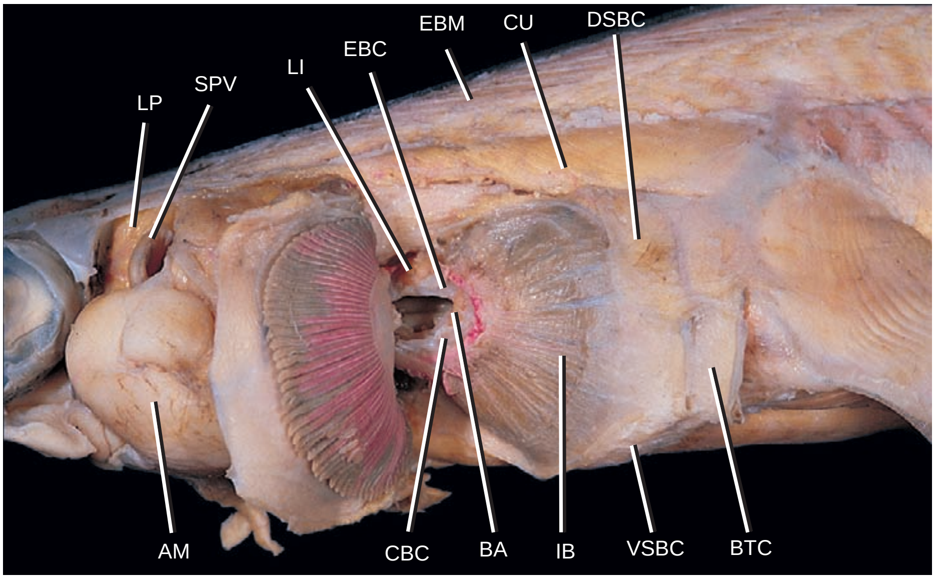

Figure 4 Epibranchial and branchiomeric cranial muscles of the spiny dogfish *Squalus acanthias* in lateral view with the gills reflected to show the deep branchial muscles. See **Table 1** for abbreviated terms. Modified from Fishbeck DW and Sebastiani AS (2008) *Manual of Vertebrate Dissection: Comparative Anatomy*, 2nd edn. Englewood, CO: Morton Publishing.

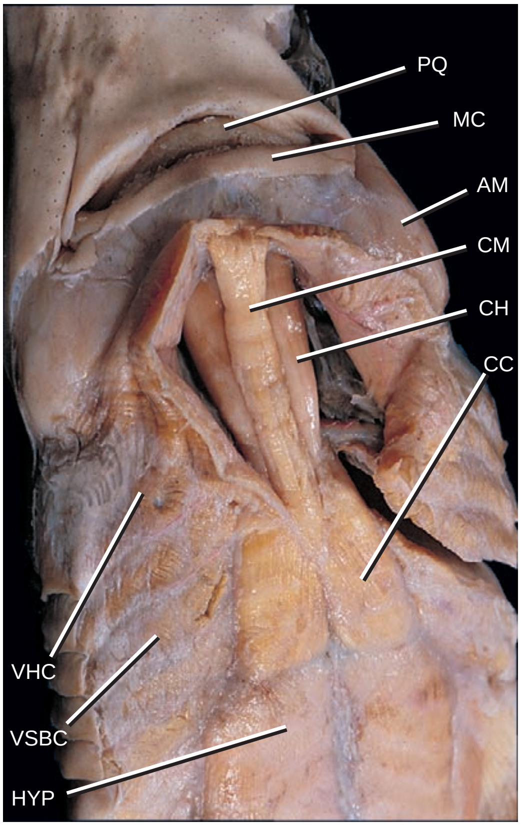

Figure 5 Branchiomeric and hypobranchial cranial muscles of the spiny dogfish *Squalus acanthias* in ventral view. The intermandibularis and interhyoideus have been removed to show the coracomandibularis and coracohyoideus. See **Table 1** for abbreviated terms. Modified from Fishbeck DW and Sebastiani AS (2008) *Manual of Vertebrate Dissection: Comparative Anatomy*, 2nd edn. Englewood, CO: Morton Publishing.

tendinous intersections of the dorsal and ventral superficial branchial constrictors, and they insert onto each of the gill slits (**Figures 1** and **4**, and **Table 2**). Collectively these muscles compress the gill pouches.

The gill arches are moved by the dorsal and lateral interarcual, branchial adductor, and interbranchial muscles. The dorsal interarcual muscles are located between the pharyngobranchial cartilages of adjacent branchial arches and control the distances between these elements. The lateral interarcual muscles originate, and insert upon, the pharyngobranchial and epibranchial cartilages of the same branchial arch. They adduct these elements. The branchial adductors originate, and insert upon, the epibranchial and ceratobranchial cartilages of the same branchial arch. They adduct these elements as well. The interbranchial muscles are an extensive series of circumferential fiber bundles that span between adjacent gill rays on each branchial arch (**Figures 2** and **4**, and **Table 2**). They control the orientation of the interbranchial septa and adduct the branchial arches. Lastly, the cucullaris originates on the epibranchial musculature, and inserts onto, the scapulocoracoid cartilage of the pectoral girdle, which it elevates (**Figures 1** and **4**, and **Table 2**).

The hypobranchial muscles are largely associated with the abduction of the visceral arches, resulting in expansion of the oropharyngeal cavity. The coracomandibularis and coracoarcualis lie in series in the floor of the mouth, with the former immediately deep to the interhyoideus (**Figures 3** and **5**, and **Table 2**). The coracohyoideus is a paired muscle lying deep to the coracomandibularis, both of which originate on the fascia of the coracoarcualis. The coracomandibularis and coracohyoideus insert onto, and abduct, the lower jaw and basihyal cartilage of the hyoid arch, respectively. The paired, segmented coracoarcualis muscles originate upon the scapulocoracoid cartilage. They assist the coracomandibularis and coracohyoideus in their functions (**Figures 2**, **3**, and **5**, and **Table 2**). The segmented coracobranchialis muscles originate on the coracoarcualis and coracoid bar, and insert onto and abduct the ventral elements of the hyoid and branchial arches.

The positions of the eyes are controlled by six extrinsic muscles, all of which originate on the chondrocranium. The lateral, medial, dorsal, and ventral rectus muscles insert onto the eyeball orthogonal to the viewing plane, while the dorsal and ventral oblique muscles insert onto the eyeball from an acute angle. The same arrangement of extrinsic eye muscles is found among all cartilaginous fishes (**Figure 6** and **Table 2**).

Coordinated Muscle Activity in Feeding and Respiration

Like other aquatic vertebrates, sharks typically capture prey by expansive, compressive, and recovery phases of the gape cycle (**see also Chondrichthyes**: Physiology of Sharks, Skates, and Rays, **Food Acquisition and Digestion:** Energetics of Prey Capture: From Foraging Theory to Functional Morphology, **Ventilation and Animal**

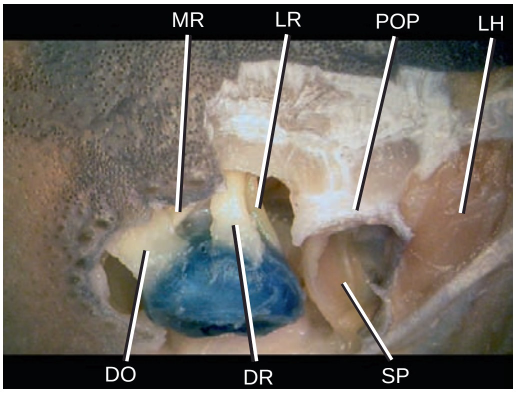

Figure 6 Extrinsic eye muscles of the southern guitarfish *Rhinobatos percellens* in dorsal view (rostrum toward the left). See **Table 1** for abbreviated terms.

Respiration: Gill Respiratory Morphometrics, **Buoyancy, Locomotion, and Movement in Fishes:** Feeding Mechanics, and **The Muscles:** Bony Fish Cranial Muscles). The expansive phase is characterized by cranial elevation via the epibranchial musculature and abduction of the ventral elements of the visceral arches. The coracomandibularis, coracohyoideus, coracoarcualis, and coracobranchialis are activated in rapid succession resulting in a posteriorly directed wave of abduction, which facilitates hydraulic transport of food and water (**Figure 7**, **Video Clip 1**). The compressive phase is characterized by contraction of the adductor mandibulae followed by the preorbitalis, which adducts both jaws while protruding the upper. Head depression occurs via relaxation of the epibranchial musculature. The palatoquadrate and hyomandibular cartilages are returned to their resting positions during the recovery phase via the levator palatoquadrati and levator hyomandibulae muscles (**Figure 7**, **Video Clip 1**).

Respiration in *S. acanthias* occurs via a suction-force pump. While experimental evidence of muscle activity patterns during shark respiration is lacking, the plausible mechanism is described as follows. The external gill slits are closed via the branchial trematic constrictors, and then water is drawn into the oropharyngeal cavity and parabranchial chambers through the mouth and spiracles as the hypobranchial muscles expand the floor of the mouth (suction pump). The mouth and spiracles are then closed via the adductor mandibulae and spiracularis muscles. The branchial chambers are then compressed via the dorsal and ventral branchial constrictors, dorsal and lateral interarcual, and branchial adductor muscles as the external gill slits open, thereby forcing water out (force pump; **Figure 8**). In addition to the suction-force pump, many sharks rely upon ram ventilation in which the mouth is held open during forward movement, resulting in water flow across the gills.

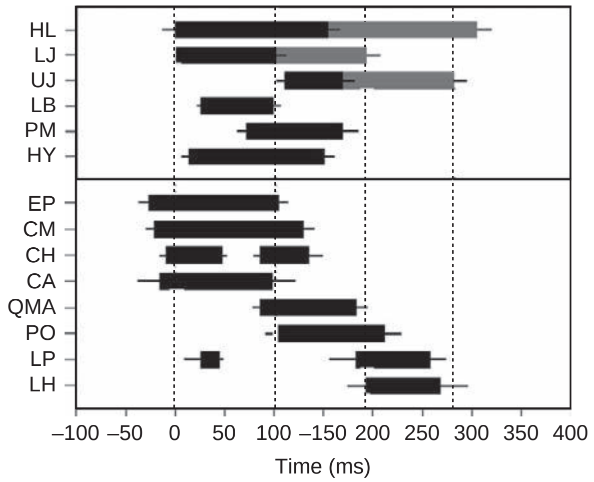

Figure 7 Kinematic (top) and motor (bottom) patterns during prey-capture in the spiny dogfish *Squalus acanthias.* Black and gray bars for kinematic events indicate onset, peak, and end of activity. Black bars for motor events indicate onset and duration of muscle activity. Dashed vertical lines indicate the onset of the expansive, compressive, and recovery phases and the end of the recovery phase. HL, head lift; HY, peak hyoid depression; LB, labial extension; LJ, lower jaw movement; PM, prey movement; QMA, quadratomandibularis anterior (subdivision of the adductor mandibulae); UJ, upper jaw movement. **Table 1** provides information on those terms not listed in the figure caption. From Wilga CD and Motta PJ (1998) Conservation and variation in the feeding mechanism of the spiny dogfish *Squalus acanthias*. *Journal of Experimental Biology* 201: 1345–1358.

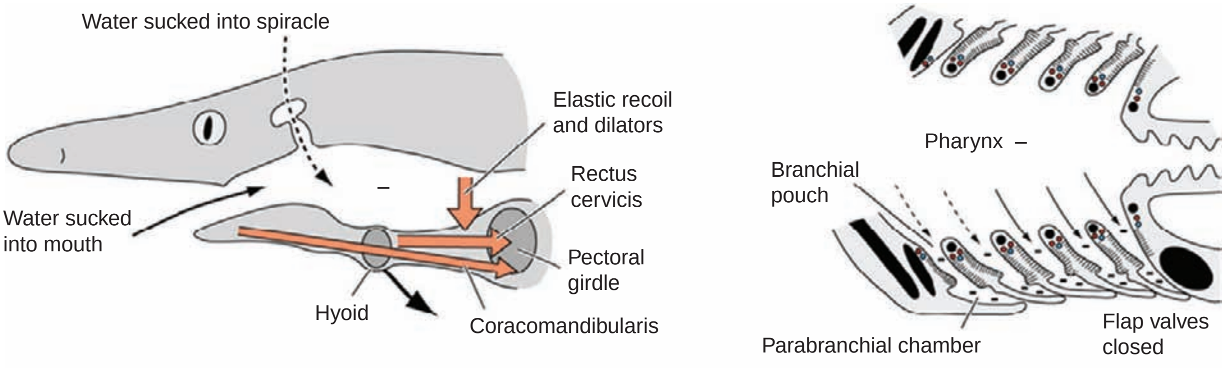
Batoid Musculature

Phylogenetic relationships among the different groups of sharks and rays (Batoidea) are still debated, although little doubt exists that elasmobranchs are monophyletic. Molecular data suggest that sharks and rays are sister groups (i.e., sharks are monophyletic), whereas morphological data suggest that rays are derived sharks (i.e., sharks are not monophyletic) and part of the Squalomorphii, a large group including the six- and seven-gill sharks, bramble sharks, dogfishes, and the superorder Hypnosqualea (sawsharks, angelsharks, and rays). Patterns in the cranial muscles corroborate the latter hypothesis because there are many subdivided muscles among species of Batoidea that are derived from the patterns seen in squalomorph sharks (e.g., in the adductor mandibulae complex).

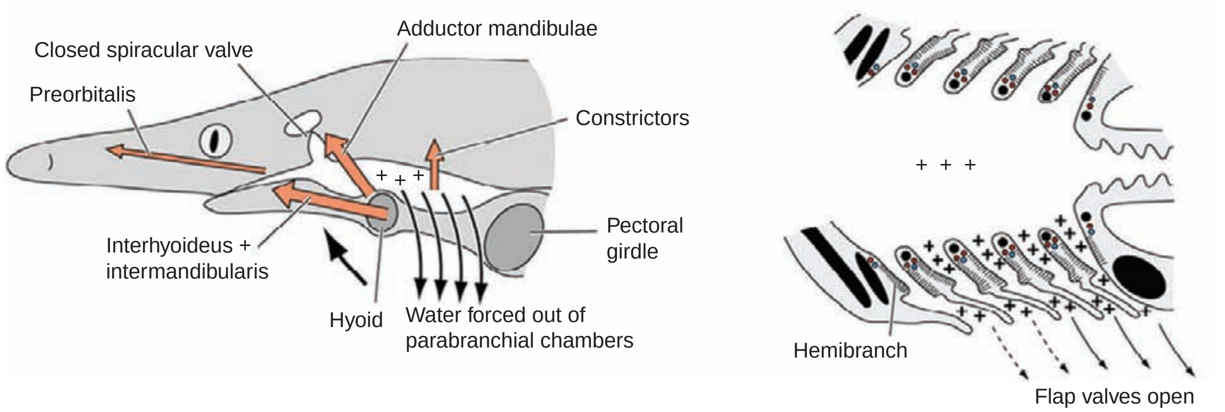
In batoids, the epaxial musculature inserts directly onto the chondrocranium and elevates the head (**Figure 9** and **Table 3**). The branchiomeric muscles of the mandibular arch include the adductor mandibulae complex, preorbitalis, levator palatoquadrati, and spiracularis muscles. The adductor mandibulae complex adducts the jaws and is composed of three divisions, all of which originate on the palatoquadrate (upper jaw) and insert onto Meckel's cartilage (lower jaw). The medial division surrounds the mouth opening, with lateral divisions 1 and 2 adjacent to it along the mandibular arch (**Figures 10** and **11**, and **Table 3**). There is great variation in the adductor mandibulae complex among batoids, with both fusions and further subdivisions common among these divisions.

The adductor mandibulae complex is partially overlain by the preorbitalis, which originates on the nasal capsule and inserts onto the lower jaw via a tendon that joins the adductor mandibulae complex (**Figures 10** and **11**, and **Table 3**). The preorbitalis both adducts the lower jaw and protrudes the upper. The levator palatoquadrati and the spiracularis originate on the otic region of the chondrocranium. The levator palatoquadrati inserts onto and elevates the upper jaw. The spiracularis inserts onto the spiracular cartilage and distal tip of the hyomandibular cartilage to form the anterior



(a) Suction pump

(b) Inspiration



(c) Force pump

(d) Expiration

Figure 8 Mechanics of gill ventilation via the suction-force pump in the spiny dogfish *Squalus acanthias* seen in lateral (a, c) and frontal (b, d) sections of the pharynx. Relative pressures are indicated by + and –. Narrow black arrows indicate the flow of water that entered the pharynx through the mouth, while dashed black arrows indicate that which has entered through the spiracle. Orange arrows indicate muscle activity and wide black arrows depict movements of the hyoid. Table 3 Origins, insertions, and actions of the cranial muscles of batoids

Muscle	*Origin*	*Insertion*	*Action*
Adductor mandibulae lateral 1	Palatoquadrate cartilage	Meckel's cartilage	Adduct lower jaw
Adductor mandibulae lateral 2	Palatoquadrate cartilage	Meckel's cartilage	Adduct lower jaw
Adductor mandibulae medial	Palatoquadrate cartilage	Meckel's cartilage	Adduct lower jaw
Branchial trematic constrictor	Propterygium of pectoral fin	Gill slits	Compress gill pouch
Coracoarcualis	Scapulocoracoid cartilage	Coracomandibularis, corachyoideus	Expand oropharyngeal cavity
Coracohyoideus	Coracoarcualis	Basihyal cartilage	Abduct hyoid arch
Coracohyomandibularis	Hypobranchial muscles and raphe	Hyomandibular cartilage	Abduct hyomandibular cartilage
Coracomandibularis	Coracoarcualis	Meckel's cartilages	Abduct lower jaw
Cucullaris	Scapulocoracoid cartilage	Propterygium of pectoral fin	Elevate pectoral fin
Depressor hyomandibularis	Hypobranchial muscles and raphe	Hyomandibular cartilage	Abduct hyomandibular cartilage
Depressor mandibulae	Hypobranchial muscles and raphe	Meckel's cartilage	Abduct lower jaw
Depressor rostri	Hypobranchial muscles and raphe	Rostrum	Depress rostrum
Dorsal hyoid constrictor	Dorsal superficial branchial constrictor	First Gill pouch	Compress gill pouch
Dorsal oblique	Chondrocranium	Eyeball	Rotate eyeball
Dorsal rectus	Chondrocranium	Eyeball	Rotate eyeball
Dorsal superficial branchial constrictor	Cucullaris	Dorsal hyoid constrictor	Compress gill pouches
Epaxialis	Scapulocoracoid cartilage	Chondrocranium	Elevate chondrocranium
Interbranchial	Hypobranchial muscles	Gill arch	Adduct gill arch
Lateral rectus	Chondrocranium	Eyeball	Rotate eyeball
Levator hyomandibulae	Chondrocranium	Hyomandibular cartilage	Elevate hyomandibular cartilage
Levator palatoquadrati	Chondrocranium	Palatoquadrate cartilage	Elevate upper jaw
Levator rostri	Chondrocranium, epibranchial musculature	Rostrum	Elevate rostrum
Medial rectus	Chondrocranium	Eyeball	Rotate eyeball
Preorbitalis	Chondrocranium	Meckel's cartilages	Adduct and elevate jaws, protrude upper jaw
Spiracularis	Chondrocranium	Spiracular and hyomandibular cartilages	Close spiracular valve
Ventral hyoid constrictor	Ventral superficial branchial constrictor	First Gill pouch	Compress gill pouch
Ventral oblique	Chondrocranium	Eyeball	Rotate eyeball
Ventral rectus	Chondrocranium	Eyeball	Rotate eyeball
Ventral superficial branchial constrictor	Propterygium of pectoral fin	Ventral hyoid constrictor	Compress gill pouches

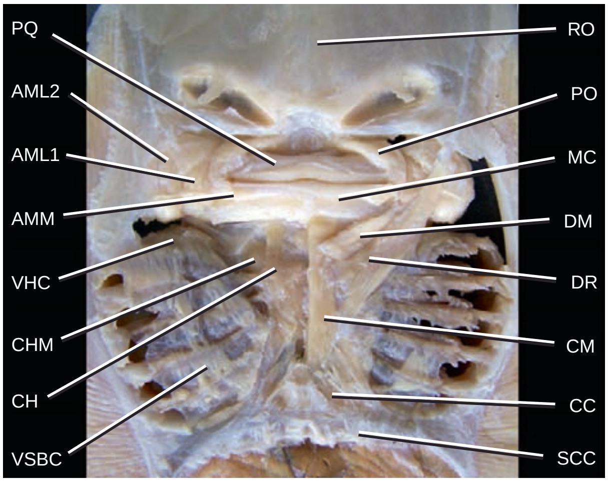

Figure 10 Branchiomeric and hypobranchial cranial muscles of the southern guitarfish *Rhinobatos percellens* in ventral view. See **Table 1** for abbreviated terms.

wall of the spiracle, which is closed via contraction of this muscle (**Figures 6** and **9**, and **Table 3**).

The branchiomeric muscles of the hyoid arch include the dorsal and ventral hyoid constrictors, levator hyomandibulae, depressor rostri, levator rostri, depressor mandibularis, and depressor hyomandibularis. The dorsal and ventral hyoid constrictors originate on the respective superficial branchial constrictors, and they unite medially to form the anterior wall of the branchial chamber, which they compress (**Figures 9** and **10**, and **Table 3**). The levator hyomandibulae originates on the otic region of the chondrocranium and inserts onto the hyomandibulae, which it retracts following a gape cycle (**Figures 6** and **9**, and **Table 3**). The rostrum is moved by the depressor and levator rostri muscles. Dorsally, the levator rostri originates on the epaxial musculature and otic capsule, and it inserts via a stout tendon between the nasal capsule and rostral cartilage. The depressor rostri originates along the ventral surface of the hypobranchial musculature and hypobranchial raphe, and it inserts onto the rostrum via a long tendon (**Figures 9–11** and **Table 3**). The depressor mandibularis appears to be a division of the depressor rostri, which inserts onto and assists in the abduction of the lower jaw (**Figures 10** and **11**, and **Table 3**). The depressor hyomandibularis originates along the ventral surface of the hypobranchial musculature, inserts onto the distal tips of the hyomandibular cartilages, and abducts these structures.

The branchiomeric muscles of the branchial arches include the dorsal and ventral superficial branchial constrictors, branchial trematic constrictor, interbranchial, and cucullaris muscles. The dorsal and ventral superficial branchial constrictors surround the gill arches. The ventral division originates on the propterygium of the pectoral fin, whereas the dorsal division originates on the cucullaris. These muscles insert onto each other and their respective hyoid constrictors, and they compress the gills (**Figures 9–11** and **Table 3**). Laterally, the branchial trematic constrictor originates under the propterygium, inserts onto the superficial branchial constrictors, and also compresses the gills. The interbranchial muscles originate on the coracohyoideus and coracohyomandibularis, and insert onto and adduct the gill arches. The cucullaris originates on the scapulocoracoid, inserts on the fifth dorsal superficial branchial constrictor, and elevates the pectoral fin (**Figure 9** and **Table 3**). Although not found in *R. percellens*, many batoids possess branchial adductor muscles that originate and insert upon the epibranchial and ceratobranchial cartilages, and adduct these structures.

The hypobranchial muscles include the coracoarcualis, coracohyoideus, coracomandibularis, and coracohyomandibularis. The coracoarcualis originates on the scapulocoracoid cartilage, and provides support for the origin of the coracohyoideus and coracomandibularis muscles, assisting these muscles in abducting the oropharyngeal

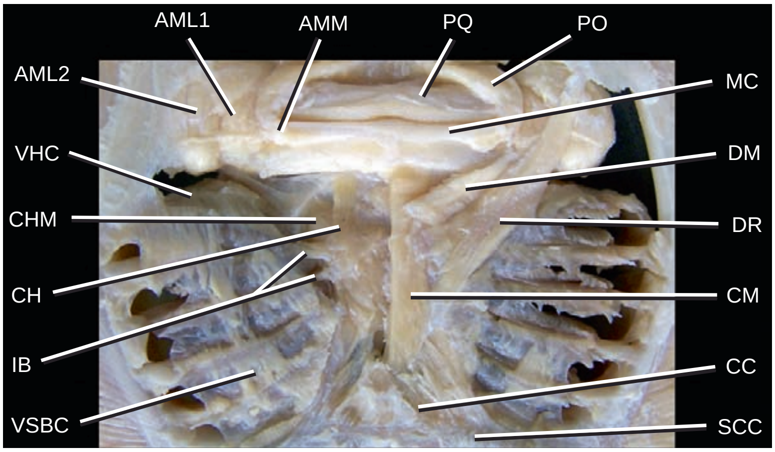

Figure 11 Close-up of the branchiomeric and hypobranchial cranial muscles of the southern guitarfish *Rhinobatos percellens* in ventral view. See **Table 1** for abbreviated terms.

cavity (**Figures 10** and **11**, and **Table 3**). The coracohyoideus and coracomandibularis insert onto, and abduct, the basihyal cartilage and lower jaw, respectively (**Figures 10** and **11**, and **Table 3**). The coracohyomandibularis originates along the hypobranchial musculature and raphe ventral to the gill arches, and it inserts through a tendon onto the hyomandibulae, further aiding the depressor hyomandibularis in abducting the structures (**Figures 10** and **11**, and **Table 3**).

Holocephalan Musculature

The epibranchial muscles of holocephalans fishes originate upon the epaxial muscle mass and insert onto the chondrocranium (**Figures 12–14** and **Table 4**). They contribute minimally to cranial elevation owing to the relatively akinetic cranial skeleton of holocephalans. The branchiomeric muscles of the mandibular arch include the labialis anterior, intermandibularis, levator anguli oris anterior and posterior, and adductor mandibulae anterior and posterior. The labialis anterior originates, and inserts upon, the premaxillary and superior maxillary cartilages, respectively. The intermandibularis originates upon the inferior maxillary cartilage and inserts onto the premandibular cartilages, a pair of fibrocartilaginous masses located at the lower jaw symphysis (**Figure 12** and **Table 4**). Contraction of these muscles protracts the upper and lower sets of labial cartilages. The levator anguli oris anterior and posterior muscles originate upon the antorbital crest of the chondrocranium and insert onto the superior maxillary cartilage, from where they retract the labial cartilages via a series of ligamentous attachments (**Figure 12** and **Table 4**). Deep to the levator anguli oris muscles, the adductor mandibulae anterior has a broad origin across the surface of the preorbital region of the chondrocranium. It is the primary jaw adductor and inserts via a stout tendon that wraps beneath the lower jaw. The adductor mandibulae posterior originates upon the suborbital ridge of the chondrocranium and its tendon merges with that of the adductor mandibulae anterior (**Figures 13** and **14**, and **Table 4**).

Branchiomeric muscles of the hyoid arch include the dorsal and ventral opercular constrictors, levator hyoideus, and interhyoideus muscles. The dorsal opercular constrictor originates from the vertebral column and pectoral girdle. The ventral opercular constrictor originates via the midventral raphe on the ventral surface of the pharyngeal cavity and inserts with the dorsal division onto the tendinous sheath overlying the opercular flap from where they compress the pharyngeal cavity (**Figure 12** and **Table 4**). The levator hyoideus originates from the ventral surface of the chondrocranium beneath the orbit and inserts onto the epihyal cartilage (**Figures 13** and **14**, and **Table 4**). The interhyoideus originates upon the symphysis of the lower jaw and inserts onto the ceratohyal cartilages (**Figure 13** and **Table 4**). These muscles abduct the hyoid arch. The

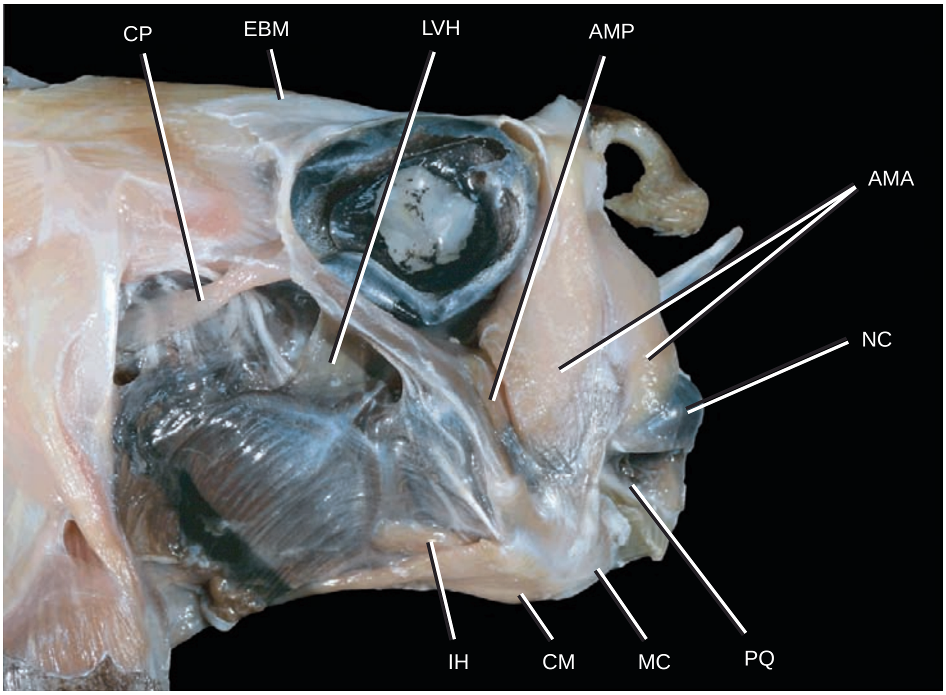

Figure 13 Epibranchial and deep branchiomeric cranial muscles of the spotted ratfish *Hydrolagus colliei* in lateral view. See **Table 1** for abbreviated terms.

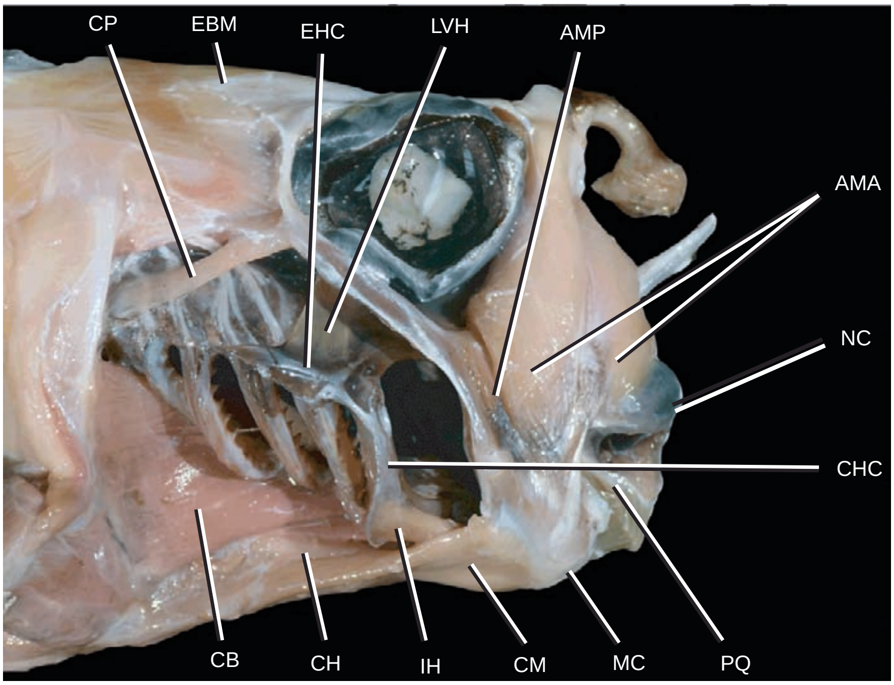

Figure 14 Epibranchial, deep branchiomeric, and hypobranchial cranial muscles of the spotted ratfish *Hydrolagus colliei* in lateral view. See **Table 1** for abbreviated terms.

levator hyoideus may assist in returning the hyoid arch to its resting position following a gape or respiratory cycle.

Branchiomeric muscles of the branchial arches include the constrictor branchialis, adductor arcuum branchialium, cucullaris superficialis, and cucullaris profundus. The constrictor branchialis originates, and inserts upon, the epibranchial and ceratobrancial cartilages of the first three branchial arches, respectively. The adductor

Table 4 Origins, insertions, and actions of the cranial muscles of Holocephalans

Muscle	*Origin*	*Insertion*	*Action*
Adductor arcuum branchialium	Epibranchial, pharyngobranchial cartilages	Ceratobranchial cartilage	Adduct gill arch
Adductor mandibulae anterior	Chondrocranium	Meckel's cartilage	Adduct lower jaw
Adductor mandibulae posterior	Chondrocranium	Meckel's cartilage	Adduct lower jaw
Constrictor branchialis	Epibranchial cartilag	Ceratobranchial cartilage	Adduct gill arch
Constrictor operculi dorsalis	Vertebral column, pectoral girdle	Tendinous sheath of operculum	Compress phayrngeal cavity
Constrictor operculi ventralis	Midventral raphe	Tendinous sheath of operculum	Compress phayrngeal cavity
Coracobranchialis	Pectoral girdle	Ceratobranchial cartilages	Abduct branchial arches
Coracohyoideus	Coracomandibularis	Basihyal cartilage	Abduct hyoid arch
Coracomandibularis	Pectoral girdle	Meckel's cartilage	Abduct lower jaw
Cucullaris profundus	Chondrocranium	Pectoral girdle	Elevate and rotate pectoral girdle
Cucullaris superficialis	Chondrocranium	Pectoral girdle	Elevate and rotate pectoral girdle
Dorsal oblique	Chondrocranium	Eyeball	Rotate eyeball
Dorsal rectus	Chondrocranium	Eyeball	Rotate eyeball
Epibranchial	Epaxialis	Chondrocranium	Elevate chondrocranium
Interhyoideus	Meckel's cartilage	Ceratohyal cartilage	Abduct hyoid arch
Intermandibularis	Inferior maxillary cartilage	Premandibular cartilage	Protract labial cartilages
Labialis anterior	Premaxillary cartilage	Superior maxillary cartilage	Protract labial cartilages
Lateral rectus	Chondrocranium	Eyeball	Rotate eyeball
Levator anguli oris anterior	Chondrocranium	Superior maxillary cartilage	Retract labial cartilages
Levator anguli oris posterior	Chondrocranium	Superior maxillary cartilage	Retract labial cartilages
Levator hyoideus	Chondrocranium	Epihyal cartilage	Elevate epihyal cartilage
Medial rectus	Chondrocranium	Eyeball	Rotate eyeball
Ventral oblique	Chondrocranium	Eyeball	Rotate eyeball
Ventral rectus	Chondrocranium	Eyeball	Rotate eyeball

arcuum branchialium has a complex origination from the epibranchial and pharyngobranchial cartilages, and inserts onto the ceratobranchial cartilages of the first four branchial arches. Both of these muscles adduct the branchial arches. The cucullaris superficialis and profundus originate upon the postorbital region of the chondrocranium, and insert onto the scapular process of the pectoral girdle, which they elevate and rotate (**Figures 12–14** and **Table 4**).

The hypobranchial muscles of holocephalans include the coracomandibularis, coracohyoideus, and coracobranchialis. The coracomandibularis originates on the coracoid bar of the pectoral girdle, and inserts onto, and abducts the lower jaw (**Figures 12–14** and **Table 4**). The coracohyoideus originates on the coracomandibularis and inserts onto the basihyal cartilage, which it abducts. The coracobranchialis has multiple divisions that originate on the coracoid bar, insert onto the ceratobranchial cartilages, and abduct the branchial arches (**Figure 14** and **Table 4**).

Glossary

Buccal pumping A two-stage cycle of expansion and compression used to generate water flow into the mouth and over the gills for respiration.

Jaw protrusion The anterior movement of the upper jaw or premaxilla. Premaxillary protrusion contributes to the expansive phase of suction feeding and is thought to enhance suction generation compared with species that cannot protrude the jaws.

Key innovation The evolutionary novelties that have a disproportionate effect (overwhelmingly positive) on the subsequent radiation of the species that possess them.

Prey capture The act of entrapping prey within the jaws or buccal cavity such that it will subsequently be ingested; the beginning is kinematically defined as the moment of jaw opening.

Prey processing Those behaviors that follow prey capture that mechanically break down or reposition the food prior to chemical digestion.

Overview

The cranial muscles of bony fishes can be divided into several groups based largely on their anatomical location: cheek muscles, body muscles, ventral cranial muscles, pharyngeal jaw muscles, and muscles associated with the pectoral girdle. This categorization is convenient for describing muscles based on their origins and insertions, but is not terribly informative for understanding functional units. Below are very generalized descriptions of the more common functions performed by or within the head, and those muscles responsible for these functions, including buccal pumping (ventilation), suction feeding, premaxillary protrusion, biting and tearing, and pharyngeal jaw prey processing.

Buccal Pumping

Of central importance to fish survival is respiration. In order for oxygen to be delivered to the tissues, most fishes, excepting those that possess various forms of air breathing organs (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction), must somehow bring water into the mouth and move it over the gills, facilitating the diffusion of oxygen from the water and into the blood. This is often termed gill ventilation.

Some species are able to utilize what is commonly referred to as ram ventilation to ventilate the gills. In ram ventilation, the animal uses forward propulsion and water passively enters the mouth, which is held open. Water continues over the gills, which are similarly abducted to avoid impediments to flow, and exits the opercular openings. A small handful of fishes, such as the tunas and other constantly active species, are obligate ram ventilators and rely on ram ventilation exclusively. This includes some shark species. However, contrary to popular myths, most sharks do not rely on ram ventilation and, therefore, do not need to swim constantly for this purpose.

The vast majority of fish species use buccal pumping for gill ventilation, whereby a current of water is drawn into the mouth and over the gills via actively generated movements of skeletal elements within the head. Benthic and sedentary species often rely exclusively on buccal pumping. Many species can readily alternate between buccal pumping and ram ventilation as conditions and swimming speeds allow.

Buccal pumping is usually described as a two-stage cycle of expansion and compression. Expansion must occur gradually, from anterior to posterior, for a current to be generated in this direction. Thus, buccal pumping can be thought of as an abbreviated form of suction generation as used for capturing aquatic prey (described next). The head of the fish is effectively divided into two chambers divided by the respiratory structures, the gills. The anterior chamber is the oral or buccal chamber, whose volume is controlled largely by mouth opening and hyoid depression. The posterior chamber is the opercular chamber that lies posterior to the gills, controlled by abduction of the gill bars and opercular opening.

During active buccal pumping, mouth opening and hyoid depression are facilitated largely by the sternohyoideus muscle (**Figure 1** and **Table 1**). This is the first stage in the two-stage cycle, and water is drawn into the mouth during this stage. Stage 2 consists of opercular expansion caused by contraction of the levator operculi and the dilatator operculi (**Figure 1**). During this second stage, water flows over the branchial arches and into the opercular region where it then exits. Note that the branchial arches are expanded as water flows from the anterior chamber of the mouth into the branchial apparatus and out the operculi. Much of the expansion of the branchial apparatus is thought to be passive, facilitated by the water itself. However, during very active ventilation, the pectoral girdle (via contraction of the hypaxial musculature) and ventral branchial muscles may be actively engaged to assist in expanding this region more fully (**Figure 2**).

During mouth opening, or stage 1, the branchial arches must be actively compressed and the operculi held closed in

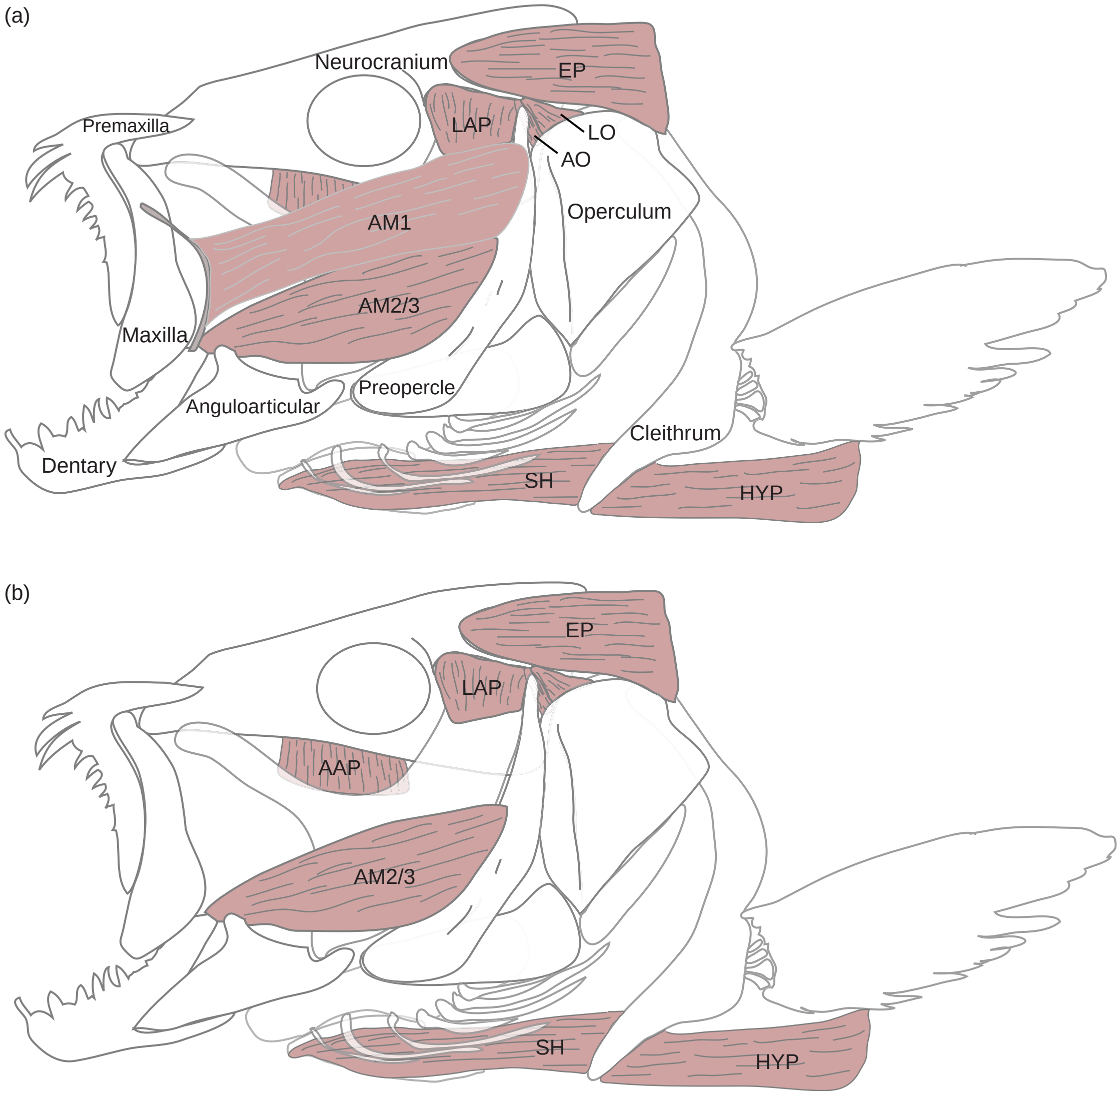

Figure 1 Musculature of the body and cheek region for a highly generalized teleostean fish. (a) The more superficial muscles. (b) The AM1 has been removed to reveal more clearly the more deeply situated AAP. Key bony elements are labeled for orientation. Muscle abbreviations present in the figure are explained in **Table 1**.

Table 1 Generalized list of muscles typically found in the heads of bony fishes, or that contribute to behaviors associated with the head, such as nearby body musculature

Muscle group	*Muscle (abbreviation as in figures)*	*Origin*	*Insertion*	*Function*
Body muscles				
	Epaxials (EP)		Back of neurocranium	Cranial elevation, as in the expansive phase of suction feeding and in some forms of premaxillary protrusion.
	Hypaxials (HYP)		Pectoral girdle/cleithrum	
Cheek muscles				
	Adductor mandibulae 1 (AM1)	Preopercle	Lower jaw and sometimes the upper jaw	Jaw closure, as in the compressive phase of suction feeding, biting, or oral jaw processing.
	Adductor mandibulae 2 (AM2)	Preopercle and suspensorium	Dentary and/or anguloarticular	Jaw closure, as in the compressive phase of suction feeding, biting, or oral jaw processing.
	Adductor mandibulae 3 (AM3)	May be shared with AM2	Medial side of the articular	Jaw closure, as in the compressive phase of suction feeding, biting, or oral jaw processing.
	Levator arcus palatini (LAP)	Posterior neurocranium (e.g., sphenotic and frontal)	Hyomandibula	Lifts the hyoid complex, as in the expansive phase of suction feeding
	Levator operculi (LO)	Postorbital region of the neurocranium	Opercle	Opercular expansion, as in during ventilation and in the expansive phase of suction feeding.
	Dilatator operculi (DO)	Posterolateral edge of neurocranium	Opercle	Opercular expansion, as in during ventilaton and in the expansive phase of suction feeding
	Adductor arcus palatini (AAP); Adductor hyomandibula	Parasphenoid and prootic	Hyomandibula and metapterygoid	Head compression, as in the preparatory and compressive phases of suction feeding.
	Adductor operculi (AO)	Auditory region of the neurocranium	Opercle	Opercular compression, as in the preparatory phase of suction feeding.
Ventral muscles				
	Intermandibularis (IM)	Ventral midline between dentaries	Dentaries	Slight medial adduction of dentaries
	Geniohyoideus (GH)/Protractor hyoideus (PH) (considered synonyms)	Hyoid arch	Dentaries	Primarily expansive role during suction feeding. May show division of labor and contribute to both mouth opening and closing, as in during ventilation.
	Hyohyoideus (HYH)	Ventral midline or urohyal	Hyoid arch	Maintains tension on the hyoid arch.
Branchial arch muscles				
	Levators interni and externi (LI, LE)	Posterolateral edge of neurocranium	Epibranchials	Brace and lift branchial arches
	Transversi ventrales (TV)			Connect the right and left sides of the branchial arches ventrally for stabilization.
	Adductorbranchialis (AD)	Epibranchials	Ceratobranchial	Connects dorsal and ventral portions of the branchial arches for compression

(*Continued*)

Table 1 (Continued)

Muscle group	*Muscle (abbreviation as in figures)*	*Origin*	*Insertion*	*Function*
Pharyngeal Jaw muscles				
	Levator internus 3 (LI)	Neurocranium	Upper pharyngeal jaw, typically pharyngobranchial 3	Elevates and moves the upper pharyngeal jaw anteriorly, serving to protract the jaws.
	Levator externus 4 (LE 4)	Neurocranium	Epibranchial 4	In most conformations causes EB4 to rotate, thereby depressing the upper pharyngeal jaw.
	Levator posterior (LP)	Neurocranium	Generally epibranchial 4; ceratobranchial 5 in some species	Action supplements levator externus 4
	Obliquus dorsalis (OD)	Pharyngobranchial 3	Epibranchial 4	Connects PB3 and EB4 dorsally, allowing flexion at the joint between PB3 and EB4
	Obliquus posterior (OP)	Epibranchial 4	Ceratobranchial 5	Pulls EB4 ventrally
	Retractor dorsalis (RD)	Anterior vertebrae	Epibranchial 4	Retracts entire pharyngeal jaw apparatus posteriorly
	Pharyngocleithralis internus (PCI)	Pectoral girdle	Posterioventral portion of the lower pharyngeal jaw, ceratobranchial 5	Rocks the lower pharyngeal jaw posteriorly during prey processing.
	Pharyngocleithralis externus (PCE)	Pectoral girdle	Anteroventral portion of ceratobranchial 5	Rocks the lower pharyngeal jaw anteriorly during prey processing, serving to open the jaws.
Muscles associated with the pectoral girdle				
	Sternohyoideus (SH)	Cleithrum	Urohyal	Hyoid and lower jaw depression, as in ventilation and the expansive phase of suction feeding.
	Protractor pectoralis (PP)	Hypaxial musculature	Cleithrum	Protraction of the pectoral girdle, assists in hyoid and lower jaw depression

The typical conformation is provided, though interesting and/or common deviations may be noted.

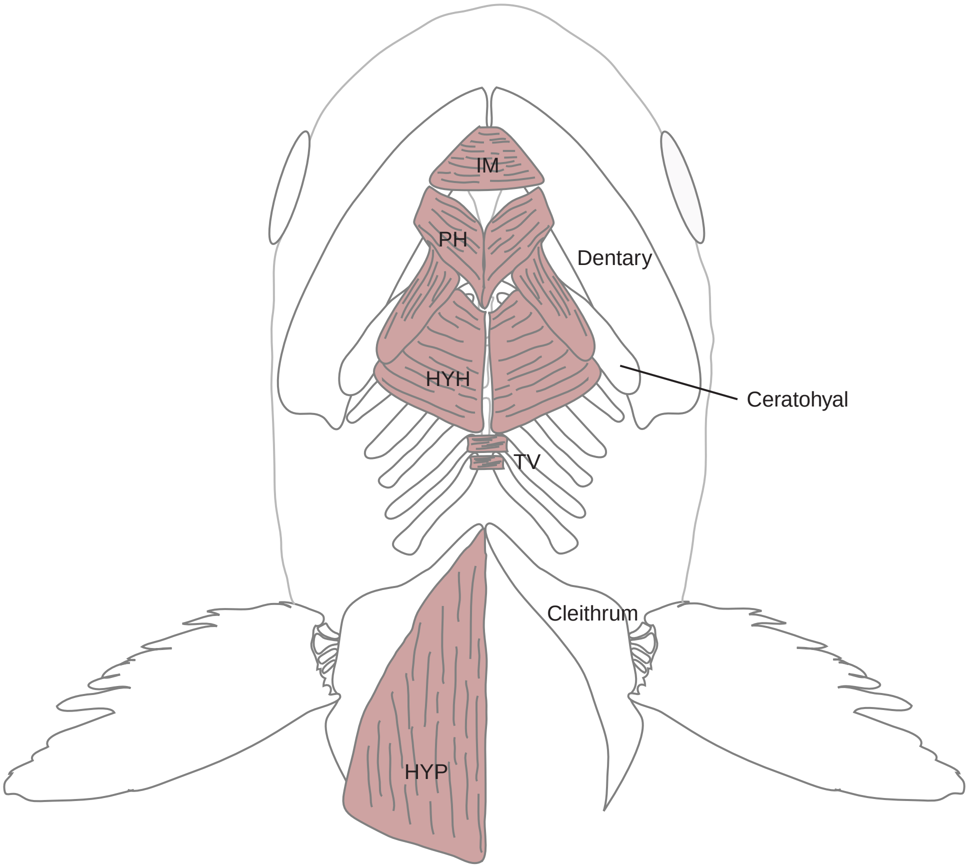

Figure 2 Ventral musculature for a highly generalized teleostean fish. Key bony elements are labeled. Muscle abbreviations present in the figure are explained in **Table 1**.

order to prevent water from entering at the gills and flowing in the wrong direction, from posterior to anterior. Such movement of the gills is due to activation of the levators externus, internus, and posterior (**Figure 3**(**a**)), which pull and contract the branchial basket dorsally. Moreover, the adductors bring the ventral portion of the basket toward the dorsal portion. This action is assisted by the muscles that compress the buccal chamber by moving the operculi medially and essentially holding them closed, mainly the adductor operculi. Similarly, during stage 2, when the branchial and opercular regions are open and expanded, the mouth must be closed again so that water moves posteriorly and does not exit the open mouth. Mouth closure is the role of the adductor mandibulae complex (see **Figure 1**).

Though the above describes the dominant mechanism among fishes, there are extensive variations on this theme. For example, during periods of shallow or very calm ventilation, the muscles associated with jaw opening are scarcely active or not active at all. Relaxation of the adductor mandibulae complex will cause the mouth to open slightly, as anyone who has held a recently anesthetized or euthanized fish can attest, and this degree of opening is sufficient for generating a small current of water into the mouth when oxygen demand is suitably low. Similarly, while the maintenance of an anterior to posterior current of water through the head is necessary for maximizing oxygen extraction at the gills, many species show periods where this current is slowed or even reversed, particularly elasmobranchs. This is also almost certainly linked with periods of low oxygen demand.

Fishes will also cough to clear the gills of noxious substances or irritants, or simply to remove excess particles or mucus. A fish cough is essentially the movements outlined here in reverse.

Suction Feeding

Suction feeding is the primary mode of prey acquisition for aquatic species. Suction feeding consists of the generation of currents of water into the head, hopefully with a prey item or items entrained in the flow (**see also Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics). Suction is a highly flexible mode of aquatic prey capture that works on a wide variety of unattached prey items, and even some attached prey. It is

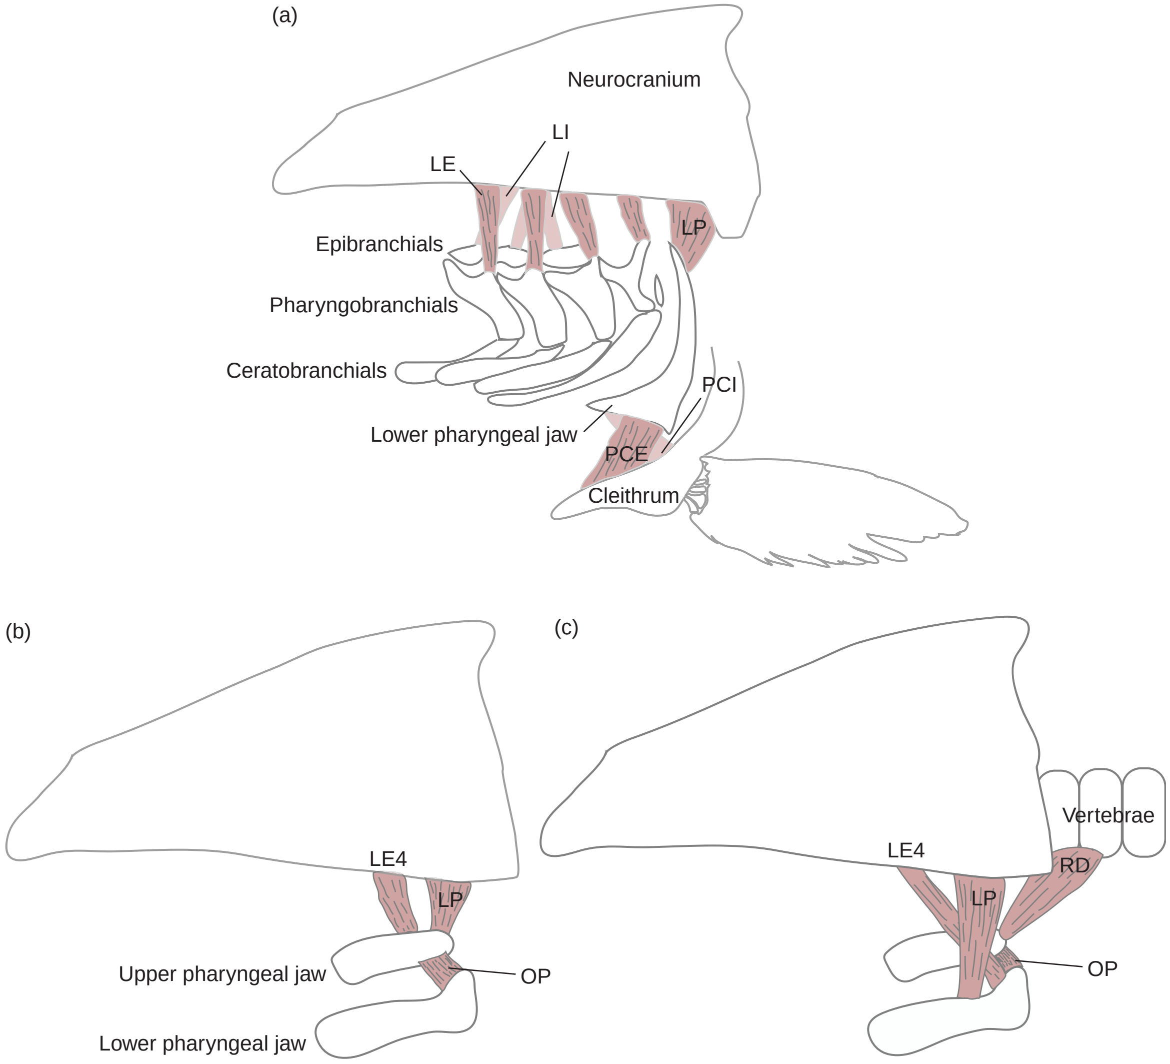

Figure 3 Branchial and pharyngeal jaw muscles. (a) The pharyngeal jaw configuration of a typical cyprinid is shown, and the muscles associated with the remainder of the branchial apparatus are also included (which are broadly consistent among teleosts). Note the pharyngeal sling, composed of the levator posterior muscle, associated with most cyprinids. (b) A stereotypical pharyngognath condition is indicated with upper and lower pharyngeal jaws shown. (c) The specialized pharyngeal sling is shown, formed by the LP and LE4, as found in the labrid fishes. The positions of other muscles in (c) are fairly general among pharyngognath fishes. Key bony elements are labeled. Muscle abbreviations present in the figure are explained in **Table 1**.

especially useful for compensating for forward locomotion of the predator. In the dense and viscous aquatic medium, forward movement creates a bow wave in front of the predator that serves to inadvertently push the desired prey item farther away from the mouth. The alternative to suction feeding is ram feeding, whereby the predator swims forward with an open mouth sufficiently large to engulf the prey and to redirect or overcome any bow wave effects. Suction is only effective a short distance from the mouth, again, because of the physical properties of the aquatic medium. Therefore, suction is often used in combination with ram feeding, biting, scraping, or any number of other feeding behaviors that essentially place the mouth close enough to the intended food item for suction to be utilized.

The hallmark of suction generation is the creation of a current of water moving through the head in an anterior to posterior direction. This behavior is massive and rapid, sometimes described as ballistic, and therefore there are typically none of the inefficiencies described above for ventilation. The generation of this current is broken into four phases, each characterized by a suite of muscle activity. These are the preparatory, expansive, compressive, and recovery phases.

The preparatory phase of suction feeding can essentially be thought of as a phase during which the head is compressed slightly. This phase is present in many, but not all feeding events, and is performed in order to expel any water remaining in the buccal and opercular cavities in preparation for the massive expansion that will occur next. The jaws are closed via the adductor mandibulae complex (**Figure 1**), the head is compressed medially via the adductor arcus palatini, the opercular region is similarly compressed via the adductor operculi. This compression is used to create a relatively negative space, compared with ambient pressure, such that when the mouth is opened during the expansive phase, water will rush in.

The massive and rapid expansive phase is typically characterized by contraction of the sternohyoideus to depress the lower jaw, and the levator arcus palatini to expand the hyoid apparatus (**Figure 1**). As in ventilation, activity may be seen in the hypaxial musculature as well as the protractor hyoideus (also referred to as the geniohyoideus) and the hyohyoideus (**Figure 2**). While these muscles are working to open and expand the mouth and ventral region of the head, the epaxial (body) musculature is commonly recruited for rotating the neurocranium dorsally, thereby expanding the head even further (**Figure 1**). The head is expanded laterally via the contribution of the levator operculi as well as the dilatator operculi. Moreover, the levator operculi has been implicated in mouth opening via the linkage of several opercular elements. Expansion at the opercular region tends to occur slightly later than mouth opening or cranial rotation in order to maintain the anterior to posterior wave of expansion so prevalent in suction feeding, and putatively required to generate the anterior to posterior flow of water into the head. The prey item is effectively captured, or not, during the expansive phase.

The compressive phase follows the expansive phase and during this time the prey item is retained in the oral cavity, while the water that was taken in with the prey is slowly ejected. Therefore, this phase is much like the preparatory phase. The jaws are closed via the adductor mandibulae complex on or around the prey and the head is compressed medially via the adductor arcus palatini. Water may exit the mouth if the food item is held in the jaws and mouth closure is prevented. However, most of the water is directed out of the operculi and the dilatator operculi holds the operculi open (**Figure 1**).

The recovery phase is a period of time characterized by little to no muscular activity, as all of the functional units within the feeding apparatus are returning to their prefeeding positions. This stage may contain prolonged or residual activity of the dilatator operculi as the operculi are being held open for the continued expulsion of water within the head. This stage may be abbreviated depending on the degree to which subsequent transport events are used for moving the prey out of the mouth and into the esophagus. Prey transport is not treated specifically here; however, many studies note that it is a full-body behavior engaging the epaxial and hypaxial musculature of the body (**Figures 1** and **2**).

Premaxillary Protrusion

Premaxillary protrusion is an important element of the expansive phase of suction feeding present in many teleostean lineages. However, it has received so much attention in the literature that it will be treated separately here from the standpoint of the different muscles necessary to create this movement. Indeed, premaxillary protrusion is thought to be a key innovation in fishes responsible, at least in part, for the incredible radiation of fishes into the most diverse group of vertebrates. Various studies suggest that this mechanism has evolved independently a number of times. All of the mechanisms commonly employed result in the protrusion of the premaxilla anteriorly or antero-ventrally, and this is thought to enhance suction production through the creation of a smaller, tubular mouth opening (**see also Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics for the specific biomechanical and hydrodynamic consequences of this).

The primary mechanism of premaxillary protrusion relies on lower jaw depression as the input force, and therefore activation of the sternohyoideus (**Figure 1**). Forces from the lower jaw are transferred largely through ligamentous connections to the maxilla, and from there to the premaxilla. The twisting-maxilla model is similar with the addition of rotation or twisting of the maxillae along their long axes in response to lower jaw depression. This places tension on the heads of the maxillae, where they articulate with the premaxillae, and the premaxillae are effectively projected anteriorly. The forces created by depression of the lower jaw are likely supplemented by contributions from cranial elevation, therefore activation of the epaxials. As the cranium is rotated dorsally and posteriorly, ligamentous tension on the premaxilla causes it to effectively slide off the cranium and be protruded anteriorly. The cranial elevation model may work in lieu of, or more typically in combination with, the lower jaw depression model.

Biting/Tearing

Biting and tearing behaviors are often employed to obtain food items that are attached or otherwise part of items too large to be taken into the mouth fully. As mentioned above, biting or tearing may occur in lieu of suction production, as food items are not affected by suction. Or, suction may be subsequently employed to move the dislodged or detached bit of food into the mouth. In species specialized for biting jaw closing muscles are often hypertrophied. These changes represent a trade-off in that the same muscles cannot simultaneously be optimized for force and speed.

Muscles with a broad cross-sectional area are good for force production (because force that can be produced by a muscle area is proportional to its cross-sectional area), while elongate muscles are good for speed. Given that suction is a rapid movement, many species specialized for biting are no longer capable of producing notable suction (though a marginal amount of suction seems possible by virtually any species just by virtue of opening the mouth under water). Bite strength strongly depends on those muscles associated with mouth closure, or the adductor mandibulae complex (**Figure 1**). Activity of the adductor mandibulae complex will tend to alternate with those muscles associated with jaw opening and head expansion: the epaxials, the levator operculi, and the sternohyoideus.

An interesting suite of modifications has arisen in a number of biting lineages, and several of these have evolved multiple times in independent lineages suggesting that they are adaptations to specific feeding challenges posed by different forms of biting. For example, a number of biting and scraping species possess a novel joint within the lower jaw called an intramandibular joint (IMJ). We have yet to determine what specifically controls this joint, be it portions of the adductor mandibulae or perhaps the protractor hyoideus (geniohyoideus), or even if movement at the joint is active or passive. Anatomical studies suggest that there is enough variation among groups that possess this joint, such as some scarids, some pomacanthids, some kyphosids, and some poeciliids, that there is likely more than one mechanism. Similarly, biting species that show complex behaviors for prey processing within the oral jaws, such as winnowing or chewing, sometimes show muscle duplications of the adductor mandibulae complex, as in the case of the tetraodontiform fishes. These duplications may allow for finer control of the mechanism when the muscles are activated individually, as well as a stronger bite when they are activated synchronously.

Pharyngeal Jaw Processing

Most perciform fishes, as well as a handful of other teleostean lineages (notably the cypriniforms), possess modified branchial elements co-opted as a second set of jaws, the pharyngeal jaws (for additional reading see Wainwright). These pharyngeal jaws consist of tooth plates fused typically to pharyngobranchial 3 (the upper pharyngeal jaw, with epibranchial 4) and ceratobranchial 5 (the lower jaw). The pharyngeal jaw apparatus (PJA) is largely responsible for prey-processing behaviors such as chewing and raking, which follow prey capture and mechanically break down the food prior to chemical digestion. When the PJA is present, the oral jaws tend to give up this role and thus the pharyngeal jaws can represent a second, decoupled source of evolutionary innovation related to feeding. Alternatively, the oral jaws can become specialized for prey acquisition while the pharyngeal jaws become specialized for prey processing.

In most fishes it is the upper pharyngeal jaw that is mobile through the action of the pivoting epibranchial bone. It can move in a circular or even figure-8 pattern, with motion in all three dimensions, as it is protracted and retracted, contacting the more (although not entirely) immobile lower pharyngeal jaw as it sweeps past. The protraction of the upper pharyngeal jaw, typically pharyngobranchial 3, is caused by the levator internus associated with this pharyngobranchial (**Figure 3**). Depression is facilitated by the levator externus (4) and the levator posterior (**Figure 3**(**b**)). The levator externus (4) causes the modified epibranchial 4 to pivot, thereby placing force on pharyngobranchial 3 and depressing it. Epibranchial 4 and pharyngobranchial 3 form a joint via the connection of the obliquus dorsalis, and the pivot motion of epibranchial 4 is aided by the obliquus posterior. Retraction of the upper jaw is facilitated largely by the retractor dorsalis (**Figure 3**(**c**)). The lower jaw is typically more restricted in its movement, as it is often more strongly associated with the pectoral girdle. The pharyngocleithralis internus serves to move the lower pharyngeal jaw posteriorly, useful for raking and scraping, and the pharyngocleithralis externus moves the lower jaw anteriorly, thereby contributing to jaw opening.

There is great variation in the elaboration of the PJA. Oddly, cypriniforms have lost the upper pharyngeal jaws and generally use a greatly hypertrophied ceratobranchial 5 (the lower pharyngeal jaw) to masticate against an enlarged basioccipital process (as shown in **Figure 3**(**a**)). Moreover, they have evolved a very large muscular sling (largely composed by the levator posterior whose insertion is believed to have changed) that suspends the lower pharyngeal jaws. Notably, the labrids have convergently evolved a muscular sling that supports the lower pharyngeal jaw and allows for extensive movement (shown in **Figure 3**(**c**)).

Glossary

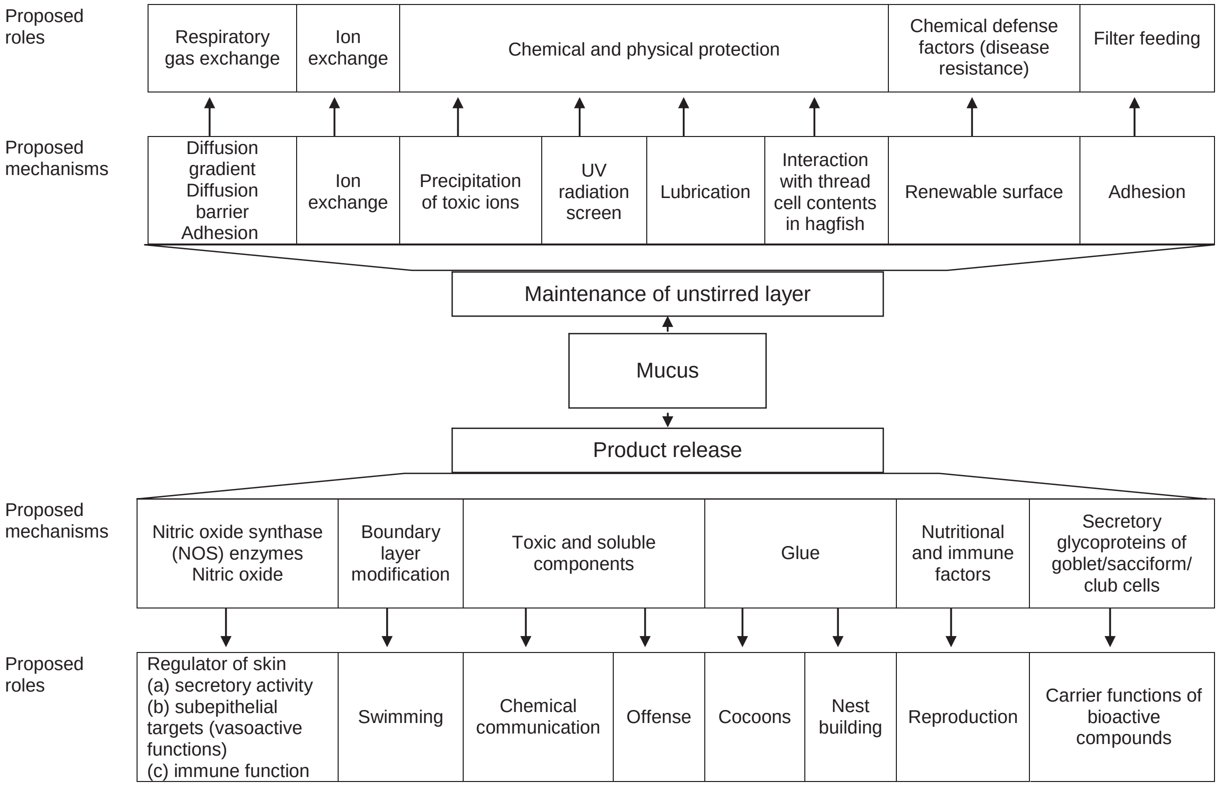
Bioactive substance A substance that has an effect on living tissue.
Integument The organ system that covers the external surfaces of a fish's body, including the fins. The integument is comprised of the epidermis and dermis of the skin (including scales, when present), and also includes skin extensions such as barbels and flaps.
Keratinization Process in which the cytoplasm of the outermost epidermal cells is replaced by keratin, a fibrous structural protein that is tough and insoluble when assembled in bundles. Keratinization of the outer skin layers is common in terrestrial vertebrates but uncommon in fishes.
Mucus (adj. mucous) A slippery secretion produced by, and covering, the skin and other mucous membranes of fish. Mucus is elaborated by goblet cells and other cells in fish epidermis, and is comprised of glycoproteins (mucins) and other substances.
Pheromone A secreted or excreted chemical factor that triggers a social response in members of the same species.

Introduction

The integument or skin of fishes has both important similarities to and important differences from the integument of other vertebrates (**see also The Skin**: Functional Morphology of the Integumentary System in Fishes). For fish, as for other vertebrates, the integument is the body envelope that not only separates and protects the animal from its environment, but also provides the means through which most of the contacts with the outer world are made. Fish integument is a large organ that is continuous with the lining of all the body openings, and also covers the fins. In addition to its protective functions, fish skin may serve important roles in communication, sensory perception, locomotion, respiration, ion regulation, excretion, and thermal regulation.

Protection

Numerous integumentary adaptations have evolved for protecting fishes in their aqueous environment. For example, mucous secretions (**Figure 1**) help to keep the skin surface free of pathogens by means of continual sloughing



Proposed roles

Reproduction
Carrier functions of bioactive compounds

Figure 1 Some of the numerous roles suggested for fish mucus, divided into roles that involve the production and maintenance of a layer of mucus surrounding the fish, and roles that involve the release of mucus and associated substances into the surrounding water. Mucus components are produced by a variety of cells in fish epidermis (**see also The Skin**: Functional Morphology of the Integumentary System in Fishes). Modified from Fig. 1 in Shephard KL (1994) Functions for fish mucus. *Reviews in Fish Biology and Fisheries* 4: 401–429, with permission from Springer; and from Fig. 10 in Zaccone G, Kapoor BG, Fasulo S, and Ainis L (2001) Structural, histochemical and functional aspects of the epidermis of fishes. *Advances in Marine Biology* 40: 253–348.

and renewal, and the presence of antimicrobial substances such as fatty acids, immunoglobulins, complement components, lectins, lysozyme, proteolytic enzymes, and other antimicrobial peptides and proteins. Through precipitative action, mucus may also help to clear suspended material from the gills and skin of fish in highly turbid or polluted waters. Research suggests that mucus of tropical reef fishes contains compounds that can absorb ultraviolet (UV) radiation and may function in screening out both UVA and UVB radiation. Certain tropical parrotfish and wrasse species (Labridae) secrete a mucous cocoon that surrounds their bodies at night; this envelope may provide protection against predators that hunt by smell or touch and may also have antimicrobial properties. In addition, mucous secretions and thickened (or rarely, keratinized) outer skin layers assist in protection against abrasion in burrowing or semiterrestrial fishes, for example, the cocoon of aestivating lungfishes (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction and **The Skin**: Hagfish Slime).

By means of their motility, nonkeratinized epithelial cells (**see also The Skin**: Functional Morphology of the Integumentary System in Fishes) serve as a key component of the unique wound repair mechanism of fish integument. Within seconds or minutes after an injury occurs, epithelial cells at the edges of the wound begin to migrate toward the wound cavity in groups, retaining contacts between the cells as they migrate. These cells quickly cover the wound and provide a mechanical barrier against infection by opportunistic pathogens from the surrounding water during the early stages of wound repair. Closure of a wound by migrating epithelial cells occurs at a rate as fast as $5-12\,\mu\mathrm{m\,min}^{-1}$ in teleosts, with complete closure occurring within a few hours to a few days. The actual rate of wound closure depends on various factors including water temperature, the size and severity of the wound, and perhaps the fish species. Nevertheless, *in vitro* studies indicate that fish epithelial cells are among the fastest migrating cells known, moving at a speed 10–20 times faster than mammalian fibroblast cells.

In addition to providing wound coverage, migrating epithelial cells may help to protect the skin surface from pathogen invasion by means of phagocytic activity. These cells may help to eliminate foreign matter from the integument by a process in which cells that become filled with foreign matter subsequently are sloughed from the skin surface. In addition, uptake and sequestration of foreign material, such as pathogens, by epithelial cells may play a role in the development of local immunity in the integument.

Epithelial cell proliferation (hyperplasia) that results in epidermal thickening is another protective response frequently observed in fish. Epidermal hyperplasia has been reported in fish infested with skin parasites or exposed to pollutants, but may also occur at times that fishes are exposed to increased skin abrasion, as during spawning activity. Although not considered part of the integument proper, the specialized gill epithelium of teleost fishes appears to be particularly adapted to mounting this type of protective response (**see also Ventilation and Animal Respiration**: Plasticity in Gill Morphology).

Scales (**see also The Skin**: Functional Morphology of the Integumentary System in Fishes) provide mechanical protection for deeper tissues, and bony encasements and spines discourage attacks by predators. Noxious substances elaborated by specialized cells in the skin (**see also The Skin**: Functional Morphology of the Integumentary System in Fishes) and venoms produced by glands associated with spines on the fins or opercula can also help to dissuade such attacks (**Figure 1**).

Wandering leukocytes (white blood cells) are also present in the skin. These cells are important components of both the innate and adaptive immune systems of fishes (**see also Blood**: Cellular Composition of the Blood). Leukocyte numbers in the skin may increase significantly during the healing of skin injuries, certain infectious diseases, or during exposure to pollutants or other stressors.

Protection can also be afforded by patterns of skin pigmentation (**see also The Skin**: Coloration and Chromatophores in Fishes) that help to conceal a fish via cryptic coloration, countershading, or disruptive coloration. Among deep-sea fishes, multiple bioluminescent organs or photophores (**see also The Skin**: Bioluminescence in Fishes) distributed over the body surface can provide camouflage through countershading or by blurring the silhouette of the fish in the glow of spontaneous bioluminescence.

Communication and Sensory Perception

Integumentary pigmentation can also play an important role in intraspecies communication. For example, bright and conspicuous skin coloration may serve to advertise rather than conceal. In fact, most color patterns are a compromise between the necessity to communicate with other members of a species and the need to avoid becoming prey. Chromatophores (pigment cells) in the skin are responsible for much of the remarkable variation in coloration seen in fishes (**see also The Skin**: Coloration and Chromatophores in Fishes). In deep-sea fishes, the photophores in the skin may substitute for color patterns for species and mate recognition. Photophores may also serve as illumination in the darkness of the deep sea, and large light organs on the heads of some fishes may function as lures to attract prey (**see also The Skin**: Bioluminescence in Fishes).

Communication among fishes can be facilitated by substances produced in the integument (**Figure 1**). For example, fright pheromones released into the water from damaged club cells in the skin of some fish species can alert other fish of the same species to the presence of predators (**see also The Skin**: Functional Morphology of the Integumentary System in Fishes and **Hormones in Communication**: Hormonal Pheromones). Several types of specialized sensory structures are located in the integument, including the mechanosensory lateral line system (**see also Hearing and Lateral Line**: Lateral Line Neuroethology), chemoreceptory structures or taste buds (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction), and electrosensory receptors (**see also Detection and Generation of Electric Signals**: Detection and Generation of Electric Signals in Fishes: An Introduction).

Locomotion

Integumentary features of fish can assist in locomotion. The slippery mucus of some fishes has marked friction-reducing properties, enabling them to move at greater speed with reduced expenditure of energy (**Figure 1**). In general, mucus taken from faster swimming predatory fishes has been shown to have better drag-reducing properties than mucus from slower moving species, although there are exceptions. The shape and distribution of scales on a fish may also contribute to drag reduction. In addition, the passive flexural stiffness that the integument provides to the body assists in the generation of the undulatory waves that propel most fishes during swimming.

Respiration, Ion Regulation, and Excretion

The skin is an important accessory organ to the breathing apparatus of some fish species. Gas exchange across the integument plays a significant role in the respiration of larval fish (**see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Respiratory Transitions). In addition, certain adult fishes that are adapted to survive temporary emersion or short terrestrial migrations can utilize atmospheric oxygen via diffusion through a well-vascularized skin (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction). For most adult fish species that have been studied in freshwater or marine environments, cutaneous respiration has been found to match the oxygen demand of the skin itself, indicating that the skin functions as an oxygen exchanger primarily for its own benefit.

The role of the integument in maintaining the balance of water and minerals inside the body of a fish is not well understood. Whereas the skin of the primitive hagfishes and perhaps lampreys is highly permeable to water, the skin of higher fishes is generally believed to have low permeability to both water and ions. Nevertheless, a few studies with teleosts (higher bony fishes) have shown significant transfer of certain ions across the skin surface. The specialized cells (ionocytes) responsible for transepithelial ion transfer in both freshwater and marine species are especially abundant in the gill epithelium and are also found in extrabranchial locations such as the opercular lining skin and external skin (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes).

The function of the integument in excretion has received relatively little attention, but it may have a significant role in the excretion of nitrogenous wastes, principally ammonia and urea. Limited experimentation has suggested that the skin is a more important site of ammonia excretion in marine fishes than in freshwater fishes, although the skin of certain larval freshwater fishes may play a significant role in ammonia excretion (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia). Some evidence also suggests that the integument of marine teleost fishes may be an important site of urea excretion (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia).

Other Functions

Although most fishes are obligate poikilotherms, they display a variety of adaptations to reduce the impact of temperature on physiological function, and some of these adaptations involve the skin. Certain tunas can maintain muscle temperature several degrees above the ambient water temperature through vascular heat exchangers, which include lateral networks of blood vessels originating in the skin (**see also Design and Physiology of Arteries and Veins**: The Retia). Antifreeze proteins are produced by fishes living in the polar oceans; some of these are abundant in the integument and appear to be important for protecting outer tissues from freezing.

In addition to other functions, mucus plays roles in feeding and reproduction of certain fishes (**Figure 1**). Epidermal mucus secreted by parent discus fish (*Symphysodon*) and certain other cichlids provides nutrients for fry that feed on the mucus by nipping at the skin surface of their parents (**see also Social and Reproductive Behaviors**: Nutritional Provision During Parental Care). For some suspension-feeding fishes that filter large volumes of water to extract minute prey such as bacteria and plankton, entrapment of food particles by mucus associated with the gill rakers and mucus-covered oral surfaces is an important component of the feeding mechanism. For certain nest-building fish species, mucus contributes glue for nest construction.

As research on fish integument has progressed, a number of bioactive substances have been identified in mucous secretions (**Figure 1**) or epidermal cells (**see also The Skin**: Functional Morphology of the Integumentary System in Fishes), although the functions of many of these substances in fish are speculative. For example, fish epidermal mucus contains certain forms of nitric oxide synthase (NOS), the enzyme responsible for the production of nitric oxide (NO). NO is a prominent vascular and neuronal messenger that regulates many epithelial functions. The possible regulatory functions of NO in fish integument have not been elucidated, but roles for NO in the regulation of mucus release and blood flow in mammalian epithelia have been suggested.

Research has shown that the scales of teleost fishes represent an important internal reservoir of calcium and that scales can be reabsorbed under certain physiological conditions such as starvation and sexual maturation. Calcium is essential for a number of vital processes such as bone formation, clotting of blood, regulation of enzymatic processes, and modulation of permeability, and excitability of plasma membranes. Mobilization of calcium from fish scales is under hormonal regulation.

In summary, fish skin is a multifunctional organ and its components serve important roles in protection, communication, sensory perception, locomotion, respiration, ion regulation, excretion, and thermal regulation.

Glossary

Club cell A secretory cell present in the middle layers of the epidermis of certain ray-finned fishes that releases its contents (e.g., pheromones) upon epidermal injury and cell membrane rupture.

Cuticle An acellular layer on the skin surface of a fish formed by secretions from epithelial cells, goblet cells, and other cells in the epidermis. The cuticle may contain a variety of protective substances including toxins and antimicrobial compounds.

Dermis The inner layer of the integument, derived from embryonic mesoderm, and consisting largely of fibrous connective tissue with collagen proteins comprising the major component, and also containing blood vessels, nerves, scales, pigment cells, and adipose (fat) tissue.

Epidermis The outer cellular layer of the integument, a multilayered epithelium derived from the ectoderm of the embryo. The basic cellular element common to the epidermis of all fish is the epithelial cell, although a variety of other cell types may be present depending on the fish species.

Elasmoid scale The scale type found on most higher bony fishes (teleosts). The elasmoid scale usually is a thin, flexible transparent structure consisting of a basal plate of collagenous tissue, with superficial mineralization. Elasmoid scales are commonly grouped into two general types, cycloid or ctenoid, based on surface sculpture. Cycloid scales lack surface projections, whereas ctenoid scales have surface projections of various types in the posterior area.

Ganoid scale An ancestral scale type of bony fishes, still present in some primitive ray-finned fishes. In ganoid scales that are least modified from the ancestral type, the scale consists of an osseous (bony) plate covered by a layer of calcified dentine (dentin) and capped by a layer of enamel-like ganoine; the scale is penetrated by canals carrying capillary blood vessels to supply the tissues exterior to the scale.

Goblet cell Unicellular mucin-secreting exocrine gland (also called mucous cell) common to most animal groups, including most fishes. Goblet cells, so-named because of their shape, are found in the epidermis of the skin of fishes as well as in mucous membranes of such organs as the intestine. Integumental goblet cells of fish exhibit holocrine secretion, with cell membrane rupture and release of the cell contents on the skin surface, followed by cell death.

Placoid scale The scale type found on cartilaginous sharks, rays, and chimaeras (Chondrichthyes). The typical placoid scale consists of a flattened, rectangular basal plate and a spine or cusp, with a structure resembling that of a tooth.

Sacciform cell Unicellular gland containing complex secretions, usually with a protein moiety. Unlike club cells, sacciform cells discharge their contents on the skin surface. Sacciform cells of some fish species may secrete alarm pheromones (see club cell), whereas sacciform cells of other species may secrete toxic or repellent substances for antipredator defense.

Introduction

The morphology of fish skin is highly adapted to carry out its multiple functions (**see also The Skin**: The Many Functions of Fish Integument). As in other vertebrates, the integument of all fishes consists of two layers: an outer epidermis and an inner dermis or corium (**Figures 1–4**). The two layers differ in origin, structure, and function. The epidermis is essentially cellular in structure, comprised of a multilayered epithelium derived from the embryonic ectoderm. For the most part, the dermis is a fibrous structure with relatively few cells, and is derived from embryonic mesenchyme of mesodermal origin.

General Morphology

Fish epidermis may vary in thickness depending on species (**Figures 2–4**), age, region of the body, and environmental conditions. In most fish species, the

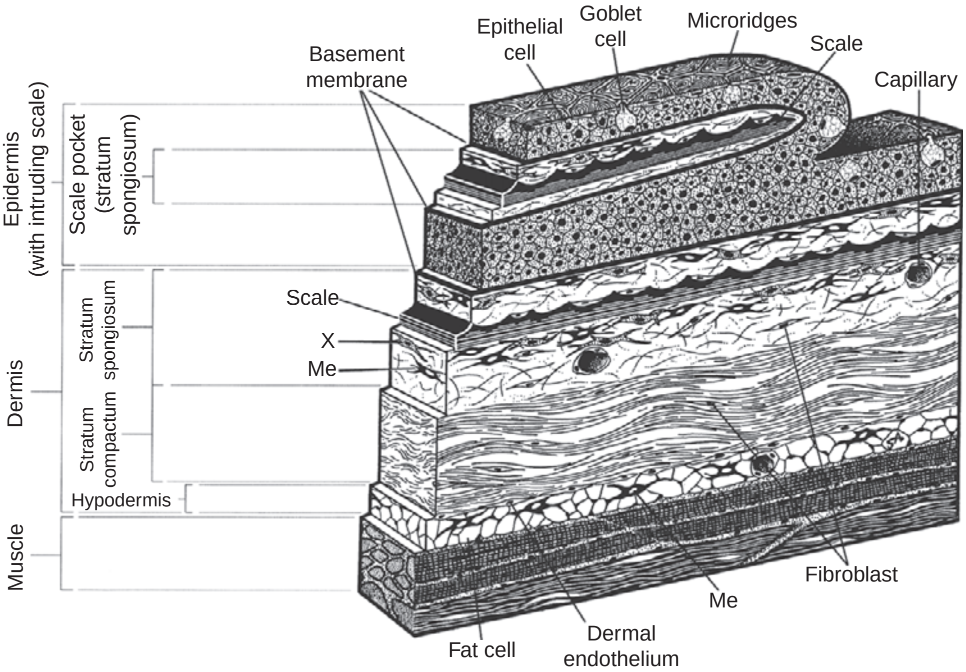

Figure 1 Three-dimensional section of the skin of a teleost fish, the coho salmon *Oncorhynchus kisutch*, showing some of the major morphological features and cell types of the epidermis and dermis. Me, melanophore; X, xanthophore (both are chromatophores or pigment cells). Reproduced from figure 17.1 in Elliott DG (2000) Integumentary system: Microscopic functional anatomy. In: Ostrander GK (ed.) *The Laboratory Fish*, pp. 271–306. London: Academic Press, artist Stewart Alcorn; partly modified from figure 15 in Hawkes JW (1974) The structure of fish skin. II. The chromatophore unit. *Cell and Tissue Research* 149: 159–172.

epidermis is thinner than the dermis. Keratinization of the epidermis to create horny surface layers, characteristic of land vertebrates, is rare among fishes. Instead, fish epidermis is generally metabolically active throughout all its layers. Because the epidermis of most fishes contains little or no pigment and therefore appears largely transparent by visual inspection, the morphological features of this tissue are generally viewed with the aid of a microscope.

The dermis of skin contains blood vessels, nerves, scales, pigment cells, and adipose (fat) tissue, but the bulk of the typical dermal layer is comprised of fibrous connective tissue (**Figure 1**). When a fish is being skinned, the collagenous fibers of connective tissue that bind the skin to the underlying muscle and bone are very obvious. With the exception of scales, morphological characteristics of most dermal features are best observed microscopically.

Scales (**Figures 1**, **3**, and **4**) are an important component of the dermal skeleton, and are the dermal structures that are generally most prominent by visual inspection, although they can vary in size from microscopic structures to huge bony plates. Scales usually are covered completely by epidermal tissue (**Figures 1** and **4**), although portions of scales may protrude from the epidermal surface in certain species such as sharks (**Figure 3**).

Fish scales differ in structure and origin from the horny scales occurring on the skin of reptiles, birds, and some mammals, despite a superficial resemblance to these other scale types. The scales of these other vertebrates (as well as appendages such as feathers, hair, hooves, nails, claws, and quills) consist largely of epidermal tissue of ectodermal origin that has become keratinized. These hard but nonmineralized features are largely comprised of keratins, a family of tough, insoluble fibrous structural proteins. In contrast, fish scales are mineralized dermal structures that are primarily of mesenchymal origin.

The type, number, and size of scales can reveal much information about a fish's lifestyle. On a bony fish, scale patterns can range from a heavy coating of mail-like armor to a few large bony plates on the back, to a dense covering of thin, flexible scales, to a few localized prickles or no scales at all. Large scales modified into bony plates function as protective armor on a number of slow-moving, bottom-oriented fishes such as sturgeons (Acipenseridae), many South American catfishes (Loricariidae, Callichthyidae, and Doradidae), poachers (Agonidae), and pipefishes and seahorses (Syngnathidae). Conversely, the bodies of free-swimming fishes are often covered with typical scales, which provide some protection against mechanical damage without adding too much weight. Fishes that are fast swimmers and those that live in fast-flowing water tend to have numerous fine scales

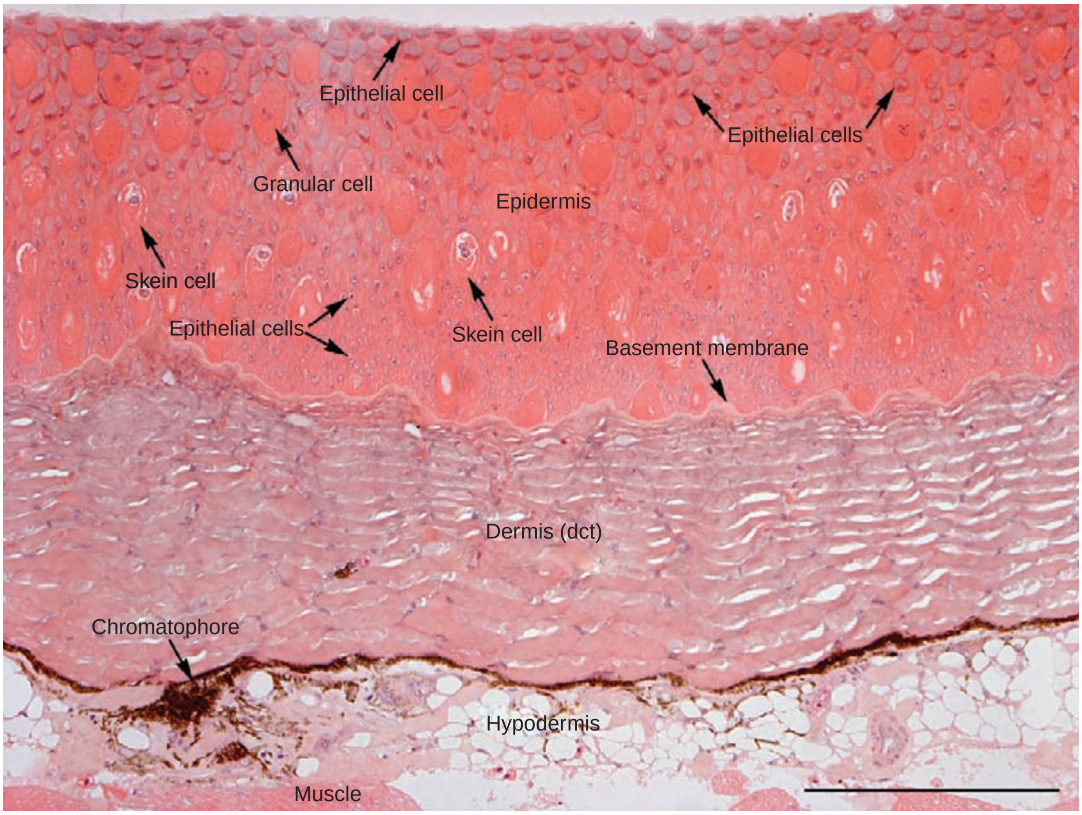

Figure 2 Histological section showing skin morphology of a primitive jawless fish, a spawning adult Pacific lamprey, *Lampetra tridentata*. The outer layer is a thick epidermis, which is separated from the dermis by an acellular basement membrane. Principal epidermal cell types are epithelial cells, secretory granular cells, and modified uninucleate or binucleate cells called skein cells, which may play a role in epidermal tissue support. The dermis of lamprey skin consists of dense collagenous tissue (dct) and lacks scales. The dermis is separated from the underlying skeletal muscle by the hypodermis, which is comprised largely of adipose (fat) tissue. Chromatophores (pigment cells) are visible in the upper hypodermis. Hematoxylin and eosin stain. Scale = 100 μm.

(e.g., trout, **Figure 4**), whereas fishes that live in quiet water and do not continuously swim at high speeds often have rather coarse scales (e.g., perch and carp). Fishes that lack scales are often bottom-dwellers in moving water (e.g., sculpins), fish that frequently hide in tight places such as caves and crevices (e.g., many catfish and eels), or fast-moving pelagic fish (e.g., swordfish and some mackerels). The primitive agnathans or jawless fishes (hagfish and lampreys) are also scaleless (**Figure 2**). However, some fishes that appear scaleless in fact have numerous deeply embedded scales (e.g., most tunas and anguillid eels). This fact emphasizes the importance of microscopy in study of fish skin.

Microscopic Features

There are many features of fish integument that can only be observed microscopically. Because there are almost 28 000 living fishes, mostly teleosts, a great diversity exists in the microscopic morphology of the integument.

Epidermis

The number of cell layers in fish epidermis may vary from two in larval fishes to 10 or more in adults. In pelagic (open-water) fish species, the epidermis is frequently thickest in the dorsal areas of the body, but in benthic (bottom-dwelling) species, the epidermis covering ventral surfaces is often thicker. In some species such as salmonids, the epidermis is often thicker in nonscaled areas, such as the top of the head and the fins, than in scaled areas of the body. The thickness and structure of the epidermis and the types of cells present can also be influenced by the size, condition, sex, and degree of sexual maturation of a fish. In addition, other factors, such as changes in ambient conditions or exposure to adverse environmental conditions, dietary deficiencies, and the presence of pathogens or other stressors, can affect the structure and cellular composition of the epidermis. Such changes may be particularly evident among fish held in captivity.

Principal epidermal cell types

As in the epidermis of other vertebrates, the fundamental structural unit of fish epidermis is the epithelial cell. This

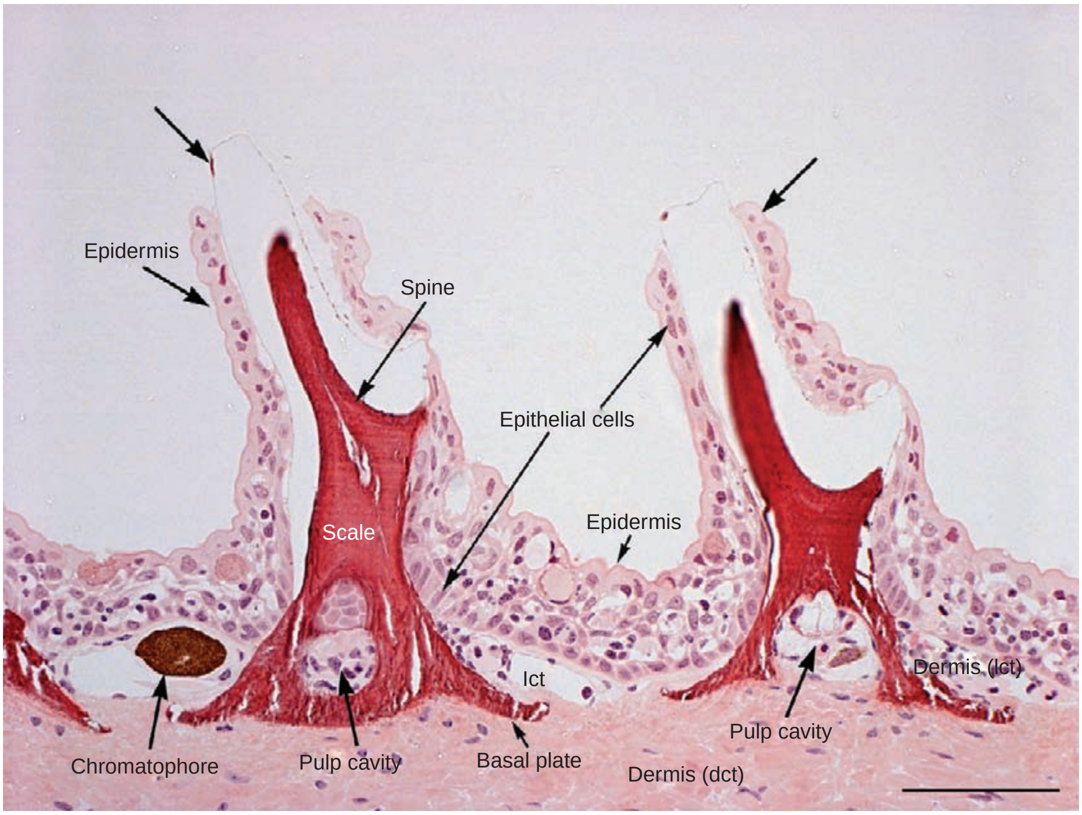

Figure 3 Histological section of fin tissue from a chondrichthyan, an adult female smooth dogfish shark, *Mustelus canis*. Tooth-like placoid scales or odontodes are visible beneath the epidermis, and show the characteristic structure including a basal plate (anchored in the dermis), a spine or cusp, and a pulp cavity. The remnants of epidermis (arrowed), possibly damaged during sampling, suggest that these scales may have been completely covered by epidermis in the living fish, but the spines of placoid scales may protrude through the epidermis in other areas of the skin. The visible dermis of the fin includes loose connective tissue (lct) of the stratum spongiosum, including a chromatophore (pigment cell), and dense connective tissue (dct) of the stratum compactum. Hematoxylin and eosin stain. Scale = 100 μm.

is the only constant feature, because a great diversity of cell types exists in the various fish taxa. Some of these include holocrine mucous cells and a variety of other secretory cells, ionocytes, sensory cells, and wandering cells such as leukocytes (white blood cells).

Epithelial cells

The basic cellular element of fish epidermis, the epithelial cell (**Figures 1–3** and **5**), has been known by many names, including malpighian cell, epidermal cell, filament-containing cell, filamentous cell, polygonal cell, polyhedral cell, keratocyte, keratinocyte, principal cell, and common cell. In primitive jawless fishes, homologous cells often have been termed 'mucous' cells, even though this adjective generally implies a goblet cell in other fishes.

Unlike the mammalian epidermal epithelial cell, the corresponding cell in most fishes is metabolically active throughout all layers of the epidermis. In teleost fishes, epithelial cells in all epidermal layers are capable of mitotic division, although active cell division is most common in the lower layers. Among the jawless fishes, dividing epithelial cells appear to be confined to the lower layers. Dead cells are regularly sloughed from the surface of fish epidermis and replaced by living cells beneath. One study showed that translocation of epithelial cells from the lower epidermal layers to the surface layer and subsequent sloughing of those cells occurred within a span of about 4 days. In comparison, a similar process of epithelial cell translocation and shedding in humans requires about 33–37 days. More recent studies of the epithelium on the gills of certain fish suggest that significant cell shedding can occur in a matter of hours under hypoxic conditions, but the gill respiratory epithelium is a highly specialized surface tissue with a single layer of epithelial cells (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy, **Ventilation and Animal Respiration**: Gill Respiratory Morphometrics, Plasticity in Gill Morphology, **Bony Fishes**: Crucian Carp, **Role of the Gills**: Morphology of Branchial Ionocytes, and **Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes).

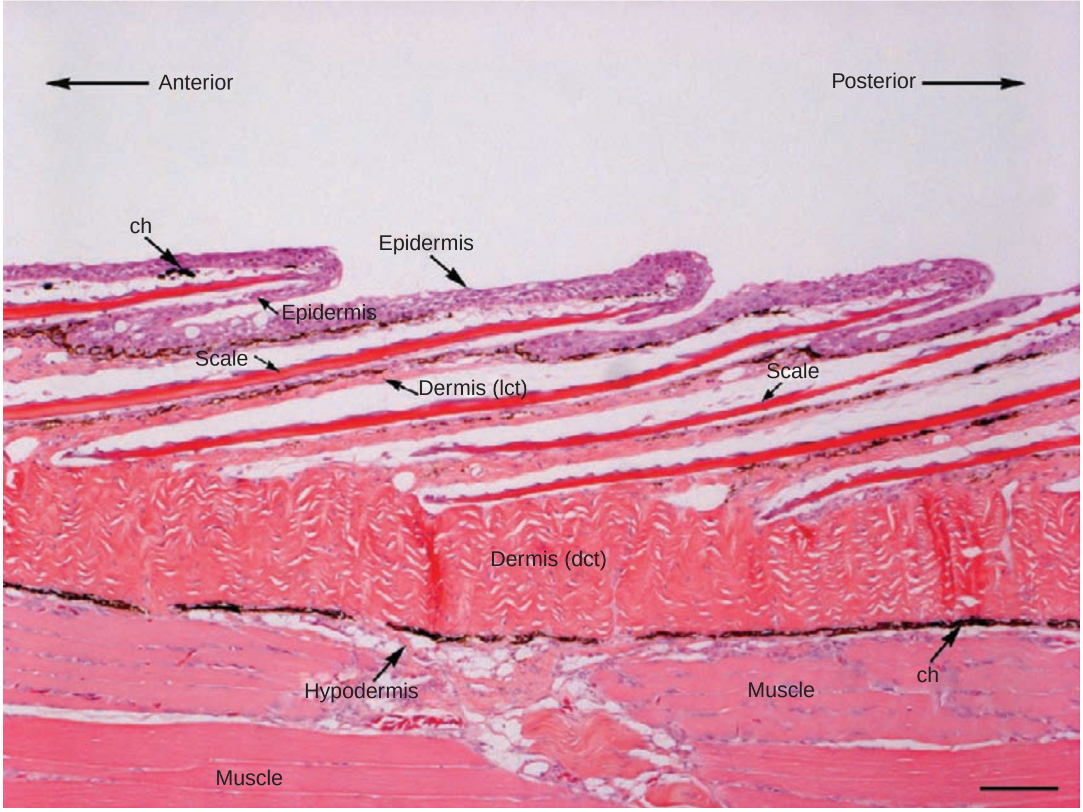

Figure 4 Histological section of skin layers of a juvenile steelhead trout, *Oncorhynchus mykiss*, showing overlapping (imbricated) scales. The thin epidermis covers and wraps around the posterior (nonoverlapped) portion of each scale. The scales lie in pockets of loose connective tissue (lct) of the stratum spongiosum of the dermis. The dense connective tissue (dct) of the stratum compactum of the dermis lies beneath the scales, separated from the skeletal muscle by a thin hypodermis comprised of adipose (fat) tissue and an upper layer of chromatophores or pigment cells (ch). Hematoxylin and eosin stain. Scale = 100 μm.

Epithelial cells typically are small relative to many other epidermal cell types, and may vary in shape depending on their position in the epidermis. The basal layer cells adjacent to the acellular basal lamina or basement membrane are cuboidal (cube-shaped) or columnar (column-shaped), whereas the superficial cells are often flattened (squamous) (**Figure 5**). The shape of the epithelial cell nucleus roughly corresponds to the shape of the cell. The presence of tonofilaments (intermediate filaments) is a distinctive cytoplasmic feature of the epithelial cell that is visible only by electron microscopy. Tonofilaments are about 7–8 nm in diameter, arranged in bundles (tonofibrils) or randomly distributed, and comprise an important component of the cytoskeleton of individual cells. Additionally, the attachment of tonofibrils to the desmosomal plaques that join adjacent epithelial cells enables the epidermis to respond as a whole to mechanical stress.

The exterior surface of superficial epithelial cells of teleosts is characterized by microridges or micropapillae that often form regular fingerprint-like patterns (**Figures 1** and **6(a)**). The function of the surface microridges is unknown, but they may provide some mechanical protection against trauma and assist in holding mucous secretions to the skin surface. Microridges also increase the absorptive surface area of epithelial cells, alter the boundary layer conditions, and may be a factor in enabling the skin to function in gas exchange. They may also scatter light differentially resulting in iridescent color patterns (**see also The Skin**: Coloration and Chromatophores in Fishes).

In a few fishes, keratinization occurs in the surface epithelial layers. Examples of keratinized external epithelium include nuptial tubercles or contact organs in breeding males of some species of Salmoniformes, Cypriniformes, and certain other teleost orders, the sometimes bizarrely shaped horny projections (unculi) on attachment organs on the lips and fins of fishes in some ostariophysan genera, and the polyhedral keratinized plaques on the skin of the Asian catfish *Bagarius*, which are believed to help protect the fish from abrasion.

The mucous secretions produced by superficial epithelial cells assist in protecting fish from pathogens and other insults (**see also The Skin**: The Many Functions of Fish Integument). These secretions form a

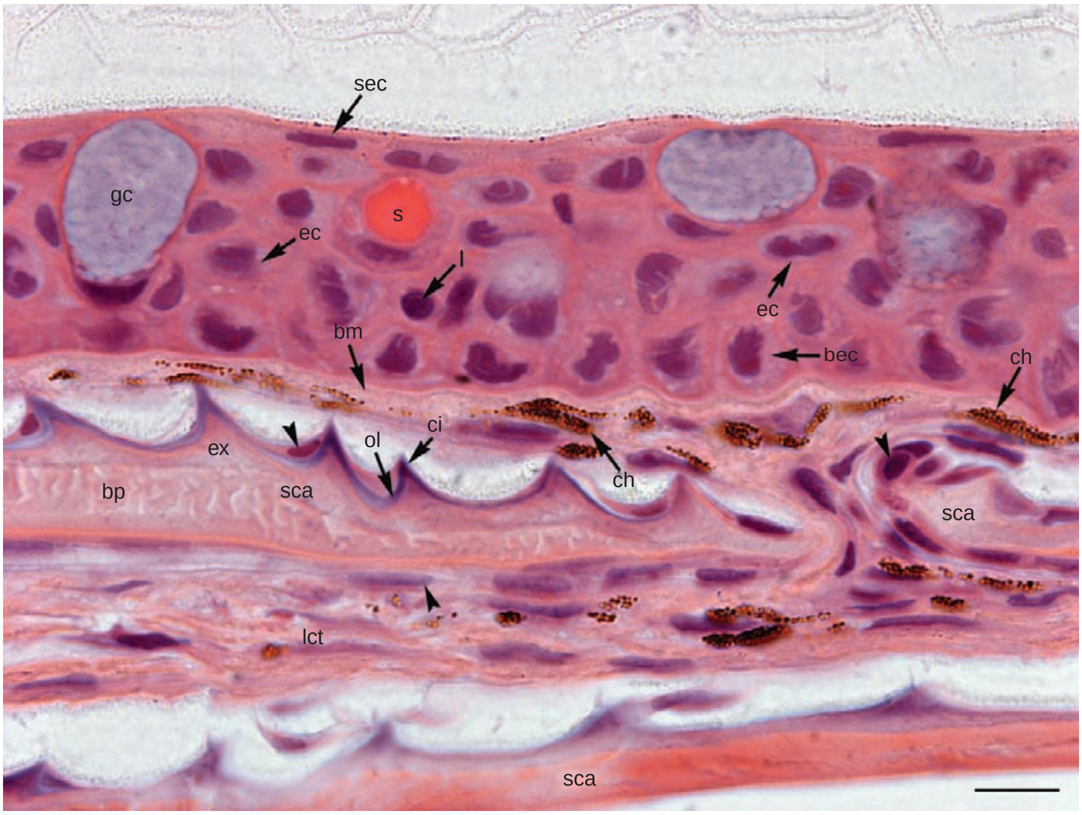

Figure 5 Histological section of the skin of a juvenile Chinook salmon, *Oncorhynchus tshawytscha*, showing the epidermis and upper dermis. Epithelial cells visible in the epidermis include basal layer epithelial cells (bec) with rounded nuclei, mid-layer epithelial cells (ec) with rounded to elongated nucli, and surface layer epithelial cells (sec) with elongated nuclei. Secretory cells in the epidermis include mucous goblet cells (gc) and an unidentified secretory cell (s) that is either a serous goblet cell or sacciform cell. Electron microscopy would be necessary for definitive identification of this cell. A wandering lymphocyte (l) is also visible in the epidermis. The epidermis is separated from the loose connective tissue (lct) of the dermis (stratum spongiosum) by an acellular basement membrane (bm). Chromatophores or pigment cells (ch) with cytoplasmic brown-black melanin granules (melanophores) are present in the dermis. The basal plate (bp), external layer (ex), outer limiting layer (ol), and circuli (ci) of one cycloid-type elasmoid scale (sca) are visible; dermal cells involved in scale growth are shown at arrowheads. Hematoxylin and eosin stain. Scale = 10 μm.

layer called the cuticle on the skin surface, where they are mixed and modified by secretions from other cells (**Figure 6**(**b**)). The cuticle layer is continually sloughed and renewed.

Goblet cells

The goblet cell (**Figure 5**) is a unicellular exocrine gland common to most animal groups. This cell is the second category of secretory cell in the fish skin, and occurs in the internal epithelia (mucous membranes) of fish as in other vertebrates. The goblet cell also is almost universally present in the skin of fishes, with a few exceptions, and is even found in the specialized gill epithelium (**see also Role of the Gills**: Morphology of Branchial Ionocytes). Lamprey epidermis contains no goblet cells; the production of mucus in lampreys is entirely from epithelial cells, which are sometimes called 'mucous cells'. Goblet cells are also lacking in the relict bony fish *Polydon* (paddlefish) and the teleost *Periophthalmus* (mudskipper).

Goblet cells are most frequently recognized in the middle to outer layers of epidermis, although in a very thin epidermis, the base of a mature goblet cell may be adjacent to the basement membrane. Evidence suggests that goblet cells differentiate from epithelial cells in the lower layers of the epidermis, and that differentiated goblet cells do not undergo further mitotic division.

Immature goblet cells are rounded but become flattened laterally and generally increase in size as they move toward the surface of the epidermis. As mucous secretions are elaborated in the maturing cell, the nucleus and organelles usually become displaced basally. Upon reaching the skin surface, the goblet cell emerges (usually between adjacent epithelial cells (**Figure 6**(**a**)), its cell membrane ruptures at the apical point, the cell contents are released, and then the cell dies.

The abundance and size of goblet cells may vary in different body regions of a fish. A specific distribution of goblet cells may help to ensure an even layer of mucus over the surface of a moving fish, or to reduce friction

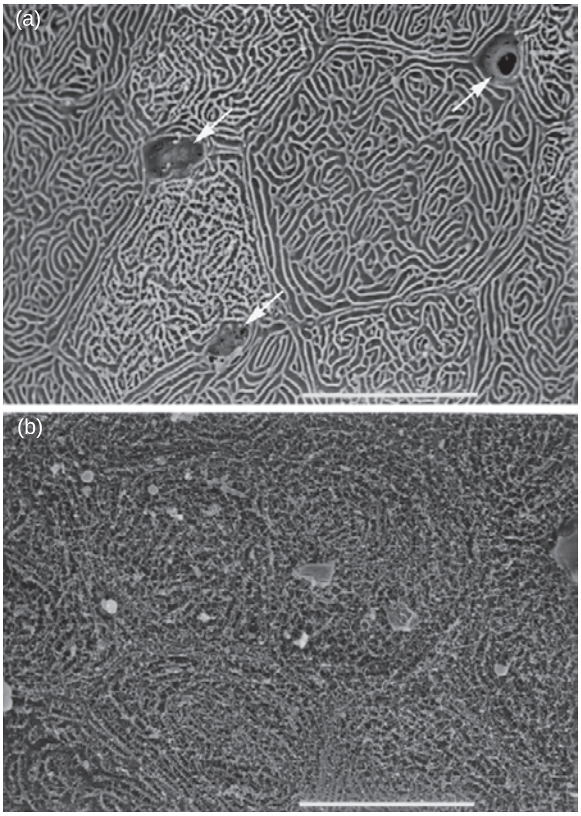

Figure 6 Scanning electron micrographs of the epidermal surface of a juvenile Chinook salmon (*Oncorhynchus tshawytscha*). (a) Individual surface epithelial cells showing 'fingerprint' microridge patterns; apical ends of superficial goblet cells (arrowed) are visible between epithelial cells. (b) Skin surface fixed to preserve the mucous cuticle on the surface of the epidermis. Microridge patterns of superficial epithelial cells are faintly visible beneath the mucous cuticle, which has trapped some surface debris. Scale = 10 μm. (b) Reproduced from figure 17.12(b) in Elliott (2000) Integumentary system: Microscopic functional anatomy. In: Ostrander GK (ed.) *The Laboratory Fish*, pp. 271–306. London: Academic Press.

between overlapping scales during flexion of the fish's body during swimming. In certain fish species, goblet cells may aggregate in patches on various areas of the body to form multicellular holocrine glands. Goblet cell abundance also may differ between male and female fish of the same species, as in certain salmonid fishes. The number of goblet cells also can change seasonally and during processes such as larval metamorphosis, sexual maturation, or adaptation to seawater.

Alterations in environmental conditions, such as sudden changes in temperature or exposure to ultraviolet radiation or contaminants, can also affect epidermal goblet cell numbers. For example, acute exposure to an irritant can cause rapid holocrine secretion by goblet cells and a consequent reduction in their numbers, whereas chronic exposure to an irritant may result in an increase in goblet cell numbers as new cells differentiate and move to the epidermal surface. In some instances, even a mild stressor, such as a single incidence of capture in a net, can promote a subsequent increase in epidermal goblet cells. Exposure to toxicants or other stressors can also alter the size or morphology of goblet cells, and can result in changes in the chemical composition of the secretion produced.

In some species such as salmonids, the greatest volume of epidermal mucous secretions is from goblet cells. The secretions of most epidermal goblet cells are glycoproteins, but a wide array of components have been demonstrated in different fishes. A variety of roles have been attributed to goblet secretions, including lubricating, protective, and possibly regulatory functions (**see also The Skin**: The Many Functions of Fish Integument).

Other epidermal cell types

In addition to epithelial and goblet cells, the epidermis of fish may include other secretory cell types. Principal among these are the club cells and sacciform cells. Club cells are present in certain taxa of ray-finned (actinopterygian) fishes, including the primitive Polypteriformes and eels of the order Anguilliformes. The largest group of fishes with club cells is the superorder Ostariophysi, which includes over one-quarter of all known fish species and three-fourths of all freshwater species. Club cells are usually large and round or oval to club-shaped, with one or two centrally located nuclei with prominent nucleoli (**Figure 7**). Club cells characteristic of eels possess a secretory vacuole in the cytoplasm, whereas club cells characteristic of Ostariophysi do not. These cells are generally located in the middle epidermal layers and lack openings to the epidermal surface. The club cells of ostariophysan fishes contain an alarm pheromone that is released into the surrounding water only when the club cells are broken, which frequently happens even with a minor injury to the fragile epidermis. Other ostariophysans detect the alarm pheromone by smell, and perform species-specific antipredator defensive reactions such as gathering into a tight school, diving for cover, or becoming motionless. Polypterids and eels do not show an alarm reaction, however, and epidermal club cells may have other functions in these species as well as in ostariophysans. Research has identified a variety of bioactive substances within club cells, including anti-pathogenic agents, toxins, and specific factors that may be involved in epidermal cell regulation (**see also The Skin**: The Many Functions of Fish Integument).

Sacciform cells have been reported in cartilaginous fishes such as rays and chimaeras, and in relict bony fishes such as polypterids. Among teleosts, sacciform cells are characteristic of the superorder Acanthopterygii (spiny-rayed fishes) and Paracanthopterygii (a group including the Gadiformes or cods), and also occur in some fishes of other teleost superorders such as Ostariophysi and

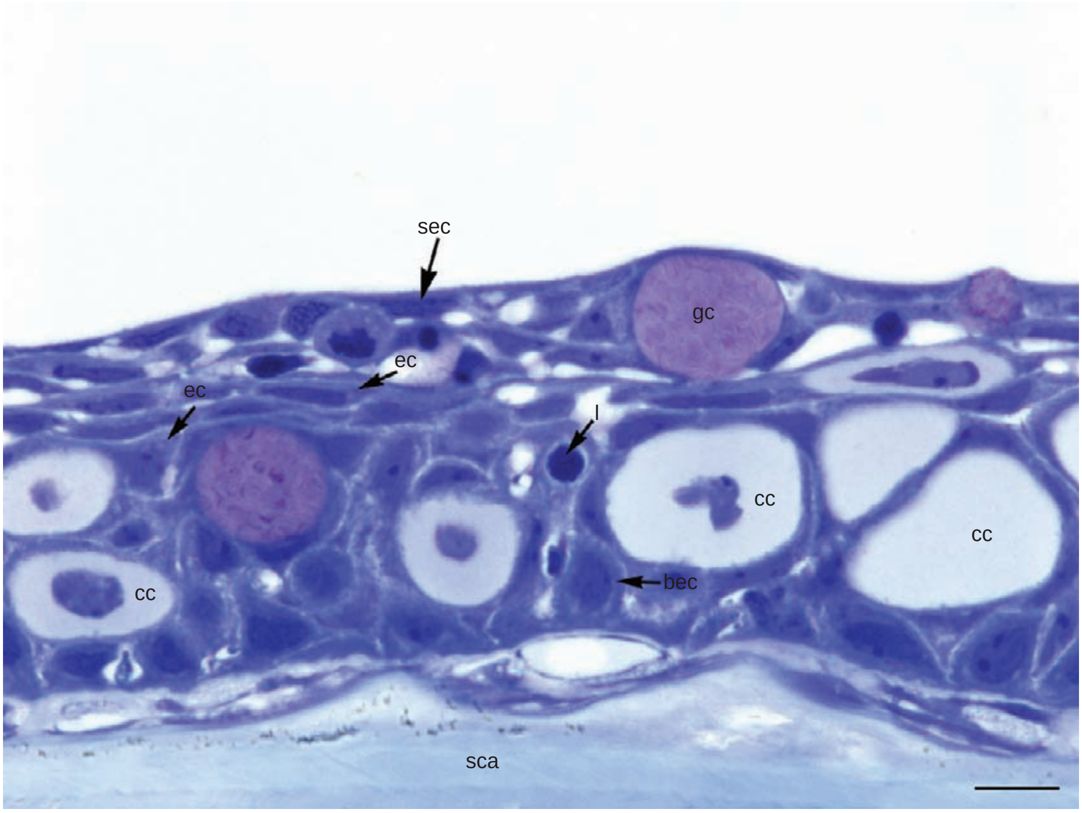

Figure 7 Histological section of the epidermis of a goldfish, *Carassius auratus*, showing typical ostariophysan-type club cells (cc) with a central nucleus (when visible) but no secretory cytoplasmic vacuole. Other epidermal cells include basal epithelial cells (bec) with rounded nuclei, mid-level epithelial cells (ec) with rounded to flattened nuclei, surface epithelial cells (sec) with elongated nuclei, mucous goblet cells (gc), and a wandering lymphocyte (l). A portion of an elasmoid scale (sca) is visible in the dermis beneath the epidermis. Methylene blue-azure II stain. Scale = 10 μm.

Protocanthopterygii. By light microscopy, sacciform cells have basally located nuclei and homogeneous to granular cytoplasm that stains readily with acid dyes (**Figure 5**). In some fishes, sacciform cells can be distinguished from certain types of goblet cells only by electron microscopy. Like goblet cells, sacciform cells of some species appear to differentiate deep in the epidermis and increase in size as they move toward the skin surface. Most mature sacciform cells open at the skin surface by an apical pore, and evidence suggests that the usual mode of secretion is holocrine. In the Gadiformes, sacciform cells are enormous and swollen, often appearing cyst like. Among pelagic gadoid fishes, sacciform cells appear not to open at the epidermal surface, whereas among benthic gadoids the typical surface openings are present. The precise functions of sacciform cell secretions are unknown, and the secretions may vary even within a species. Sacciform cell secretions usually include a protein moiety, and various enzymes, serotonin, cholesterol, and other lipids have been identified. Research has suggested that in some fish species, sacciform cells may be analogous to the granular glands of amphibian skin, producing secretions that are toxic or repellent to predators (**see also The Skin**: The Many Functions of Fish Integument). In other fishes, sacciform cells may produce regulatory peptides or intraspecific alarm pheromones (**see also The Skin**: The Many Functions of Fish Integument).

Additional secretory cell types are present in the epidermis of certain fishes. Included among these is the elongate oval thread cell of hagfish, which releases an impressive protein thread when the animal is stressed. The protein threads released from thread cells mix with the contents of mucous goblet cells to form the thick and copious slime that has given the hagfish the nickname 'slime eel' (**see also Hagfishes and Lamprey**: Hagfishes, and **The Skin**: Hagfish Slime, and The Many Functions of Fish Integument). Venomous fishes have multicellular nonducted holocrine glands associated with spines to form defensive organs. Release of venom into a wound made by the spine generally follows rupture of the fine epidermal covering of the tip of the spine. The granular cell in the middle to upper layers of lamprey epidermis (**Figure 2**) is a large cell with a centrally located nucleus and prominent nucleolus, numerous small granules in the cytoplasm, and appendages penetrating deep into the epidermis. Granular cells release their contents when lamprey skin is damaged, but the function of the proteinaceous secretion is unknown.

Epidermal paraneurons are receptosensory cells that possess a receptive site and a secretory site on their plasma membranes. These cells release signal substances that are common to neuronal secretions, and may have regulating functions. The spectrum of bioactive substances synthesized by paraneurons, and the physiological functions of these cells, vary among vertebrate species. Ultrastructural and immunohistochemical markers enable easy recognition of paraneurons by their polarization, but the paraneurons of fish have received relatively little attention. Merkel cells are paraneuronal cells that have been found in the epidermis of teleosts, dipnoans (lungfish), and lampreys, although their functions are unknown. Studies in mammals suggest that Merkel cells may play a role in a variety of functions, including touch perception, nerve growth, and proliferation of certain cell types. Additional studies in fish have demonstrated putative paraneurons among mechanoreceptor cells, electroreceptor cells, and chemosensory cells in fish integument.

Further discussion of certain epidermal cell types can be found elsewhere in the encyclopedia. For links to these articles, **see The Skin**: The Many Functions of Fish Integument.

Dermis

In primitive vertebrates, as in annelid worms, the dermis consists essentially of two sets of collagen fibers arranged in opposing spirals around the body, creating a bias sleeve that has the ability to bend without wrinkling. Most fishes require the accommodation of lateral flexions only, but the hagfishes are so flexible that they can tie themselves in knots (**see also Hagfishes and Lamprey**: Hagfishes). The overall thickness of the dermis varies with species, position on the body, and life stage.

The dermis of most fishes is divided into two major layers. The upper (outer) layer is a loose network of collagenous connective tissue (**Figures 1** and **3–5**) and is called the stratum spongiosum or stratum laxum, whereas the lower layer is a dense layer consisting primarily of orthogonal collagen bands (**Figures 1**, **3**, and **4**) and is called the stratum compactum. The relative thickness of the two layers depends on the presence or absence of scales, and the separation between dermal layers may be indistinct in nonscaled areas. In fin tissue, the dense connective tissue layer may be reduced. In lampreys and some primitive actinopterygians, the dermis consists primarily of dense collagenous tissue (**Figure 2**).

The dermis is separated from the epidermis by an acellular basement membrane (also called the basal lamina or adepidermal membrane; **Figures 1**, **2**, and **5**). The deep face of the dermis is bounded by a single layer of cells termed the dermal endothelium (**Figure 1**). Immediately below the dermal endothelium, and separating the dermis from the underlying skeletal musculature, is a layer of well-vascularized loose connective tissue called the hypodermis or subcutis (**Figures 1**, **2**, and **4**).

Specialized dermal elements

Chromatophores

Integumentary colors are primarily dependent on the presence of chromatophores (pigment cells) in the skin (**Figures 1–5**). In all fishes from the primitive cyclostomes to higher teleosts, these cells occur in the dermis, where they may be found in the stratum spongiosum, in the hypodermis, or both (**see also The Skin**: Coloration and Chromatophores in Fishes).

Scales

As evidenced by their fundamental differences in structure, scales evolved independently in cartilaginous and bony fishes (**Figures 8** and **9**). The cartilaginous sharks, rays, and chimaeras (Chondrichthyes) possess placoid scales (also called odontodes). A typical placoid scale consists of a flattened, rectangular basal plate embedded in the upper layer of dermis, and a spine or cusp that projects backward and often through the epidermal surface (**Figures 3**, **8**(**a**), and **9**(**a**)). The protruding spines of placoid scales give shark skin its characteristic rough texture. The structure of the placoid scale resembles that of a tooth (**Figure 9**(**a**)). The spine is comprised of a cap or cone of dentine that is covered with a layer of hard, transparent enameloid, and encloses a pulp cavity. Blood vessels, nerves, and presumptive lymph channels enter the pulp cavity through one or more openings that perforate the basal plate. Placoid scales show modifications in shape for a variety of functions, including protection from predators and ectoparasites, reduction of mechanical abrasion, accommodation of bioluminescent and sensory organs, and reduction of frictional drag. These scales may fit close together or be set apart, but they usually are nonoverlapping except where they protect the lateral line canal. Placoid scales do not exhibit continuous, indefinite growth; they may be replaced when old, worn out, or lost.

In contrast to the scales of Chondrichthyes, the scales of bony fishes (Osteichthyes) are layered plates, with bone as one of the layers. The ganoid scale, an ancestral scale type of bony fishes, is still present in some primitive actinopterygian (ray-finned) fishes. Ganoid scales are rigid plates that are often rhomboidal or diamond-shaped (**Figure 8**(**b**)). They may slightly overlap and articulate with one another by peg-and-socket joints at the margins, and frequently are bound together by connective tissue bundles called Sharpey's fibers. In the bichirs (Polypteridae), ganoid scales are least modified from their ancestral form (**Figure 9**(**b**)). In these fishes, a thick osseous basal plate lies beneath a stack of thin, incompletely mineralized collagenous layers

(elasmodine) arranged in a plywood-like pattern. The elasmodine is covered by a layer of vascular dentine that is capped by a layer of enamel-like, hypermineralized ganoine. Each scale is penetrated by canals carrying capillary blood vessels to supply the tissues exterior to the scale. The capillaries are part of the secondary circulation that contains very few red blood cells and is unique to fishes (**see also Design and Physiology of Capillaries**

and Secondary Circulation: Secondary Circulation and Lymphatic Anatomy). The scales of gars (Lepisosteidae) have no dentine layer but still have a ganoine layer (**Figure 8**(**b**)). Small tooth-like odontodes may project from the surface of the scales of some bichirs and gars, although they may be only transiently present in juvenile or regenerating scales of gars (**Figure 8**(**b**)). The dermal ossification of sturgeons (Acipenseridae) and paddlefish (Polydontidae) is reduced to bony denticles or scales without dentine or ganoine. These structures are present only as isolated vestigial denticles in paddlefish, but exist as rows of large articulated bucklers and small denticles in sturgeon. One primitive actinopterygian, the bowfin (*Amia*), does not have ganoid scales; its scales are elasmoid scales of the cycloid type, very similar to those of teleosts.

Most living bony fishes are teleosteans, and the majority of these possess elasmoid (bony-ridge) scales (**Figures 1**, **4**, **5**, **8**(**c**), **8**(**d**), and **9**(**c**)). The elasmoid scale lacks dentine and ganoine and is usually reduced to a relatively thin, flexible, transparent structure consisting of: (1) a basal plate (the thickest layer) comprised of elasmodine that is partially mineralized and consists of several layers of collagen organized into a plywood-like structure (2) the external layer, a thin well-mineralized layer comprised of a network of interwoven collagen fibrils; and (3) the limiting layer (or outer limiting layer), a hyper-mineralized layer that lacks collagen fibrils; and is deposited at the scale surface in the region close to the epidermis (**Figures 5** and **9**(**c**)). Each elasmoid scale is usually marked by calcified concentric ridges (bony ridges) called circuli or striae (**Figures 5**, **8**(**c**), **8**(**d**), and **9**(**c**)). The circuli and the backward-facing denticles (**Figure 8**(**d**)) that are often present on their edges may assist in the mechanical anchoring of the scale into the covering dermis. Uncalcified grooves called sulci or radii converge on the scale center (focus) and allow flexibility (**Figures 8**(**c**) and **8**(**d**)).

On the basis of their surface sculpture, the elasmoid scales of teleosts are commonly grouped into two general types: cycloid and ctenoid. The cycloid scale is generally a round, thin, flat scale (**Figure 8**(**c**)). Ctenoid scales differ from cycloid scales in that they have stiff comb-like projections (cteni or ctenii), soft projections (ciliated cteni), or short tubercles or grains in the posterior area (**Figure 8**(**d**)). The function of the cteni or other posterior projections (collectively called granulation) is not well understood, but some scientists have hypothesized that they may improve the hydrodynamic efficiency of swimming and help to reduce drag by affecting the profile of the overlying epidermis.

Cycloid scales are characteristic of the more primitive teleosts with soft-rayed fins, including fishes such as trout and salmon (Salmonidae) (**Figures 4** and **5**), minnows (Cyprinidae) (**Figure 7**), and herring (Clupeidae), whereas ctenoid scales are found on many spiny-rayed fishes (Acanthopterygii) such as perch (Percidae), most mullets (Mugilidae), and scorpionfishes (Scorpaenidae). Nevertheless, certain soft-rayed fishes, such as a few of the characins (Characidae), have ctenoid-like contact organs on their scales, and conversely, some spiny-rayed fishes such as the brook silverside (*Labidesthes*) and wrasses (Labridae) have only cycloid scales. In certain species such as the mud dab (*Limanda*) and the freshwater basses (*Micropterus*), both cycloid and ctenoid scales may be present on the same individual. Furthermore, the scale types observed may differ depending on the age or sex of a fish.

Elasmoid scales are most often arranged in an overlapping (imbricated) pattern like shingles on a roof (**Figure 4**), with the free margin directed posteriorly to minimize friction with the water. The cteni of ctenoid scales are located on the posterior area that is not overlapped by other scales, and cycloid scales often have less distinct circuli in the posterior nonoverlapped area than in the anterior area. In certain fishes, the posterior edge of each scale approaches the epidermis, which forms only a slight indentation or tuck beneath the scale, while in other (usually pelagic) species, both the scale and the covering epidermis protrude and overlap the epidermis that covers the scale behind (**Figure 4**). Certain fishes such as burbots (*Lota*) and immature adult freshwater eels (*Anguilla*) have mosaic patterns of scalation; the scales are minutely separated or meet adjacent scales only at the margins rather than overlapping one another.

Growth of the formed elasmoid scale generally continues throughout life, with circuli marking successive stages in the growth of the scale. Closely spaced circuli discernible on magnified scales represent periods of slow growth. When these occur on an annual basis they are termed annuli (**Figures 8**(**c**) and **8**(**d**)). Annuli or accessory annuli (discontinuity of circuli that do not represent an annual cycle) may form as a result of decreased metabolism and appetite in cold seasons, fasting periods associated with spawning or unavailability of food, partial scale decalcification and resorption in females with developing eggs or young, or mechanical injury. Specific patterns of scale growth and morphology are used in fish life history and growth studies. Distinctive marks can also be induced on fish scales by manipulation of water temperature and feeding regimes; these are used for batch marking of hatchery-reared fish for later identification of specific groups. An advantage of using scales rather than certain other hard structures such as otoliths (ear bones) or vertebrae for such studies is that scales can be sampled without killing the fish. Scales may also store the history of environmental exposure, whether it be seawater versus freshwater or certain toxicants. Laser ablation coupled with ionic analysis with mass spectrometry of scales can be used to trace this history. For example, the ratio of strontium and calcium is often used to trace previous movements between freshwater and seawater.

Most teleost fish lose their scales at least once during their lifetimes, but both the lost scales and the overlying epidermis that is torn when the scales are shed usually regenerate quickly unless the integumental injury is severe. Some fishes lose their scales more easily than others, and excessive scale loss may be lethal among bycatch of certain fisheries.

Modified scales

A variety of scale modifications exist in fishes; most of these serve protective functions. Placoid scales of Chondrichthyes may be enlarged or fused to form defensive weapons that are particularly effective when associated with venom glands. Examples of such modifications include the tail spine or 'stinger' of stingrays (Dasyatidae), and the dorsal fin spines of the spiny dogfish shark (*Squalus*) and chimaeroids (*Chimaera*, *Hydrolagus*).

Many modifications of cycloid and ctenoid scales have evolved in teleost fishes as well. Specially perforated and sometimes tubulated scales provide protection and surface outlets for the lateral line sensory canal. The two knife-like spines that are carried in sheaths of skin at the base of the tail of surgeonfish (*Acanthurus*) are modified scales that swing out in an attack. Spinous scales are also present in teleosts such as triggerfishes (*Balistes*), filefishes (*Monacanthus*), the batfish (*Ogocephalus*), and frogfish (*Antennarius*). The numerous sharp bony spines that stand erect when a porcupine fish (Diodontidae) or puffer (Tetraodontidae) inflates its body are modified scales. In certain fishes such as seahorses and pipefishes (Syngnathidae), a dermal skeleton of bony plates is arranged segmentally and forms a protective semirigid case. For South American armored catfishes (e.g., Callichthyidae), protection is provided by large bony plates or scutes bearing tooth-like structures (dermal denticles) (**Figure 8**(**e**)). Among fishes, the most extreme examples of protective armor may be the rigid encasements of trunkfishes (Ostraciidae), which rival those of the most completely boxed turtles.

Fin rays

Dermal rays or spines support the fins of fishes. The fin supports in lampreys and hagfishes are unsegmented cartilaginous rods that provide only weak support. In both elasmobranchs and bony fishes, the dermal fin rays are known collectively as dermotrichia. These include several kinds of collagenous structures with varying types and degrees of mineralization. Dermotrichia may be segmented or unsegmented, branched or unbranched, biserial (two lateral elements paired on the midline) or uniserial. The fin rays (lepidotrichia) present in all Osteichthyes except dipnoans are comprised of mineralized bone and are believed to have derived from modified scales in early vertebrates.

Integumentary Extensions

Fishes have evolved a wide variety of integumentary modifications, including extensions of the skin. For example, barbels are integumentary extensions that have developed independently in many taxa as accessory feeding structures carrying sensory organs. Barbels that differ in structure and location are present on sturgeons

(Acipenseridae), goatfishes (Mullidae), marine and freshwater catfishes (Siluriformes), and some Cypriniformes such as carp (*Cyprinus carpio*) and loaches (Cobitidae).

The most frequently cited examples of the extension of skin into flaps are those of the sargassum fish (*Histrio*) and seadragon (e.g., *Phyllopteryx*). The function ascribed to the exaggerated skin flaps in these fishes is protective resemblance to the seaweed in which they hide. Although the skin extensions in certain other fishes, such as scorpionfishes (*Scorpaena*), are less prominent, these extensions, combined with mottled coloration, also likely aid in camouflage.

Certain less permanent skin extensions assist in reproduction, and may be reduced in size or shed completely after the breeding season. Keratinized breeding (nuptial) tubercles or pearl organs of Cypriniformes and certain other fishes function primarily to facilitate contact between spawning individuals. However, the antler-like breeding tubercles of breeding male stonerollers (*Campostoma anomala*) are used in defense of nests against intruding males. Outgrowths of abdominal skin or fin tissue of skin-brooding fishes enable the attachment of eggs to the skin.

Glossary

Chromatophores A variety of pigmented cells involved in the coloration of the skin of fish and other vertebrates and invertebrates. In fish, these are melanophores (black or brown), xanthophores (orange or yellow), erythrophores (red), cyanophores (blue), leukophores (whitish), and iridophores (iridescent).

Chromatosomes Pigmented organelles found within chromatophores. Their movements result in physiological color changes of fish.

Countershading A color scheme used by many fishes; the dorsal (upper) surface is a dark color to conceal the fish when viewed from above, and the ventral (lower) surface is a very pale color to conceal the fish when viewed from below.

Hue Variety of color or tint.

Iridescent Display of lustrous colors, which may vary with the angle of viewing. It is produced by interference of light waves with phase differences, when reflected from outer and inner surfaces of a transparent structure such as a crystal or membrane.

Melanin-concentrating hormone (MCH) A cyclic peptide neurosecretory hormone synthesized in the hypothalamus, stored in the pars nervosa of the pituitary, from which it is secreted, producing intracellular aggregation of melanosomes, paling skin in teleosts.

Melanophore-stimulating hormone (MSH) A peptide hormone synthesized in and secreted by the pars intermedia of the pituitary. It induces intracellular dispersion of melanosomes, resulting in skin darkening, and dispersion of xanthophore pigments, as well as longer-term morphological increases in melanophores and their melanogenesis.

Mononeuronic regulation Control of teleost melanophore physiological responses by a single nerve type (adrenergic) mediating bidirectional movements of melanosomes through α-adrenoceptors and either β-adrenoceptors or an ATP co-transmitter.

Morphological color changes Changes in the amount of pigmentation, or in the number of chromatophores, in the skin, including prolonged adaptations to background coloration and seasonal development of nuptial colors associated with breeding.

Physiological color change Rapid and slower changes in skin color due to chromatophore intracellular pigmentary movements.

Pigmentary coloration The color of melanophore, xanthophore, erythrophore, and cyanophore pigments depends on their selective absorption of incident light.

Structural coloration The microscopic structure of fish skin and the presence of iridophores and leukophores can reflect and scatter light to produce white, silvery, and, often, iridescent structural colors.

Color: An Important Characteristic in Fish Integumentary Function

The skin is the boundary between fish and its environment. It has special qualities, including a diversity of colors, often due to pigmented cells termed 'chromatophores', which serve vital roles in the survival of species. For example, varying abilities to change color may aid in the need to become obscure, or to advertise socially.

Such color changes have generated curiosity over a long historical period; in Roman times, they were reported by Pliny. At major aquaria, the enormous diversity in coloration and patterns is instantly apparent to an interested public. Many species display spectacular colors, others may be brown, gray, or black. Stripes and spots can be attributes of coloration and some species have the capacity to change pattern texture as well as color. Regardless of public and scientific interest, coloration has been studied in detail in very few of the over 20 000 extant fish species. Such studies have made significant contributions to fish ethology, physiology, cell biology, and our understanding of vertebrate autonomic neural and hormonal regulatory systems, including their interaction at the peripheral level.

Cyclostomes, elasmobranchs, and many teleosts are often dark gray, brown, or black. However, even darkly colored skin can display patterns as in some marine and freshwater rays. The actinopterygii (ray-finned teleosts) include the most brightly colored species, particularly those inhabiting coral reefs and other shallow tropical waters. Often, there is countershading in which a dark upper surface provides camouflage when viewed from above; a pale lower surface blending with bright surface water. This differentiation may be absent as in wolfish, *Anarrhichas lupus*, while in scribbled leatherjacket, *Aluterus scriptus*, both upper and lower surfaces are patterned dark and blue. Peritoneal melanophores also occur; their function invites investigation, although they can darken the stomach to conceal bioluminescent ingested prey.

The capacity of cyclostome, elasmobranch, and teleost species to change color in response to different types of stimuli varies and the extent of this phenomenon is unknown. Some actinopterygii, such as European minnow, *Phoxinus phoxinus*, and flatfish (order Pleuronectidae) inhabiting shallow clear water can change color rapidly on different backgrounds. Photocycle illumination periodicity may evoke chromatic change in various species, including cyclostomes; even brightly colored neon tetra, *Paracheirodon innesi*, and regal tang fish, *Paracanthurus hepatus*, dim at night. During breeding, Atlantic salmon (*Salmo salar*), Pacific salmon (*Oncorhynchus* sp.), and stickleback (*Gasterosteus* sp.) display gender-related nuptial color change, but this is not so in *Phoxinus* and *Pleuronectes*, which do respond chromatically to background. Stress is another factor that evokes color change in various species.

Possible relationships between skin coloration and fish color vision raise interesting questions. Deep-sea fish are generally black; those in blue-water depths (100–1000 m), including redfish such as the golden redfish, *Sebastes marinus*, appear black or gray in wavelengths penetrating this depth, but appear red at the surface.

Pigmentary and Structural Coloration

Integumentary colors can be pigmentary or structural, or a combination of both, resulting in the enormous intraspecific and interspecific range of hues and patterns. Pigmentary colors are caused by selective absorption of specific wavelengths of incident light by pigments contained within organelles. The perceived hue is the product of any residual reflected wavelengths. Structural coloration is associated with the physical nature of intracellular and extracellular surfaces that are reflective and cause interference or scattering of light. Iridescence depends on reflected wavelength phase shifts and phase interactions, perceived colors changing with the angle of viewing; in contrast, scattering involves shorter wavelengths and is caused by very small particles, producing colors which are not influenced by the angle of viewing.

Chromatophores

The pigmented cells that give coloration to the skin of fish and other vertebrates and invertebrates are called ‘chromatophores’. Therefore, chromatophores can be subdivided into those that absorb light (pigmentary) and those that reflect light (structural), and then further subdivided according to the pigment they contain (**Table 1**).

Origin and location of chromatophores

In fish, as in other vertebrates, all chromatophores originate from embryonic neural crest cells, differentiating during migration, or after distribution. The current view is that the various types of chromatophores are replenished from stem cells, or chromatoblasts, within the skin.

Table 1 Fish chromatophores

Chromatophore	*Color*	*Organelle*	*Pigment*
Light absorbing			
Melanophore	Black, brown	Melanosome	Melanins
Xanthophore	Yellow, orange	Xanthosome	Carotenoids
		Erythrosome	Pteridines
Erythrophore	Red, orange, yellow	Xanthosome	Carotenoids
		Erythrosome	Pteridines
Cyanophore	Blue	Cyanosome	
Light reflecting			
Leukophore	Whitish	Leukosome	Purine, uric acid
Iridophore	Iridescent		Purine platelets

The melanophores, xanthophores, erythrophores, cyanophores, and leukophores are dendritic cells associated with their shared embryonic origins with neurons and are categorized as 'paraneurons'; their pigmented organelles are collectively called 'chromatosomes'.

Fish chromatophores occur mainly in the upper layers of the dermis. In elasmobranchs and some teleosts, for example, flatfish species, both dermal and epidermal melanophores occur (**Figures 1(a)–1(d)**). The presence of epidermal xanthophores in the emerald rockcod, *Trematomus bernacchii*, suggests that other epidermal chromatophores may be found in fish in future. Dendritic processes of dermal melanophores have a stellate (star-shaped) or reticulate (net-like) arrangement, with intra- and interspecific variation and are more irregular in epidermal melanophores (**Figures 1(c)** and **1(d)**). The dendritic processes of dermal melanophores have a two-dimensional distribution, parallel to the skin surface; those of epidermal melanophores are three dimensional, adapted to being between tightly compressed cells. Dendritic processes have an intracellular organization of radiating cytoskeletal actin filaments and microtubules. Iridophores are usually round or oval, but in the dark sleeper, *Odontobutis obscura*, dendritic iridophores have been described.

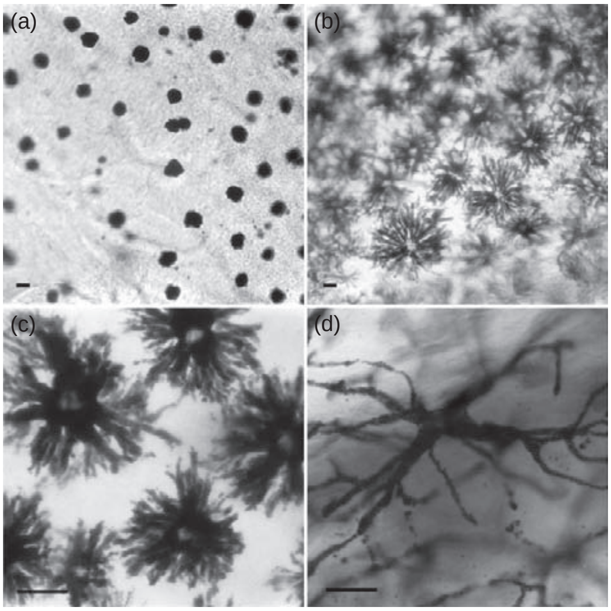

Figure 1 Dendritic chromatophores represented by melanophores of winter flounder, *Pseudopleuronectes americanus*. Dermal melanophores with melanosomes (a) aggregated into the cell center, (b) dispersed into the dendritic processes. (c) Dermal melanophores under higher magnification demonstrating the morphology of the melanosome-filled dendritic processes. (d) Epidermal melanophores with dispersed melanosomes demonstrating the morphological difference in the dendritic processes compared with dermal melanophores in (c). Scale = 20 μm. The colors

Without chemical analysis, it is safest to call yellowish organelles as xanthosomes and reddish organelles as erythrosomes. Cyanophores (blue) have recently been described in two callionymid species: the mandarin fish, *Synchiropus splendidus*, and psychedelic fish, *Synchiropus picturatus*. Leukophores (white) are known in few genera, including *Fundulus*, *Oryzias*, and *Lebistes*.
